Estimating actual exposure via water involves analyzing the level of the contaminant in the water consumed and assessing daily water intake (WHO 2003). Biological monitoring using blood or urine samples can be a precise tool for measuring total exposure from water, food, and air (Yassi and others 2001).

Health Effects. No published estimates are available of the global burden of disease resulting from the overall effects of chemical pollutants in water. The burden in specific local areas may be large, as in the example cited in box 43.2 of arsenic in drinking water in Bangladesh. Other examples of a high local burden of disease are the nervous system diseases of methylmercury poisoning (Minamata disease), the kidney and

bone diseases of chronic cadmium poisoning (Itai-Itai disease), and the circulatory system diseases of nitrate exposure (methemoglobinemia) and lead exposure (anemia and hypertension).

Acute exposure to contaminants in drinking water can cause irritation or inflammation of the eyes and nose, skin, and gastrointestinal system; however, the most important health effects are due to chronic exposure (for example, liver toxicity) to copper, arsenic, or chromium in drinking water. Excretion of chemicals through the kidney targets the kidney for toxic effects, as seen with chemicals such as cadmium, copper, mercury, and chlorobenzene (WHO 2003).

Pesticides and other chemical contaminants that enter waterways through agricultural runoff, stormwater drains, and industrial discharges may persist in the environment for long periods and be transported by water or air over long distances. They may disrupt the function of the endocrine system, resulting in reproductive, developmental, and behavioral problems. The endocrine disruptors can reduce fertility and increase the occurrence of stillbirths, birth defects, and hormonally dependent cancers such as breast, testicular, and prostate cancers. The effects on the developing nervous system can include impaired mental and psychomotor development, as well as cognitive impairment and behavior abnormalities (WHO and International Programme on Chemical Safety 2002). Examples of endocrine disruptors include organochlorines, PCBs, alkylphenols, phytoestrogens (natural estrogens in plants), and pharmaceuticals such as antibiotics and synthetic sex hormones from contraceptives. Chemicals in drinking water can also be carcinogenic. Disinfection by-products and arsenic have been a particular concern (International Agency for Research on Cancer 2004).

INTERVENTIONS

The variety of hazardous pollutants that can occur in air or water also leads to many different interventions. Interventions pertaining to environmental hazards are often more sustainable if they address the driving forces behind the pollution at the community level rather than attempt to deal with specific exposures at the individual level. In addition, effective methods to prevent exposure to chemical hazards in the air or water may not exist at the individual level, and the only feasible individual-level intervention may be treating cases of illness.

Figure 43.1 shows five levels at which actions can be taken to prevent the health effects of environmental hazards. Some would label interventions at the driving force level as policy instruments. These include legal restrictions on the use of a toxic substance, such as banning the use of lead in gasoline, or community-level policies, such as boosting public transportation and reducing individual use of motor vehicles.

Interventions to reduce pressures on environmental quality include those that limit hazardous waste disposal by recycling hazardous substances at their site of use or replacing them with

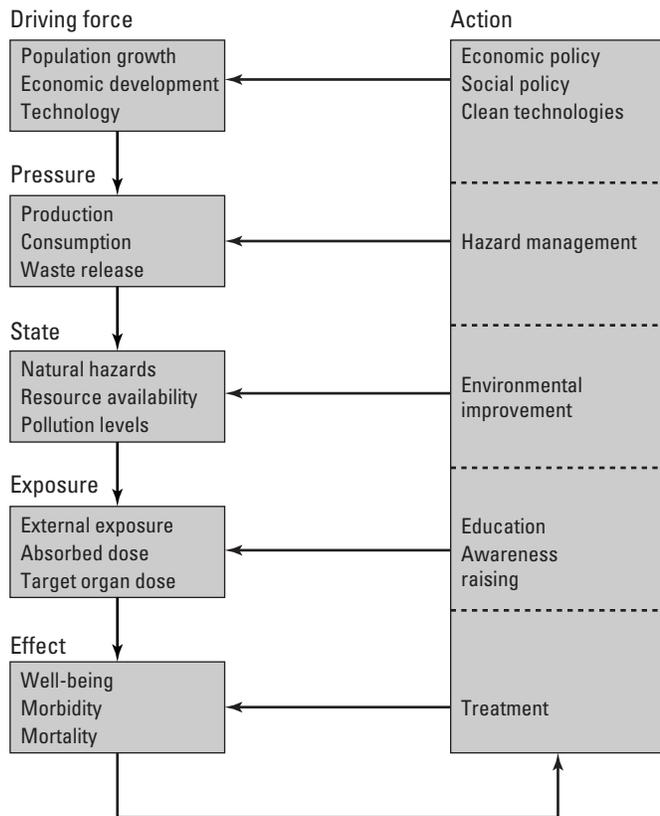

less hazardous materials. Interventions at the level of the state of the environment would include air quality monitoring linked to local actions to reduce pollution during especially polluted periods (for example, banning vehicle use when pollution levels reach predetermined thresholds). Interventions at the exposure level include using household water filters to reduce arsenic in drinking water as done in Bangladesh. Finally, interventions at the effect level would include actions by health services to protect or restore the health of people already showing signs of an adverse effect.

Interventions to Reduce Air Pollution

Reducing air pollution exposure is largely a technical issue. Technologies to reduce pollution at its source are plentiful, as are technologies that reduce pollution by filtering it away from the emission source (end-of-pipe solutions; see, for example, Gwilliam, Kojima, and Johnson 2004). Getting these technologies applied in practice requires government or corporate policies that guide technical decision making in the right direction. Such policies could involve outright bans (such as requiring lead-free gasoline or asbestos-free vehicle brake linings or building materials); guidance on desirable technologies (for example, providing best-practice manuals); or economic instruments that make using more polluting technologies more expensive than using less polluting technologies (an example of the polluter pays principle).

Examples of technologies to reduce air pollution include the use of lead-free gasoline, which allows the use of catalytic converters on vehicles' exhaust systems. Such technologies significantly reduce the emissions of several air pollutants from vehicles (box 43.3). For trucks, buses, and an increasing number of smaller vehicles that use diesel fuel, improving the quality of the diesel itself by lowering its sulfur content is another way to reduce air pollution at the source. More fuel-efficient vehicles, such as hybrid gas-electric vehicles, are another way forward. These vehicles can reduce gasoline consumption by about 50 percent during city driving. Policies that reduce "unnecessary" driving, or traffic demand management, can also reduce air pollution in urban areas. A system of congestion fees, in which drivers have to pay before entering central urban areas, was introduced in Singapore, Oslo, and London and has been effective in this respect.

Power plants and industrial plants that burn fossil fuels use a variety of filtering methods to reduce particles and scrubbing methods to reduce gases, although no effective method is currently available for the greenhouse gas carbon dioxide. High chimneys dilute pollutants, but the combined input of pollutants from a number of smokestacks can still lead to an overload of pollutants. An important example is acid rain, which is caused by SO_2 and NO_x emissions that make water vapor in the

Figure 43.1 Framework for Environmental Health Interventions

Box 43.3

Air Pollution Reduction in Mexico City

Mexico City is one of the world's largest megacities, with nearly 20 million inhabitants. Local authorities have acknowledged its air quality problems since the 1970s. The emissions from several million motor vehicles and thousands of industries created major concerns about health effects. Annual average particulate matter (PM₁₀) levels of 50 to 100 µg/m³ have been measured in the worst-polluted central area and can be associated with annual mortality excess of 15 to 30 percent. Even if only 20 percent of the population were exposed to such high levels, that exposure would account for 6,000 to 12,000 additional deaths per year. To tackle the problem, Mexico City started air quality monitoring and health studies in the 1980s. High-risk groups were the 2.2 million children, 250,000 street vendors, and 250,000 commercial drivers. After 20 years of policies and actions, interventions for better health have borne fruit.

The first intervention was lead-free gasoline in 1990, which enabled the government to require catalytic converters on new cars, thus dramatically reducing carbon

monoxide, NO_x, and hydrocarbon emissions. In 1997, leaded gasoline was completely phased out. The annual average concentration of lead in the air in the worst-polluted area was reduced from 1.2 µg/m³ in 1990 to less than 0.1 µg/m³ in 2000. Surveys of blood lead levels in children showed reductions from 200 to 100 µg/liter during the same period, implying that the intervention had protected thousands of children from lead poisoning. Another key concern was SO₂ emissions from industry and diesel vehicles. Heavy fuel oil was phased out in the mid 1990s, and the sulfur content of diesel was reduced. In addition, power plants and some industry shifted to natural gas in the early 1990s. The result was a 90 percent reduction of SO₂ in ambient air in five years.

Air quality standards, emission standards for vehicles, and other technical actions to reduce air emissions were tightened during the 1990s, contributing to downward trends of carbon monoxide, NO_x, and ozone levels. Levels of emissions were reduced by half at some sites, resulting in an estimated reduction of 3,000 to 6,000 excess deaths.

Sources: Fernandez 2002; McMichael, Kjellstrom, and Smith 2001; WHO 2000.

atmosphere acidic (WHO 2000). Large combined emissions from industry and power stations in the eastern United States drift north with the winds and cause damage to Canadian ecosystems. In Europe, emissions from the industrial belt across Belgium, Germany, and Poland drift north to Sweden and have damaged many lakes there. The convergence of air pollutants from many sources and the associated health effects have also been documented in relation to the multiple fires in Indonesia's rain forest in 1997 (Brauer and Hisham-Hashim 1998); the brown cloud over large areas of Asia, which is mainly related to coal burning; and a similar brown cloud over central Europe in the summer, which is caused primarily by vehicle emissions.

Managing air pollution interventions involves monitoring air quality, which may focus on exceedances of air quality guidelines in specific hotspots or on attempts to establish a specific population's average exposure to pollution. Sophisticated modeling in combination with monitoring has made it possible to start producing detailed estimates and maps of air pollution levels in key urban areas (World Bank 2004), thus providing a powerful tool for assessing current health impacts and estimated changes in the health impacts brought about by defined air pollution interventions.

Interventions to Reduce Water Pollution

Water pollution control requires action at all levels of the hierarchical framework shown in figure 43.1. The ideal method to abate diffuse chemical pollution of waterways is to minimize or avoid the use of chemicals for industrial, agricultural, and domestic purposes. Adapting practices such as organic farming and integrated pest management could help protect waterways (Scheierling 1995). Chemical contamination of waterways from industrial emissions could be reduced by cleaner production processes (UNEP 2002). Box 43.4 describes one project aimed at effectively reducing pollution.

Other interventions include proper treatment of hazardous waste and recycling of chemical containers and discarded products containing chemicals to reduce solid waste buildup and leaching of toxic chemicals into waterways. A variety of technical solutions are available to filter out chemical waste from industrial processes or otherwise render them harmless. Changing the pH of wastewater or adding chemicals that flocculate the toxic chemicals so that they settle in sedimentation ponds are common methods. The same principle can be used at the individual household level. One example is the use of iron chips to filter out arsenic from contaminated well water in Bangladeshi households (Kinniburgh and Smedley 2001).

Box 43.4

Water Pollution Control in India

In 1993, the Demonstration in Small Industries for Reducing Wastes Project was started in India with support from the United Nations Industrial Development Organization. International and local experts initiated waste reduction audits in four pulp and paper plants, four textile dyeing and finishing factories, and four pesticide production units. The experts identified priority areas, estimated the likely reduction in the pollutant load, and came up with more than 500 pollution prevention options. The 12 companies spent a total of US\$300,000 to implement pollution prevention options and saved US\$3 million in raw materials and wastewater treatment costs.

The most impressive savings were in the pulp and paper sector. For instance, the Ashoka Pulp and Paper Company participated in the project with the dual objectives of reducing production costs and complying with

environmental regulations in a cost-effective manner. Pressure from the public to improve environmental performance and the need to conserve water, especially during the summer, added urgency to the project. The company implemented 24 waste minimization options, with 13 additional options under consideration, resulting in net annual savings of about US\$160,000. The payback period for the implemented options was less than seven months, and the annual savings will continue.

The project demonstrated that waste minimization can cut pollution and business costs at the same time, especially when the environmental protection effort is directed toward the production process itself rather than to end-of-pipe treatment. The key to success lies in the sustained involvement of local experts and committed factory managers.

INTERVENTION COSTS AND COST-EFFECTIVENESS

This chapter cannot follow the detailed format for the economic analysis of different preventive interventions devised for the disease-specific chapters, because the exposures, health effects, and interventions are too varied and because of the lack of overarching examples of economic assessments. Nevertheless, it does present a few examples of the types of analyses available.

Comparison of Interventions

A review of more than 1,000 reports on cost per life year saved in the United States for 587 interventions in the environment and other fields (table 43.2) evaluated costs from a societal perspective. The net costs included only direct costs and savings. Indirect costs, such as forgone earnings, were excluded. Future costs and life years saved were discounted at 5 percent per year. Interventions with a cost per life year saved of less than or equal to zero cost less to implement than the value of the lives saved. Each of three categories of interventions (toxin control, fatal injury reduction, and medicine) presented in table 43.2 includes several extremely cost-effective interventions.

The cost-effective interventions in the air pollution area could be of value in developing countries as their industrial and transportation pollution situations become similar to the United States in the 1960s. The review by Tengs and

others (1995) does not report the extent to which the various interventions were implemented in existing pollution control or public health programs, and many of the most cost-effective interventions are probably already in wide use. The review did create a good deal of controversy in the United States, because professionals and nongovernmental organizations active in the environmental field accused the authors of overestimating the costs and underestimating the benefits of controls over chemicals (see, for example, U.S. Congress 1999).

Costs and Savings in Relation to Pollution Control

A number of publications review and discuss the evidence on the costs and benefits of different pollution control interventions in industrial countries (see, for example, U.S. Environmental Protection Agency 1999). For developing countries, specific data on this topic are found primarily in the so-called gray literature: government reports, consultant reports, or reports by the international banks.

Air Pollution. Examples of cost-effectiveness analysis for assessing air quality policy include studies carried out in Jakarta, Kathmandu, Manila, and Mumbai under the World Bank's Urban Air Quality Management Strategy in Asia (Grønskei and others 1996a, 1996b; Larssen and others 1996a, 1996b; Shah, Nagpal, and Brandon 1997). In each city, an emissions inventory was established, and rudimentary dispersion modeling was carried out. Various mitigation measures for

Table 43.2 Median Cost Per Life Year Saved, Selected Relatively Low-Cost Interventions (1993 U.S. dollars)

Intervention	Cost per life year saved
<i>Toxin control</i>	
Control coal-fired power plant emissions through high chimneys and other means	≤ 0
Reduce lead in gasoline from 1.1 to 0.1 grams per gallon	≤ 0
Ban amitraz pesticide on apples	≤ 0
Introduce a chloroform emission standard at selected pulp mills	≤ 0
Control SO ₂ by desulfuring residual fuel oil	≤ 0
Initiate sedimentation, filtration, and chlorination of drinking water	4,200
Introduce radon remediation in homes with levels greater than 21.6 picocuries per liter	6,100
Ban asbestos in brake linings	29,000
Set arsenic emission standards at selected copper smelters	36,000
<i>Fatal injury reduction</i>	
Make motorcycle helmet laws mandatory	≤ 0
Install automatic seat belts in cars	≤ 0
Require bad drivers to attend driving improvement schools	≤ 0
Pass a law requiring smoke detectors in homes	≤ 0
Improve standards for concrete construction	≤ 0
Ban residential growth in tsunami-prone areas	≤ 0
Make seat belt use in cars mandatory	69
Install smoke detectors in airplane lavatories	30,000
<i>Medicine</i>	
Require all common types of early childhood vaccinations	≤ 0
Implement annual stool colon cancer screening for people age 55 and older	≤ 0
Introduce detoxification or methadone maintenance for heroin addicts	≤ 0
Screen newborns for phenylketonuria	≤ 0
Recommend cervical cancer screening every three years for women age 65 and older	≤ 0
Introduce universal prenatal care for expectant mothers	≤ 0
Vaccinate all citizens against influenza	140
Screen men age 45–54 for hypertension	5,200
Institute annual mammography and breast examinations for women age 40–64	17,000
Perform three-vessel coronary artery bypass surgery for severe angina	23,000

Source: Based on Tengs and others 1995.

Note: The fatal injury reduction and medicine categories are included for comparison purposes.

reducing PM₁₀ and health impacts were examined in terms of reductions in tons of PM₁₀ emitted, cost of implementation, time frame for implementation, and health benefits and their associated cost savings. Some of the abatement measures that have been implemented include introducing unleaded gasoline, tightening standards, introducing low-smoke lubricants for two-stroke engine vehicles, implementing inspections of vehicle exhaust emissions to address gross polluters, and reducing garbage burning.

Transportation policies and industrial development do not usually have air quality considerations as their primary objec-

tive, but the World Bank has developed a method to take these considerations into account. The costs of different air quality improvement policies are explored in relation to a baseline investment and the estimated health effects of air pollution. A comparison will indicate the cost-effectiveness of each policy. The World Bank has worked out this “overlay” approach in some detail for the energy and forestry sectors in the analogous case of greenhouse gas reduction strategies (World Bank 2004).

Water Pollution. The costs and benefits associated with interventions to remove chemical contaminants from water need to

be assessed on a local or national basis to determine specific needs, available resources, environmental conditions (including climate), and sustainability. A developing country for which substantial economic analysis of interventions has been carried out is China (Dasgupta, Wang, and Wheeler 1997; Zhang and others 1996).

Another country with major concerns about chemicals (arsenic) in water is Bangladesh. The arsenic mitigation programs have applied various arsenic removal technologies, but the costs and benefits are not well established. Bangladesh has adopted a drinking water standard of 50 µg/L (micrograms per liter) for arsenic in drinking water. The cost of achieving the lower WHO guideline value of 10 µg/L would be significant. An evaluation of the cost of lowering arsenic levels in drinking water in the United States predicts that a reduction from 50 to 10 µg/L would prevent a limited number of deaths from bladder and lung cancer at a cost of several million dollars per death prevented (Frost and others 2002).

Alternative water supplies need to be considered when the costs of improving existing water sources outweigh the benefits. Harvesting rainwater may provide communities with safe drinking water, free of chemicals and micro-organisms, but contamination from roofs and storage tanks needs to be considered. Rainwater collection is relatively inexpensive.

ECONOMIC BENEFITS OF INTERVENTIONS

One of the early examples of cost-benefit analysis for chemical pollution control is the Japan Environment Agency's (1991) study of three Japanese classical pollution diseases: Yokkaichi asthma, Minamata disease, and Itai-Itai disease (table 43.3). This analysis was intended to highlight the economic aspects of pollution control and to encourage governments in developing countries to consider both the costs and the benefits of industrial development. The calculations take into account the 20 or 30 years that have elapsed since the disease outbreaks occurred and annualize the costs and benefits over a 30-year period. The

pollution damage costs are the actual payments for victims' compensation and the cost of environmental remediation. The compensation costs are based on court cases or government decisions and can be seen as a valid representation of the economic value of the health damage in each case. As table 43.3 shows, controlling the relevant pollutants would have cost far less than paying for damage caused by the pollution.

A few studies have analyzed cost-benefit aspects of air pollution control in specific cities. Those analyses are based mainly on modeling health impacts from exposure and relationships between doses and responses. Voorhees and others (2001) find that most studies that analyzed the situation in specific urban areas used health impact assessment to estimate impacts avoided by interventions. Investigators have used different methods for valuing the economic benefits of health improvements, including market valuation, stated preference methods, and revealed preference methods. The choice of assumptions and inputs substantially affected the resulting cost and benefit valuations.

One of the few detailed studies of the costs and benefits of air pollution control in a specific urban area (Voorhees and others 2000) used changing nitric oxide and NO₂ emissions in Tokyo during 1973–94 as a basis for the calculations. The study did not use actual health improvement data but calculated likely health improvements from estimated reductions in NO₂ levels and published dose-response curves. The health effects included respiratory morbidity (as determined by hospital admissions and medical expenses), and working days lost for sick adults, and maternal working days lost in the case of a child's illness. The results indicated an average cost-benefit ratio of 1 to 6, with a large range from a lower limit of 3 to 1 to an upper limit of 1 to 44. The estimated economic benefits of reductions in nitric oxide and NO₂ emissions between 1973 and 1994 were considerable: US\$6.78 billion for avoided medical costs, US\$6.33 billion for avoided lost wages of sick adults, and US\$0.83 billion for avoided lost wages of mothers with sick children.

Blackman and others' (2000) cost-benefit analysis of four practical strategies for reducing PM₁₀ emissions from

Table 43.3 Comparison of Actual Pollution Damage Costs and the Pollution Control Costs That Would Have Prevented the Damage, for Three Pollution-Related Disease Outbreaks, Japan (¥ millions, 1989 equivalents)

Pollution disease	Main pollutant	Pollution control costs	Pollution damage costs			Total
			Health damage	Livelihood damage	Environmental remediation	
Yokkaichi asthma	SO ₂ , air pollution	14,800	21,000 (1,300) ^a	Not estimated	Not estimated	21,000
Minamata disease	Mercury, water pollution	125	7,670	4,270	690	12,630
Itai-Itai disease	Cadmium, water and soil pollution	600	740	880	890	2,510

a. Based on actual compensation payments to a fraction of the population. The larger figure is what it would have cost to compensate all those who were affected.

traditional brick kilns in Ciudad Juárez in Mexico suggests that, given a wide range of modeling assumptions, the benefits of three control strategies would be considerably higher than the costs. Reduced mortality was by far the largest component of benefits, accounting for more than 80 percent of the total.

Pandey and Nathwani (2003) applied cost-benefit analysis to a pollution control program in Canada. Their study proposed using the life quality index as a tool for quantifying the level of public expenditure beyond which the use of resources is not justified. The study estimated total pollution control costs at US\$2.5 billion per year against a monetary benefit of US\$7.5 billion per year, using 1996 as the base year for all cost and benefit estimates. The benefit estimated in terms of avoided mortality was about 1,800 deaths per year.

El-Fadel and Massoud's (2000) study of urban areas in Lebanon shows that the health benefits and economic benefits of reducing PM concentration in the air can range from US\$4.53 million to US\$172.50 million per year using a willingness-to-pay approach. In that study, the major monetized benefits resulted from reduced mortality costs.

Aunan and others (1998) assessed the costs and benefits of implementing an energy saving and air pollution control program in Hungary. They based their monetary evaluation of benefits on local monitoring and population data and took exposure-response functions and valuation estimates from Canadian, U.S., and European studies. The authors valued the average total benefits of the interventions at US\$1.56 billion per year (with 1994 as the base year), with high and low bounds at US\$7.6 billion and US\$0.4 billion, respectively. They estimated the cost-benefit ratio at 1 to 3.4, given a total cost of interventions of US\$0.46 billion per year. Many of the benefits resulted from reduced mortality in the elderly population and from reduced asthma morbidity costs.

Misra (2002) examined the costs and benefits of water pollution abatement for a cluster of 250 small-scale industries in Gujarat, India. Misra's assessment looked at command-and-control, market-based solutions and at effluent treatment as alternatives. In a cost-benefit analysis, Misra estimated the net present social benefits from water pollution abatement at the Nandesari Industrial Estate at Rs 0.550 billion at 1995–96 market prices using a 12 percent social discount rate. After making corrections for the prices of foreign exchange, unskilled labor, and investment, the figure rose to Rs 0.62 billion. It rose still further to about Rs 3.1 billion when distributional effects were taken into account.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

The foregoing examples demonstrate that interventions to protect health that use chemical pollution control can have an attractive cost-benefit ratio. The Japan Environment

Agency (1991) estimates the national economic impact of pollution control legislation and associated interventions. During the 1960s and early 1970s, when the government made many of the major decisions about intensified pollution control interventions, Japan's gross domestic product (GDP) per capita was growing at an annual rate of about 10 percent, similar to that of the rapidly industrializing countries in the early 21st century. At that time, Japan's economic policies aimed at eliminating bottlenecks to high economic growth, and in the mid 1960s, industry was spending less than ¥50 billion per year on pollution control equipment. By 1976, this spending had increased to almost ¥1 trillion per year. The ¥5 trillion invested in pollution control between 1965 and 1975 accounted for about 0.9 percent of the increase in GDP per capita during this period. The Japan Environment Agency concluded that the stricter environmental protection legislation and associated major investment in pollution control had little effect on the overall economy, but that the resulting health benefits are likely cumulative.

Air

The broadest analysis of the implementation of control strategies for air pollution was conducted by the U.S. Environmental Protection Agency in the late 1990s (Krupnick and Morgenstern 2002). The analysis developed a hypothetical scenario for 1970 to 1990, assuming that the real costs for pollution control during this period could be compared with the benefits of reduced mortality and morbidity and avoided damage to agricultural crops brought about by the reduction of major air pollutant levels across the country during this period. The study estimated reduced mortality from dose-response relationships for the major air pollutants, assigning the cost of each death at the value of statistical life and the cost of morbidity in relation to estimated health service utilization. The study used a variety of costing methods to reach the range of likely present values presented in table 43.4. It assumed that the reduction of air pollution resulted from the implementation of the federal Clean Air Act of 1970 and associated state-level regulations and air pollution limits.

The analysis showed a dramatically high cost-benefit ratio and inspired debate about the methodologies used and the results. One major criticism was of the use of the value of statistical life for each death potentially avoided by the reduced air pollution. A recalculation using the life-years-lost method reduced the benefits for deaths caused by PM from US\$16,632 billion to US\$9,100 billion (Krupnick and Morgenstern 2002). The recalculated figure is still well above the fifth percentile estimate of benefits and does not undermine the positive cost-benefit ratio reported. Thus, if a developing country were to implement an appropriate control strategy for urban air pollution, it might derive significant

Table 43.4 Present Value of Monetary Benefits and Costs Associated with Implementation of the U.S. Clean Air Act, 1970–90 (1990 US\$ billions)

Category	Pollutant	Present value, 5th percentile	Present value, mean	Present value, 95th percentile
Mortality	PM	2,369	16,632	40,957
Mortality	Lead	121	1,339	3,910
Chronic bronchitis	PM	409	3,313	10,401
IQ reduction	Lead	271	399	551
Other morbidity	Several	227	337	501
Soil damage	PM	6	74	192
Visibility reduction	PM	38	54	71
Agricultural damage	Ozone	11	23	35
Total benefits	All	3,452	22,171	56,618
Total costs	All	Not estimated	523	Not estimated
Net benefits (total benefits – total costs)	All	Not estimated	21,648	Not estimated

Source: Krupnick and Morgenstern 2002.

economic benefits over the subsequent decades. The country's level of economic development, local costs, and local benefit valuations will be important for any cost-benefit assessment. WHO's (2000) air quality guidelines are among the documents that provide advice on analytical approaches.

Water

We were unable to find an analysis for water similar to the broad analysis presented for air, but the examples of water pollution with mercury, cadmium, and arsenic described earlier indicate the economic benefits that can be reaped from effective interventions against chemical water pollution. Since the pollution disease outbreaks of mercury and cadmium poisoning in Japan, serious mercury pollution situations have been identified in Brazil, China, and the Philippines, and serious cadmium pollution has occurred in Cambodia, China, the Lao People's Democratic Republic, and Thailand. Arsenic in groundwater is an ongoing, serious problem in Bangladesh, India, and Nepal and a less serious problem in a number of other countries.

WHO has analyzed control strategies for biological water pollution and water and sanitation improvements in relation to the Millennium Development Goals (Hutton and Haller 2004). The analysis demonstrated the considerable benefits of water and sanitation improvements: for every US\$1 invested, the economic return was in the range of US\$5 to US\$28 for a number of intervention options. Careful analysis of the same type is required for populations particularly vulnerable to chemical water pollution to assess whether control of chemical pollution can also yield significant benefits.

RESEARCH AND DEVELOPMENT AGENDA

Even though a good deal of information is available about the health risks of common air and water pollutants, further research is needed to guide regulations and interventions. The pollutants that were most common in developed countries in the past are still major problems in developing countries; however, direct application of the experiences of developed countries may not be appropriate, because exposed populations in developing countries may have a different burden of preexisting diseases, malnutrition, and other factors related to poverty. Research on specific vulnerabilities and on relevant dose-response relationships for different levels of economic development and for various geographic conditions would therefore be valuable for assessing risks and targeting interventions. In addition, global chemical exposure concerns, such as endocrine disruptors in air, water, and food, require urgent research to establish the need for interventions in both industrial and developing countries.

An important research topic is to clearly describe and quantify the long-term health effects of exposure to air pollution. The existing literature indicates that long-term exposure may have more adverse health effects than short-term exposure and, hence, have higher cost implications. Another topic is to assess the health issue pertaining to greenhouse gases and climate change, which are related to the same sources as urban air pollution (Intergovernmental Panel on Climate Change 2001). Research and policy analysis on how best to develop interventions to reduce health risks related to climate change need to be considered together with the analysis of other air pollutants.

In addition, to improve analysis of the economic costs of health impacts, better estimates are needed of the burden of disease related to chemical air and water pollution at local, national, and global levels. Cost-effectiveness analysis of air and water pollution control measures in developing countries needs to be supported by further research, as cost levels and benefit valuations will vary from country to country, and solutions that are valid in industrial countries may not work as well in developing countries. Strategies for effective air and water resource management should include research on the potential side effects of an intervention, such as in Bangladesh, where tube wells drilled to supply water turned out to be contaminated with arsenic (see box 43.2). Research is also needed that would link methodologies for assessing adverse health effects with exposure and epidemiological studies in different settings to permit the development of more precise forecasting of the health and economic benefits of interventions.

The variety of health effects of urban air pollution and the variety of sources create opportunities for ancillary effects that need to be taken into account in economic cost-effectiveness and cost-benefit analysis. These are the beneficial effects of reducing air pollution on other health risks associated with the sources of air pollution. For example, if the air pollution from transportation emissions is reduced by actions that reduce the use of private motor vehicles by, say, providing public transportation, not only are carbon dioxide levels reduced; traffic crash injuries, noise, and physical inactivity related to the widespread use of motor vehicles also decline (Kjellstrom and others 2003).

One of the key challenges for policies and actions is to find ways to avoid a rapid buildup of urban air pollution in countries that do not yet have a major problem. The health sector needs to be involved in assessing urban planning, the location of industries, and the development of transportation systems and needs to encourage those designing public transportation and housing to ensure that new sources of air pollution are not being built into cities.

Decades of economic and industrial growth have resulted in lifestyles that increase the demands on water resources simultaneous with increases in water pollution levels. Conflicts between household, industrial, and agricultural water use are a common public health problem (UNESCO 2003). The developing countries need to avoid the experiences of water pollution and associated disease outbreaks in industrial countries. Strategies to ensure sufficient pollution control must be identified at the same time as strategies to reduce water consumption. High water use depletes supplies and increases salinity in groundwater aquifers, particularly in coastal regions. The impact of climate change must also be taken into consideration (Vorosmarty and others 2000).

CONCLUSION: PROMISES AND PITFALLS

Evidence shows that a number of chemicals that may be released into the air or water can cause adverse health effects. The associated burden of disease can be substantial, and investment in research on health effects and interventions in specific populations and exposure situations is important for the development of control strategies. Pollution control is therefore an important component of disease control, and health professionals and authorities need to develop partnerships with other sectors to identify and implement priority interventions.

Developing countries face major water quantity and quality challenges, compounded by the effects of rapid industrialization. Concerted actions are needed to safely manage the use of toxic chemicals and to develop monitoring and regulatory guidelines. Recycling and the use of biodegradable products must be encouraged. Technologies to reduce air pollution at the source are well established and should be used in all new industrial development. Retrofitting of existing industries and power plants is also worthwhile. The growing number of private motor vehicles in developing countries brings certain benefits, but alternative means of transportation, particularly in rapidly growing urban areas, need to be considered at an early stage, as the negative health and economic impacts of high concentrations of motor vehicles are well established. The principles and practices of sustainable development, coupled with local research, will help contain or eliminate health risks resulting from chemical pollution. International collaboration involving both governmental and nongovernmental organizations can guide this highly interdisciplinary and intersectoral area of disease control.

Chapter 44

Prevention of Chronic Disease by Means of Diet and Lifestyle Changes

Walter C. Willett, Jeffrey P. Koplan, Rachel Nugent, Courtenay Dusenbury, Pekka Puska, and Thomas A. Gaziano

Coronary artery disease (CAD), ischemic stroke, diabetes, and some specific cancers, which until recently were common only in high-income countries, are now becoming the dominant sources of morbidity and mortality worldwide (WHO 2002). In addition, rates of cancers and cardiovascular disease (CVD) among migrants from low-risk to high-risk countries almost always increase dramatically. In traditional African societies, for example, CAD is virtually nonexistent, but rates among African Americans are similar to those among Caucasian Americans. These striking changes in rates within countries over time and among migrating populations indicate that the primary determinants of these diseases are not genetic but environmental factors, including diet and lifestyle. Thus, considerable research has been aimed at identifying modifiable determinants of chronic diseases.

Prospective epidemiological studies, some randomized prevention trials, and many short-term studies of intermediate endpoints such as blood pressure and lipids have revealed a good deal about the specific dietary and lifestyle determinants of major chronic diseases. Most of these studies have been conducted in Western countries, in part because of the historical importance of these diseases in the West, but also because they have the most developed research infrastructure. A general conclusion is that reducing identified, modifiable dietary and lifestyle risk factors could prevent most cases of CAD, stroke, diabetes, and many cancers among high-income populations (Willett 2002). These findings are profoundly important, because they indicate that these diseases are not inevitable consequences of a modern society. Furthermore, low rates of these diseases can be attained without drugs or expensive medical

facilities, an outcome that is not surprising, because their rates have historically been extremely low in developing countries with few medical facilities. However, preventing these diseases will require changes in behaviors related to smoking, physical activity, and diet; investments in education, food policies, and urban physical infrastructure are needed to support and encourage these changes (see box 44.1).

CHRONIC DISEASE PREVENTION

In this section, we briefly review dietary and lifestyle changes that reduce the incidence of chronic disease. The potential magnitude of benefit is also discussed.

Recommended Lifestyle Changes

Specific changes in diet and lifestyle and likely benefits are summarized in table 44.1. These relationships and supporting evidence are summarized here.

Avoid Tobacco Use. Avoidance of smoking by preventing initiation or by cessation for those who already smoke is the single most important way to prevent CVD and cancer (chapter 46). Avoiding the use of smokeless tobacco will also prevent a good deal of oral cancer.

Maintain a Healthy Weight. Obesity is increasing rapidly worldwide (chapter 45). Even though obesity—a body mass index (BMI) of 30 or greater—has received more attention

Box 44.1

The Insulin Resistance Syndrome

In recent years, researchers have recognized the insulin resistance syndrome (also known as the *metabolic syndrome*) as a common contributing factor to the development of diabetes, CAD, and some cancers. The syndrome is characterized by increased waist circumference, low HDL (high-density lipoprotein) cholesterol, high levels of triglycerides, hypertension, and glucose intolerance. The

most direct causes are overweight and inactivity, but dietary factors contribute. Genetic factors, which are probably beneficial during periods of food shortages, also play a role. Recent evidence indicates that the populations of Asia, Latin America, and probably Africa are particularly susceptible (Dickinson and others 2002; Harris and others 1998).

Table 44.1 Convincing and Probable Relationships between Dietary and Lifestyle Factors and Chronic Diseases

Dietary and lifestyle factors	CVD	Type 2 diabetes	Cancer	Dental disease	Fracture	Cataract	Birth defects	Obesity	Metabolic syndrome	Depression	Sexual dysfunction
Avoid smoking	↓	↓	↓	↓	↓	↓		↑			↓
Pursue physical activity	↓	↓	↓		↓			↓	↓	↓	↓
Avoid overweight	↓	↓	↓		↑	↓			↓		↓
<i>Diet</i>											
Consume healthy types of fats ^a	↓	↓							↓		
Eat plenty of fruits and vegetables	↓		↓		↓	↓	↓	↓			
Replace refined grains with whole grains	↓	↓						↓	↓		
Limit sugar intake ^b	↓	↓		↓				↓	↓		
Limit excessive calories								↓	↓		
Limit sodium intake	↓										

Source: Authors' summary of a review by the WHO and FAO 2003; Bacon and others 2003; Fox 1999; IARC 2002.

Note: **Bold** = convincing; Standard = probable relation; ↑ = increase in risk; ↓ = decrease in risk.

a. Replace trans and saturated fats with mono- and polyunsaturated fats, including a regular source of N-3 fatty acids.

b. Includes limiting sugar-based beverages.

than overweight, overweight (BMI of 25 to 30) is typically even more prevalent and also confers elevated risks of many diseases. For example, overweight people experience a two- to threefold elevation in the risks of CAD and hypertension and a more than tenfold increase in the risk of type 2 diabetes compared with lean individuals (BMI less than 23) (Willett, Dietz, and Colditz 1999). Both overweight and obese people also

experience elevated mortality from cancers of the colon, breast (postmenopausal), kidney, endometrium, and other sites (Calle and others 2003).

Many people with a BMI of less than 25 have gained substantial weight since they were young adults and are also at increased risk of these diseases, even though they are not technically overweight (Willett, Dietz, and Colditz 1999). For

example, in rural China, where the average BMI was less than 21 for both men and women, F. B. Hu and others (2000) found that the prevalence of hypertension was nearly five times greater for those with a BMI of approximately 25 than for the leanest people. Because many Asians are experiencing adverse consequences of excess body fat with a BMI of less than 25, the definition of overweight for Asia has recently been expanded to include a BMI of 23 to 25 (WHO 2000). For most people, unless obviously malnourished as an adolescent or young adult, bodyweight should ideally not increase by more than 2 or 3 kilograms after age 20 to maintain optimal health (Willett, Dietz, and Colditz 1999). Thus, a desirable weight for most people should be within the BMI range of 18.5 to 25.0, and preferably less than 23.

Additional valuable information can be obtained by measuring waist circumference, which reflects abdominal fat accumulation. In many studies, waist circumference is a strong predictor of CAD, stroke, and type 2 diabetes, even after controlling for BMI (Willett, Dietz, and Colditz 1999). A waist circumference of approximately 100 centimeters for men and 88 centimeters for women has been used as the criterion for the upper limit of the healthy range in the United States, but for many people this extent of abdominal fat would be far above optimal. Because abdominal circumference is easily assessed, even where scales may not be available, further work to develop locally appropriate criteria could be worthwhile. In the meantime, increases of more than 5 centimeters can be used as a basis for recommending changes in activity patterns and diet.

Views about the causes of obesity and ways to prevent or reduce it have been controversial. Diets low in fat and high in carbohydrates were believed to limit caloric intake spontaneously and thus to control adiposity, but such diets have not reduced bodyweight in trials that have lasted for a year or more (Willett and Leibel 2002). Some researchers have suggested that diets with a high energy density, referring to the amount of energy per volume, offer an alternative explanation for the observed increases in obesity (Swinburn and others 2004), but long-term studies have not examined this theory. Sugar-sweetened beverages contribute significantly to the overconsumption of calories, in part because calories in fluid form appear to be poorly regulated by the body (E. A. Bell, Roe, and Rolls 2003). In children, an increase in soda consumption of one serving per day was associated with an odds ratio of 1.6 for incidence of obesity (Ludwig, Peterson, and Gortmaker 2001), and in a randomized trial, replacement of a standard soda with a zero-calorie diet soda was associated with significant weight loss (Raben and others 2002). Reductions in dietary fiber and increases in the dietary glycemic load (large amounts of rapidly absorbed carbohydrates from refined starches and sugar) may also contribute to obesity (Ebbeling and others 2003; Swinburn and others 2004).

Aspects of the food supply unrelated to its macronutrient composition are also likely to be contributing to the global rise in obesity. Inexpensive food energy from refined grains, sugar, and vegetable oils has become extremely plentiful in most countries. Food manufacturers and suppliers use carefully researched methods to make products based on these cheap ingredients maximally convenient and attractive.

Maintain Daily Physical Activity and Limit Television Watching. Contemporary life in developed nations has markedly reduced people's opportunities to expend energy, whether in moving from place to place, in the work environment, or at home (Koplan and Dietz 1999). Dramatic reductions in physical activity are also occurring in developing countries because of urbanization, increased availability of motorized transportation to replace walking and bicycle riding, and mechanization of labor. However, regular physical activity is a key element in weight control and prevention of obesity (IARC 2002; Swinburn and others 2004). For example, among middle-aged West African women, more walking was associated with a three-unit lower BMI (Sobngwi, Gautier, and Mbanya 2003), and in China, car owners are 80 percent more likely to be obese (Hu 2002).

In addition to its key role in maintaining a healthy weight, regular physical activity reduces the risk of CAD, stroke, type 2 diabetes, colon and breast cancer, osteoporotic fractures, osteoarthritis, depression, and erectile dysfunction (table 44.1). Important health benefits have even been associated with walking for half an hour per day, but greater reductions in risk are seen with longer durations of physical activity and more intense activity.

The number of hours of television watched per day is associated with increased obesity rates among both children and adults (Hernandez and others 1999; Ruangdaraganon and others 2002) and with a higher risk of type 2 diabetes and gallstones (F. B. Hu and others 2001; Leitzmann and others 1999). This association is likely attributable both to reduced physical activity and to increased consumption of foods and beverages high in calories, which are typically those promoted on television. Decreases in television watching reduce weight (Robinson 1999), and the American Academy of Pediatrics recommends a maximum of two hours of television watching per day.

Eat a Healthy Diet. Medical experts have long recognized the effects of diet on the risk of CVD, but the relationship between diet and many other conditions, including specific cancers, diabetes, cataracts, macular degeneration, cholelithiasis, renal stones, dental disease, and birth defects, have been documented more recently. The following list discusses six aspects of diet for which strong evidence indicates important health implications (table 44.1). These goals are consistent with a detailed

2003 World Health Organization (WHO) report (WHO and FAO 2003).

- *Replace saturated and trans fats with unsaturated fats, including sources of omega-3 fatty acids.* Replacing saturated fats with unsaturated fats will reduce the risk of CAD (F. B. Hu and Willett 2002; Institute of Medicine 2002; WHO and FAO 2003) by reducing serum low-density lipoprotein (LDL) cholesterol. Also, polyunsaturated fats (including the long-chain omega-3 fish oils and probably alpha-linoleic acid, the primary plant omega-3 fatty acid) can prevent ventricular arrhythmias and thereby reduce fatal CAD. In a case-control study in Costa Rica, where fish intake was extremely low, the risk of myocardial infarction was 80 percent lower in those with the highest alpha-linoleic acid intake (Baylin and others 2003). Intakes of omega-3 fatty acids are suboptimal in many populations, particularly if fish intake is low and the primary oils consumed are low in omega-3 fatty acids (for example, partially hydrogenated soybean, corn, sunflower, or palm oil). These findings have major implications, because changes in the type of oil used for food preparation are often quite feasible and not expensive.

Trans fatty acids produced by the partial hydrogenation of vegetable oils have uniquely adverse effects on blood lipids (F. B. Hu and Willett 2002; Institute of Medicine 2002) and increase risks of CAD (F. B. Hu and Willett 2002); on a gram-for-gram basis, both the effects on blood lipids and the relationship with CAD risk are considerably more adverse than for saturated fat. In many developing countries, trans fat consumption is high because partially hydrogenated soybean oil is among the cheapest fats available. In South Asia, vegetable ghee, which has largely replaced traditional ghee, contains approximately 50 percent trans fatty acids (Ascherio and others 1996). Independent of other risk factors, higher intakes of trans fat and lower intakes of polyunsaturated fat increase risk of type 2 diabetes (F. B. Hu, van Dam, and Liu 2001).

- *Ensure generous consumption of fruits and vegetables and adequate folic acid intake.* Strong evidence indicates that high intakes of fruits and vegetables will reduce the risk of CAD and stroke (Conlin 1999). Some of this benefit is mediated by higher intakes of potassium, but folic acid probably also plays a role (F. B. Hu and Willett 2002). Supplementation with folic acid reduces the risk of neural tube defect pregnancies. Substantial evidence also suggests that low folic acid intake is associated with greater risk of colon—and possibly breast—cancer and that use of multiple vitamins containing folic acid reduces the risk of these cancers (Giovannucci 2002). Findings relating folic acid intake to CVD and some cancers have major implications for many parts of the developing world. In many areas, consumption

of fruits and vegetables is low. For example, in northern China, approximately half the adult population is deficient in folic acid (Hao and others 2003).

- *Consume cereal products in their whole-grain, high-fiber form.* Consuming grains in a whole-grain, high-fiber form has double benefits. First, consumption of fiber from cereal products has consistently been associated with lower risks of CAD and type 2 diabetes (F. B. Hu, van Dam, and Liu 2001; F. B. Hu and Willett 2002), which may be because of both the fiber itself and the vitamins and minerals naturally present in whole grains. High consumption of refined starches exacerbates the metabolic syndrome and is associated with higher risks of CAD (F. B. Hu and Willett 2002) and type 2 diabetes (F. B. Hu, van Dam, and Liu 2001). Second, higher consumption of dietary fiber also appears to facilitate weight control (Swinburn and others 2004) and helps prevent constipation.
- *Limit consumption of sugar and sugar-based beverages.* Sugar (free sugars refined from sugarcane or sugar beets and high-fructose corn sweeteners) has no nutritional value except for calories and, thus, has negative health implications for those at risk of overweight. Furthermore, sugar contributes to the dietary glycemic load, which exacerbates the metabolic syndrome and is related to the risk of diabetes and CAD (F. B. Hu, van Dam, and Liu 2001; F. B. Hu and Willett 2002; Schulze and others 2004). WHO has suggested an upper limit of 10 percent of energy from sugar, but lower intakes are usually desirable because of the adverse metabolic effects and empty calories.
- *Limit excessive caloric intake from any source.* Given the importance of obesity and overweight in the causation of many chronic diseases, avoiding excessive consumption of energy from any source is fundamentally important. Because calories consumed as beverages are less well-regulated than calories from solid food, limiting the consumption of sugar-sweetened beverages is particularly important.
- *Limit sodium intake.* The principle justification for limiting sodium is its effect on blood pressure, a major risk factor for stroke and coronary disease (chapter 33). WHO has suggested an upper limit of 1.7 grams of sodium per day (5 grams of salt per day) (WHO and FAO 2003).

Potential of Dietary and Lifestyle Factors to Prevent Chronic Diseases

Several lines of evidence indicate that realistic modifications of diet and lifestyle can prevent most CAD, stroke, diabetes, colon cancer, and smoking-related cancers. Less progress has been made in identifying practically modifiable causes of breast and prostate cancers.

Box 44.2

Success in Finland

Finland provides one of the best-documented examples of a community intervention. In 1972, Finland had the world's highest CVD mortality rate. Planners examined the policy and environmental factors contributing to CVD and sought appropriate changes, such as increased availability of low-fat dairy products, antismoking legislation, and improved school meals. They used the media; schools; worksites; and spokespersons from sports, education, and agriculture to educate residents. After five years, signifi-

cant improvements were documented in smoking, cholesterol, and blood pressure. By 1992, CVD mortality rates for men age 35 to 64 had dropped by 57 percent. The program was so successful that it was expanded to include other lifestyle-related diseases. Twenty years later, major reductions in CVD risk-factor levels, morbidity, and mortality were attributed to the project. Recent data show a 75 percent decrease in CVD mortality (Puska and others 1998).

One line of evidence is based on declines in CAD in countries that have implemented preventive programs. Rates of CAD mortality have been cut in half in several high-income countries, including Australia, the United Kingdom, and the United States. The most dramatic example is that of Finland (box 44.2).

Other evidence derives from randomized intervention studies. These often have serious limitations for estimating the potential magnitude of benefits, because typically only one or a few factors are modified, durations are usually only a few years, and noncompliance with lifestyle change is often substantial. Nevertheless, some examples are illustrative of the potential benefit. In two randomized studies among adults at high risk of type 2 diabetes, those assigned to a program emphasizing dietary changes, weight loss, and physical activity experienced only half the risk of incident diabetes (Knowler and others 2002; Tuomilehto and others 2001). The Lyon Heart Study, conducted among those with existing heart disease, found a Mediterranean-type diet high in omega-3 fatty acids reduced recurrent infarction by 70 percent compared with an American Heart Association diet (de Lorgeril and others 1994).

A third approach is to estimate the percentage of disease that is potentially preventable by reducing multiple behavioral risk factors using prospective cohort studies. Among U.S. adults, more than 90 percent of type 2 diabetes, 80 percent of CAD, 70 percent of stroke, and 70 percent of colon cancer are potentially preventable by a combination of nonsmoking, avoidance of overweight, moderate physical activity, healthy diet, and moderate alcohol consumption (Willett 2002).

Collectively, these findings indicate that the low rates of these diseases suggested by international comparisons and time trends are attainable by realistic, moderate changes that are compatible with 21st-century lifestyles.

INTERVENTIONS

Interventions aimed at changing diet and lifestyle factors include educating individuals, changing the environment, modifying the food supply, undertaking community interventions, and implementing economic policies. In most cases, quantifying the effects of the intervention is difficult, because behavioral changes may take many years and synergies are potentially important but hard to estimate in formal studies. Substantial nihilism often exists regarding the ability to change populations' diets or behaviors, but major changes are possible over extended periods of time. For example, per capita egg consumption in the United States decreased from approximately 420 to 270 per year between 1940 and 1990 following recommendations for preventing CAD (though in reality, the evidence for benefits was meager). Similarly, the prevalence of smoking, despite its being a physically addictive behavior, halved among men in the United States between 1965 and 2000. Because changing behaviors related to diet and lifestyle require sustained efforts, long-term persistence is needed. However, opportunities exist that do not require individual behavior changes, and these can lead to more rapid benefits.

Educational Interventions

Efforts to change diets, physical activity patterns, and other aspects of lifestyle have traditionally attempted to educate individuals through schools, health care providers, worksites, and general media. These efforts will continue to play an important role, but they can be strongly reinforced by policy and environmental changes.

School-Based Programs. School-based programs include the roles of nutrition and physical activity in maintaining physical

Box 44.3

The Planet Health Program

Planet Health, developed for middle school students, in the United States, has an immediate goal of reducing television viewing time with the long-range goal of preventing unhealthy weight gain (Gortmaker and others 1999). Teachers incorporate messages about reducing television watching, nutrition, and increasing fitness into mathematics, social studies, science, and language arts lessons. Fitness units and periodic “FitChecks” during physical

education complement the classroom lessons. Teacher training, student self-assessment using graphs, and student reflection about enjoyable activities that could replace at least a portion of the time they spend watching television are key elements. This program has reduced television watching and weight in girls (Gortmaker and others 1999). Because the program is integrated into existing classes, its cost is minimal.

Box 44.4

Live for Life®

Johnson & Johnson introduced Live for Life in 1979 with the goal of making its employees the healthiest in the world (Bly, Jones, and Richardson 1986). In 1993, the company integrated its health and wellness program with its disability management, employee assistance, and occupational medicine programs. Instead of using physicians and nurses to treat symptoms, the combined program sought to use a variety of health professionals to change individual behavior and improve health status. Employees

were offered US\$500 in benefit credits for participation. The program included routine health risk assessment, health promotion after recovery from a medical event, and support when returning to work after a major illness. Even though the intervention program had little effect on body-weight, physical fitness did increase. By the end of the third year, savings to the company were more than US\$400 per year per employee.

and mental health (box 44.3). School food services should provide healthy meals, both because they directly affect health and because they provide a special opportunity to teach by example. In many countries, school-based physical education remains a significant source of physical activity for young people. In China, 72 percent of children age 6 to 18 engage in moderate to vigorous physical activity for a median of 90 to 100 minutes per week (Tudor-Locke and others 2003). Maintaining these programs should be a high priority because they have likely contributed to the historically low rates of obesity in such countries.

Worksite Interventions. Worksite interventions can efficiently include a wide variety of health promotion activities because workers spend a large portion of their waking hours and eat a large percentage of their food there. Interventions can include educating employees; screening them for behavioral risk factors; offering incentive programs to walk, ride a bicycle, or take public transportation to work; offering exercise

programs during breaks or after work; improving the physical environment to promote activity; and providing healthier foods in cafeterias (box 44.4). Worksite health promotion can result in a positive return on investment through lower health costs and fewer sick days.

Interventions by Health Care Providers. Controlled intervention trials for smoking cessation and physical activity have shown that physician counseling, especially when accompanied by supporting written material, can be efficacious in modifying behavior. Studies of dietary counseling by physicians indicate that even brief messages about nutrition can influence behavior and that the magnitude of the effect is related to the intensity of the intervention (Pignone and others 2003). Identifying patients who are overweight or obese, or who are gaining weight but are not yet overweight, is an initial step in preventing and treating overweight. However, many physicians are not well trained to measure and calculate BMI and identify weight problems.

Box 44.5

Reducing Automobile Use in Brazil

Curitiba, Brazil, provides an example of the benefits of a strategy that reduces automobile use and increases use of public transportation. In 1965, city planners adopted a master plan that promoted development along designated corridors along with a bus system so efficient that it has virtually eliminated the need for automobiles. Minibuses

are used to quickly and efficiently transport individuals from residential neighborhoods to express bus lines. These bus lines run almost every 90 seconds and can carry up to 270 passengers each. Compared with other Brazilian cities of its size, Curitiba uses 30 percent less gasoline per capita, and its air pollution is among the lowest in the nation.

Transportation Policy and Environmental Design

Transportation policies and the design of urban environments are fundamental determinants of physical activity and therefore influence the risks of obesity and other chronic diseases. Countries can take a number of steps to make positive changes.

Limit the Role of Automobiles. In wealthy countries, the automobile has strongly influenced the trend toward low-density, automobile-based suburban developments, many built without sidewalks. These sprawling settlements tend to have few services within walking distance and are usually not linked to public transportation. Dependence on automobiles affects physical activity, because those who use public transportation tend to walk more. In a prospective study in eight provinces in China, 14 percent of households acquired a car between 1889 and 1997, and the likelihood of men becoming obese during the same period was twice as great in households that acquired a car than in those that did not (A. C. Bell, Ge, and Popkin 2002).

National policies strongly influence automobile use and dependency. In the United States, low taxes on gasoline, free parking, and wide streets encourage car ownership: almost 92 percent of U.S. households own at least one car, and 59 percent own two or more cars (Pucher and Dijkstra 2003). In contrast, in most of Western Europe, narrow streets, limited parking, and high gasoline prices make the costs of automobile use almost double those in the United States (Pucher and Dijkstra 2003). As a result, Europeans walk or bike more and use their cars approximately 50 percent less than their American counterparts. Investment in roads rather than in public transportation creates a vicious cycle: poor public transportation systems lead to more dependency on the automobile.

As car use grows, injuries and deaths associated with automobile accidents also grow. In China, the number of four-wheeled vehicles increased from about 60,000 to more than 50 million between 1951 and 1999, and traffic fatalities increased from about 6,000 to more than 413,000 (S. Y. Wang and others 2003). Many innovative strategies have been

developed to discourage private automobile use and to promote public transportation, walking, and bicycling (see box 44.5). Singapore has long been in the lead in relation to such efforts: a combination of limiting the number of licenses issued, implementing a vehicle quota system, and introducing a road pricing system has limited personal car ownership and congestion throughout the country. Other nations and regions are now enacting similar road pricing systems or congestion taxes. For example, London's congestion charging system levies a fee of approximately US\$8 per day for cars entering central London. Since its inception in 2003, the charge has reduced congestion in the city and is expected to channel funds back into the city's transportation facilities.

Unfortunately some countries, particularly China, have taken a different approach to their future transportation needs. Government initiatives that encourage families to buy automobiles include lowering taxes, simplifying registration procedures, and allowing foreign financing. In Beijing alone, residents purchased 400,000 cars in 2003.

Promote Walking and Bicycle Riding. Walking or cycling for transportation and leisure are effective and practical means of engaging in physical activity and are still the most common ways to travel in many developing countries. In Bangkok and Manila, only 25 percent of travel is by car, motorcycle, or taxi, compared with 75 percent by public transportation or walking (Pendakur 2000). In Madras, India, only 8 percent of the population travels by private, motorized transportation; 22 percent of people walk; 20 percent bike; and the rest use public transportation (Pendakur 2000). In China, approximately 90 percent of the urban population walks or rides a bicycle to work, shopping, or school each day (G. Hu and others 2002). Walking or biking is more likely to be prevalent in smaller cities—that is, those with 1 million to 5 million people—than in larger ones.

Bicycle riding and walking are also important for children's health. Most American children do not walk or bike to school, even when distances are short (box 44.6). In contrast, almost

Box 44.6

Walking and Cycling to School

One of the most effective ways to promote walking and cycling is through local schools. The Safe Routes to School program (<http://www.saferoutestoschools.org/>), established in Marin County, California, is a private-public partnership that created a citywide map of safe biking and

walking routes and proposed solutions for problem areas. The program also sponsors walk- and bike-to-school days, frequent-rider contests, and other promotional events (Stanton, Hubsmith, and Kallins 2003).

90 percent of Chinese children under 12 walk or ride a bicycle to school (Hu 2002).

In many areas, the shift toward private car use has not yet begun and can perhaps be forestalled by policies that benefit walkers and cyclists rather than drivers. Such policies include implementing road designs that promote a safe and well-lit environment for walking and cycling, including traffic-calming measures to reduce automobile speeds.

Many Western European countries have taken steps to increase safety for cyclists and walkers. In Germany and the Netherlands, bike paths serve as travel routes, not just weekend recreational destinations as they do in the United States. The former countries have invested heavily in bike paths and have also created extensive car-free areas in cities, with well-lit sidewalks, clearly marked crosswalks, and pedestrian islands that have improved safety. Both countries have increased the number of bicycle-friendly streets (on which cars are permitted but bicycles have the right of way) and have created systems to separate streams of traffic, including cars, pedestrians, and bicycles. A meta-analysis of selected traffic-calming studies in many countries reported reductions in traffic speed, accidents, injuries, and fatalities and an increase in bicycle use and walking (Bunn and others 2003).

Design Cities and Towns to Promote Health. Handy and others' (2002) comprehensive assessment of recent research on urban planning concludes that a combination of urban design, land-use patterns, and transportation systems that promotes walking and bicycling will help create active, healthier, and more livable communities. In densely developed cities that have been built around public transportation rather than away from it, individuals are much more likely to take public transit, walk, or bicycle than in other areas and to weigh less and be less likely to suffer from hypertension (Ewing, Schieber, and Zegeer 2003; Lopez 2004; Saelens, Sallis, and Frank 2003).

Those living in walker-friendly neighborhoods also appear to be more mentally healthy and are more likely to know their neighbors, to be socially active, and to participate in the political process (Leyden 2003). In contrast, urban sprawl has been

linked to decreases in mental health and social capital (Frumkin 2002) as well as anger and frustration over long commutes (Surface Transportation Policy Project 1999). Sprawl adversely affects the elderly in particular because they are unable to walk to places of interest and many cannot drive. Such isolation does not promote good physical or mental health.

The so-called smart growth movement has resulted from concerns about urban sprawl and unsustainable development and is encouraging governments worldwide to rethink how they develop new areas and redevelop older suburbs and cities. Smart growth principles include mixing land uses, using compact building designs, including a range of transportation and housing choices, building walker-friendly neighborhoods in attractive communities with a distinctive sense of place, and implementing a philosophy of directing development toward existing communities and the preservation of open space (Office of the Administrator 2001) (box 44.7).

The involvement of public health practitioners in transportation planning and building design is becoming more common. In Edinburgh, a health impact assessment conducted on proposed options for transportation policy showed the effects of specific choices on both affluent members of the community and the poor. Its recommendations, now adopted, included new spending on pedestrian safety, a citywide bicycle network, more greenways and park-and-ride programs, and more rail transportation or bus services. Priorities are to benefit pedestrians first, cyclists second, public transportation users third, freight and delivery people fourth, and car users last. Establishing criteria for building design can also lead to increases in physical activity. For example, increasing signage promoting stair use, as well as the attractiveness of the facilities themselves, encourages people to use the stairs (Boutelle and others 2001) (box 44.8).

Improved Food Supply

People's diets can be enhanced by improving the food supply. The usual position of the food industry is that it simply

Box 44.7

Enhancing Urban Life in the Republic of Korea

In Seoul, the government is managing growth by creating six satellite communities with high-rise residential buildings outside the city center. These communities are intended to become new job-creation centers and to shift

the balance of employment away from one centralized location to provide a more regional balance. Major expressways are being removed to create parks, sidewalks, and bikeways (<http://www.itdp.org/STe/ste6/#seoul>).

Box 44.8

Promoting Physical Activity in Brazil

One successful example of increasing activity is Agita São Paulo, a multilevel physical activity initiative designed for the 34 million citizens of Brazil's São Paulo state (Matsudo and others 2002). The program was launched in 1996 to increase the public's knowledge of the benefits of exercise and expand participation in physical fitness activities by encouraging people to do 30 minutes of moderate activity at least five times a week. As elsewhere, program designers perceived a lack of time as the major factor preventing daily exercise. They chose three settings as places to promote activity: home (gardening, chores, avoidance of television watching); transportation (walking, taking the stairs); and leisure time (dancing). Agitol, a prescription for exercise, was developed for physicians to dispense. Its

message is displayed on electricity bills and stickers, and it is touted by radio stations and other media outlets.

After four years, 55.7 percent of those surveyed had heard about Agita, 37 percent knew its purpose, and those who knew of the program's purpose were more likely to be active. Agita appears to have played a role in increasing activity in the region (Matsudo and others 2002). It is closely linked to a national program to promote healthy diets and active lifestyles by nutritional content labeling, promotion of healthy diets in schools, communication of guidelines for healthy eating, and encouragement of innovative community-based initiatives (Coitinho, Monteiro, and Popkin 2002).

provides whatever consumers demand, but this argument is misleading, because the industry spends more than US\$12 billion annually to influence consumer choices just within the United States and many times this amount globally. Much of this sum goes to promote foods with adverse health effects, and children are primary targets.

Improving Processing and Manufacturing. Altering the manufacturing process can rapidly and effectively improve diets because such action does not require the slow process of behavioral change. One example is eliminating the partial hydrogenation of vegetable oils, which destroys essential omega-3 fatty acids and creates trans fatty acids. European manufacturers have largely eliminated trans fatty acids from their food supply by altering production methods.

Regulations can facilitate changes in manufacturing directly or indirectly by providing an incentive for manufacturers to change their processes. For example, in 2003, the U.S. Food and

Drug Administration announced that food manufacturers had to include trans fatty acid content on the standard food label. Following imposition of this requirement, several large food companies said that they would reduce or eliminate trans fats, and many more are planning to do so (U.S. Food and Drug Administration 2003). In Mauritius, the government required a change in the commonly used cooking oil from mostly palm oil to soybean oil, which changed people's fatty acid intake and reduced their serum cholesterol levels (Uusitalo and others 1996). Changes in types of fat can often be almost invisible and inexpensive. Omega-3 fatty acid intakes can be increased by incorporating oils from rapeseed, mustard, or soybean into manufactured foods, cooking oils sold for use at home, or both. Selective breeding and genetic engineering provide alternative ways to improve the healthfulness of oils by modifying their fatty acid composition.

When the consumption of processed food is high, a reduction in salt consumption will usually require changes at the

manufacturing level, because processed food is a major salt source. If the salt content of foods is reduced gradually, the change is imperceptible to consumers. Coordination among manufacturers or government regulation is needed; otherwise producers whose foods are lower in salt may be placed at a disadvantage. Unfortunately, good examples are not available. Another example of improved processing would be to reduce the refining of grain products, which can be done in small, almost invisible decrements.

Fortifying Food. Food fortification has eliminated iodine deficiency, pellagra, and beriberi in much of the world. In regions where iodine deficiency remains a serious problem, fortification should be a high priority. Folic acid intake is sub-optimal in many regions of both developing and developed countries. Fortifying foods with folic acid is extremely inexpensive and could substantially reduce the rates of several chronic diseases. Grain products—such as flour, rice, and pasta—are usually the best foods to fortify, and in many countries, they are already being fortified with other B vitamins. Since 1998, grain products in the United States have been fortified with folic acid, which has almost eliminated folate deficiency, and rates of neural tube defect pregnancies have declined by about 19 percent (Honein and others 2001). Where intakes of vitamins B12 and B6 are also low and contribute to elevations of homocysteine, as among vegetarian populations in India, simultaneous fortification of food with these vitamins should be considered. The effects of fortification on reducing CVD are not considered proven, but the potential benefits are huge; therefore, intervention trials to evaluate the effects of fortification should be a high priority.

Increasing the Availability and Reducing the Cost of Healthy Foods. Policies regarding the production, importation, distribution, and sale of specific foods can influence their cost and availability. Policies may be directed at the focus of agricultural research and the types of production promoted by extension services. Policies often promote grains, dairy products, sugar, and beef, whereas those that encourage the production and consumption of fruits, vegetables, nuts, legumes, whole grains, and healthy oils would tend to enhance rather than reduce health.

Promoting Healthy Food Choices and Limiting Aggressive Marketing to Children. Almost every national effort to improve nutrition incorporates the promotion of healthy food choices, such as fruits, vegetables, and legumes. Ideally, such efforts are coordinated among government groups, retailers, professional groups, and nonprofit organizations, and investment in such efforts should include the careful testing and refining of social-marketing strategies.

Another strategy is to protect consumers from aggressive marketing of unhealthy foods. Producers spend billions of dollars a year encouraging children to consume foods that are detrimental to their health. Manufacturers and fast-food chains personify food products with cartoon characters; display food brands on toys; and issue “educational” card games that subvert children’s natural gift for play, story telling, and make believe. The willingness to limit advertising depends on a country’s political culture, but the public clearly distinguishes between advertising aimed at adults and that targeted at children. For example, in the United States, 46 percent of adults surveyed supported restrictions on advertising to children (Blendon 2002). Restrictions can range from banning advertising to children to limiting the types of products that advertisers may promote to this audience.

Initiatives at the Community Level

Nations and regions can promote a variety of initiatives to encourage greater physical activity and better nutrition. These initiatives are likely to be most effective when they are multifaceted and coordinated and when they are developed with the active involvement of individuals and organizations within communities (Puska and others 1998).

Many countries are undertaking efforts to educate their populations about healthy lifestyles. In the Islamic Republic of Iran, the Isfahan Healthy Heart Program, a WHO collaborating center for research and training for CVD control, prevention, and rehabilitation for cardiac patients, has developed a comprehensive, integrated community intervention that involves schools, worksites, health care facilities, food services, urban planners, and the media. Physical activity is promoted by creating safe routes for walking and bicycle riding and by organizing recreational walking that involves entire families (<http://ihhp.mui.ac.ir>).

South Africa’s Community Health Intervention Programme, a partnership between an insurance company and an academic institution, has created programs targeted to specific age groups, including children and older adults. The program’s twice-weekly classes have reduced blood pressure and increased strength and balance (Lambert, Bohlmann, and Kolbe-Alexander 2001) (box 44.9).

Singapore’s Fit and Trim Program uses a multidisciplinary approach to increase physical activity and healthy diets among schoolchildren. Between 1992 and 2000, the rate of obesity declined by 13.1 to 16.6 percent for children age 11 to 12 and 15 to 16 (Toh, Cutter, and Chew 2002) (box 44.10 outlines the national program for adults).

Economic Policies

Economic policies can have important effects on behavior and choices, and these policies have been particularly useful in

Box 44.9

A Comprehensive Intervention Approach in South Africa

The Coronary Risk Factor Study in South Africa (Rossouw and others 1993) tested community interventions at different levels of intensity in two communities with a third control community. The target population was Caucasian South Africans. Interventions included direct media campaigns, public health messages delivered in a variety of ways, and home mailings. Also included were community activities, such as fun walks, public meetings, involvement of community-based organizations, free screening for blood pressure, small-group personal interventions, and encouragement of food substitution in stores and restaurants. The

results showed an improvement in the community risk factor profile for CAD in the intervention communities, especially in relation to blood pressure, smoking, and overall risk. The results indicate no additional benefit of the personal intervention for high-risk individuals beyond that already offered by the mass media program. Estimated per capita costs of the heavy intervention program were roughly four times as much as for the mild intervention program (US\$22 per capita compared with US\$5 per capita), and the low-intervention community received almost the same level of benefits as the high-intervention community.

Box 44.10

The Singapore National Healthy Lifestyle Program

Because CVD and cancer had become the major causes of death in Singapore, the government adopted the National Healthy Lifestyle Program in 1992 (Cutter, Tan, and Chew 2001). This coordinated, multisectoral approach involved government ministries, health professionals, employers, unions, and community organizations. The program aimed at improving the social and physical environment so as to promote healthy living. Healthy diets, regular physical exercise, and nonsmoking were emphasized. The program used the mass media; legislative measures to discourage smoking; and widespread school, workplace, and community health promotion packages.

In a follow-up survey after six years, cigarette smoking had decreased from 34 to 27 percent among men, the proportion of adults who exercised regularly had increased from 14 to 17 percent, and the prevalence of obesity was stable. However, hypertension and high LDL cholesterol levels had increased modestly. From 1991 to 1999, the age-standardized incidence of myocardial infarction declined from 98.2 to 83.0 per 100,000 residents (Mak and others 2003) and age-standardized mortality from CAD decreased from 60.8 to 47.2 per 100,000 residents.

reducing the prevalence of smoking (see chapter 46). Policies that could influence diet and physical activity deserve careful consideration because they are rarely neutral and often support unhealthy behaviors. Consider the following examples:

- Subsidies can favor the consumption of less healthy foods, such as sugar, refined grains, beef, and high-fat dairy products as opposed to fruits, vegetables, whole grains, nuts, legumes, and fish. Poland provides a striking example of how changes in subsidies can affect health (box 44.11). Governments often subsidize foods indirectly by sheltering them from sales taxes in the recognition that they are essential; however, this logic should not extend to foods with adverse health effects, such as sugar-sweetened beverages

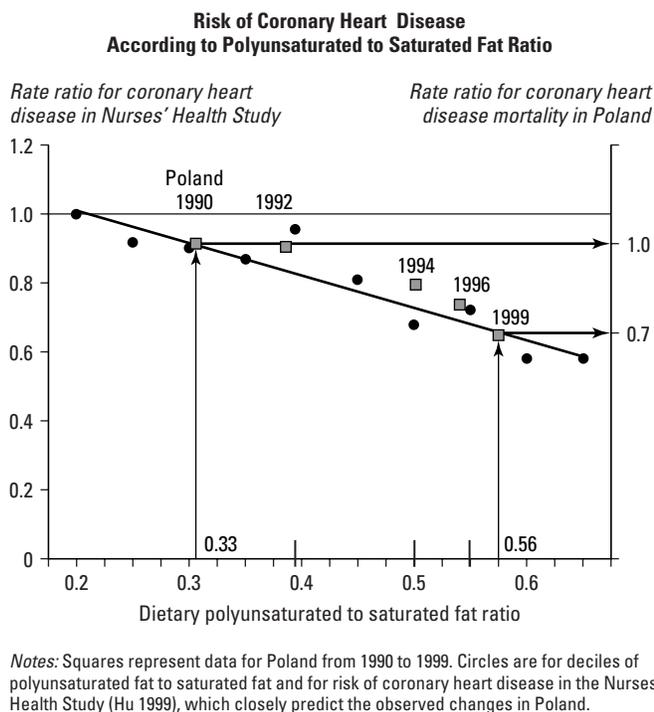

and those high in trans fats. Legislation can make this distinction, providing a modest economic incentive for healthier choices and at the same time conveying important nutritional messages (see chapter 11).

- Use of individual automobiles is often subsidized by building and maintaining highways, providing inexpensive parking, and imposing low taxes on petroleum products that do not fully reflect their societal and environmental costs. Increasing taxes on petroleum products and subsidizing public transportation could have an important effect on choice of transportation modality, which as noted earlier, has major effects on health.
- Walking, riding bicycles, and using public transportation can be promoted by economic policies that, in addition

Box 44.11

Poland: A Dramatic Decline in Heart Disease

After Poland's transition to a democratic government in the early 1990s, the government removed large subsidies for butter and lard, and consumption of nonhydrogenated vegetable fat increased rapidly (Zatonski, McMichael, and Powles 1998). The ratio of dietary polyunsaturated to saturated fat increased from 0.33 in 1990 to 0.56 in 1999, and during this period mortality rates from CAD dropped by 28 percent (data provided by W. Zatonski). Changes in smoking and in the consumption of fruits and vegetables probably played a minor role in this decrease (see figure).

to providing better infrastructure, include discounts on transportation fares, provide secure bicycle parking, and reduce health insurance premiums.

COST-EFFECTIVENESS OF INTERVENTIONS

Only a few studies have described interventions for lifestyle diseases in developing countries.

Modeling Likely Interventions

Primary targets for reducing lifestyle diseases include changing the fat composition of the diet, limiting sodium intake, and engaging in regular physical activity.

Using available data, we calculated a range of estimates under given assumptions for the cost-effectiveness of replacing dietary saturated fat with monounsaturated fat, replacing trans fat with polyunsaturated fat, and reducing salt intake. An increase in moderate physical activity by three to five hours per week is considered likely to lower the risk of many diseases, but data to model the cost-effectiveness of this intervention are not currently available. For further details of methods and assumptions underlying the analyses presented here, see the Web site version of this book.

Reducing Saturated Fat Content. In the base case, assuming a 3 percent drop in cholesterol and a US\$6 per person cost of the intervention, averting one disability-adjusted life year (DALY) would cost as little as US\$1,865 in South Asia and as much as US\$4,012 in the Middle East and North Africa. The intervention's effectiveness could be increased by replacing part of the saturated fat with polyunsaturated fat, which has additional beneficial effects mediated by mechanisms other than LDL cholesterol (see tables 44.2 and 44.3).

Replacing Dietary Trans Fat from Partial Hydrogenation with Polyunsaturated Fat. We could not use the model for saturated fat to estimate the effects of replacing trans fat with polyunsaturated fat because only a small part of the benefit is attributable to reducing LDL cholesterol (F. B. Hu and Willett 2002). Trans fats also adversely affect high-density lipoprotein (HDL) cholesterol, triglycerides, endothelial function, and inflammatory markers. In addition, increases in polyunsaturated fat (assuming a mix of N-6 and omega-3 fatty acids) will reduce LDL cholesterol, insulin resistance, and probably fatal cardiac arrhythmias.

In calculations that are based only on the adverse effects on LDL and HDL, replacing 2 percent of the energy from trans fat

Table 44.2 Incremental Cost-Effectiveness Ratios, Selected Interventions, by Region
(US\$/DALY averted)

Region	Media campaign to reduce saturated fat content	Substituting 2 percent of energy from trans fat with polyunsaturated fat				Reducing salt content by means of legislation plus public education
		7 percent CAD reduction		40 percent CAD reduction		
		Intervention cost of US\$0.50/adult ^a	Intervention cost of US\$6.00/adult	Intervention cost of US\$0.50/adult ^a	Intervention cost of US\$6.00/adult	
East Asia and the Pacific	2,769	73	1,583	Cost saving	227	2,056
Europe and Central Asia	2,929	65	1,670	Cost saving	228	2,170
Latin America and the Caribbean	3,297	40	1,865	Cost saving	225	2,476
Middle East and North Africa	4,012	25	2,259	Cost saving	252	3,056
South Asia	1,865	38	1,014	Cost saving	138	1,325
Sub-Saharan Africa	2,356	53	1,344	Cost saving	184	1,766

a. Based on the U.S. Food and Drug Administration's analysis of the costs of the intervention in the United States.

Table 44.3 Two-Way Sensitivity Analysis of the Costs of the Intervention to Reduce Saturated Fat Content and of the Relative Risk Reduction in CAD Events, South Asia (US\$/DALY averted)

Relative risk reduction in CAD events (percent)	Cost per individual		
	US\$0.25	US\$3.00	US\$6.00 ^a
10	Cost saving	318	680
5	Cost saving	680	1,403
4 ^b	Cost saving	911	1,865
1	258	3,572	7,188

Source: Authors' calculations.

a. Threshold analysis reveals that at the base assumption of US\$6 for the intervention, no level in the range of assumed CAD reduction is cost saving.

b. Threshold analysis reveals that at a cost below US\$0.36 per individual and a 4 percent reduction in CAD (base assumption), the intervention is cost saving.

with polyunsaturated fat was estimated to reduce CAD by 7 to 8 percent (Grundy 1992; Willett and Ascherio 1994). Epidemiological studies, which include the contributions of the additional causal pathways, suggest a much greater reduction, from about 25 to 40 percent (F. B. Hu and others 1997; Oomen and others 2001). Another likely benefit is a reduction in the incidence of type 2 diabetes: estimates indicate that the same 2 percent reduction would reduce incidence by 40 percent (Salmeron and others 2001).

Because voluntary action by industry (as has nearly been achieved in the Netherlands) or by regulation (as occurred in Denmark) can eliminate partially hydrogenated fat from the diet, this initiative does not require consumer education, and the costs can be extremely low. In an analysis required before implementing food labeling, the U.S. Food and Drug Administration (2003) estimated that trans fat labeling would be highly cost-effective. Even though the effect of labeling itself

was estimated to have only a modest effect on consumer behavior, as noted earlier, it is having a major effect on manufacturers' behavior.

The potential for reducing CVD rates by replacing trans fats with polyunsaturated fats will depend on the diets of specific populations. Whereas the intake of trans fat is low in China, it is likely to be high in parts of India, Pakistan, and other Asian countries because of the extraordinarily high content in commonly used cooking fats.

Table 44.2 presents the results of a cost-effectiveness analysis assuming the two different estimates for CAD reduction: 7 percent and 40 percent. We used costs of US\$0.50 per adult per year, which was the maximal cost in the U.S. Food and Drug Administration analysis, and of US\$6.00 per adult per year using traditional health education approaches. The lower estimate—or one even lower—is possible because trans fat can be eliminated at the source rather than depending entirely on changes in individual behavior. With the lower cost, the smaller effect estimate leads to a cost-effectiveness ratio of between US\$25 and US\$73 per DALY averted, depending on the region, and with the higher-effect estimate, the intervention can be cost saving.

Reducing the Salt Content of Manufactured Foods through Legislation and an Accompanying Education Campaign.

Table 44.2 shows the base-case cost-effectiveness of a legislated reduction in salt content. The intervention appears to be relatively cost-effective, with a cost per DALY averted of US\$1,325 in South Asia to US\$3,056 in the Middle East and North Africa. Those regional variations are attributable to differing risk profiles across regions as well as to price differentials for the costs of treating disease sequelae.

The actual blood pressure reduction from lower salt consumption could vary from the base-case assumption, as could the costs of the education campaign. Table 44.4 shows the

Table 44.4 Two-Way Sensitivity Analysis of the Costs of the Intervention to Reduce Salt Content and Its Effectiveness, South Asia (US\$/DALY averted)

Blood pressure reduction (millimeters of mercury)	Cost per individual		
	US\$1a	US\$3	US\$6
4	9	308	608
3	49	448	847
2 ^b	129	727	1,326
1	368	1,565	2,761

Source: Authors' calculations.

a. Threshold analysis reveals that at a cost of US\$1 per individual, a blood pressure reduction would have to be greater than 5 millimeters of mercury for the intervention to be cost saving. At the base-case assumption of a cost of US\$6 for the intervention, there is no cost saving threshold level of reduction.

b. Threshold analysis reveals that at a cost of less than US\$0.47 per individual the intervention is cost-saving.

results of lower costs of the education campaign and higher or lower effects of the intervention on blood pressure. These results may argue for initial efforts to focus on reductions in the use of salt during the manufacturing process with no public education campaign. The cost-effectiveness of such a change is high and could be augmented with a public education campaign only if needed to support the legislated change. At lower implementation costs, the intervention is highly cost-effective, even with half the assumed effect on blood pressure.

Adopting Physical Activity Interventions. Even though health experts believe that physical activity interventions are effective in reducing the risk of lifestyle diseases, no studies of their cost-effectiveness are available from developing countries. If people walk voluntarily (the model assumes no opportunity cost), a net economic benefit would accrue to all segments of the U.S. population. If we project the economic benefits to the entire U.S. population and assume 25 percent compliance by the sedentary population, the voluntary program would generate US\$6.8 billion in savings (in 2001 U.S. dollars).

Aggregate Costs of Obesity and Unhealthy Lifestyles

A series of U.S. studies appears to confirm that the avoidable costs of chronic diseases are substantial, although many developing countries have not yet experienced the full demands on their health sectors resulting from these conditions. Colditz (1999) estimates that obesity is responsible for 7 percent of all U.S. direct health care costs and that inactivity is responsible for an additional 2.4 percent of all health care costs. Indirect costs associated with obesity and inactivity account for another 5 percent of health care costs. Pronk and others (1999) assess the difference in health care costs between adult patients with

and without risk factors for noncommunicable diseases (physical activity, BMI, and smoking status) and find that a healthier lifestyle of physical activity three times per week, a moderate BMI, and nonsmoking status reduce health care costs by 49 percent compared with an unhealthy lifestyle.

Cost-Effectiveness of Community-Based Interventions

Populationwide and community-based interventions appear to be cost-effective if they reach large populations, address high-mortality and high-morbidity diseases, and are multipronged and integrated efforts. The full costs of achieving changes in behavior and policy are often complex and difficult to estimate. Interventions may yield additional spinoff benefits. For instance, decisions to reduce children's television viewing could easily improve school outcomes as well as reduce childhood obesity. Similarly, increasing walking and bicycle riding for transportation could reduce air pollution.

RESEARCH AND DEVELOPMENT PRIORITIES

A number of research and development priorities have been identified:

- Conduct randomized trials of the use of folic acid and alpha-linoleic acid to prevent CAD in developing countries. These interventions cost little, and the potential benefits are large and rapid.
- Develop prospective cohort studies of dietary and lifestyle factors in developing and transition countries to refine the understanding of risk factors in those contexts. To date, almost all such studies have taken place in Europe and North America.
- Develop surveillance systems for chronic diseases and for major risk factors, such as obesity, in developing countries.
- Develop additional multifaceted, community-based demonstration programs in developing countries to document the feasibility of lifestyle changes and to learn more about effective strategies.
- Conduct detailed cost-effectiveness analyses of various prevention strategies to modify dietary and lifestyle factors.

RECOMMENDED PRIORITY INTERVENTIONS

An overall objective is to develop comprehensive national and local plans that take advantage of every opportunity to encourage and promote healthy eating and active living. These plans would involve health care providers; worksites; schools; media; urban planners; all levels of food production, processing, and preparation; and governments. The goal is cultural change in the direction of healthy living. An important element in

cultural change is national leadership by individuals and by professional organizations. Specific interventions will depend on local physical and cultural conditions and should be based on careful analysis of existing dietary and activity patterns and their determinants; however, the following interventions can be considered (specific interventions for control of smoking are discussed elsewhere):

- Physical activity:
 - Develop transportation policies and a physical environment to promote walking and riding bicycles. This intervention includes constructing sidewalks and protected bicycle paths and lanes that are attractive, safe, well-lighted, and functional with regard to destinations.
 - Adopt policies that promote livable, walker-friendly communities that include parks and are centered around access to public transportation.
 - Encourage the use of public transportation and discourage overdependence on private automobiles.
 - Promote the use of stairs. Building codes can require the inclusion of accessible and attractive stairways.
- Healthy diets:
 - Develop comprehensive school programs that integrate nutrition into core curricula and healthy nutrition into school food services. Regional or national standards to promote healthy eating should be developed for school food services. Programs should also aim at limiting television watching, in part by promoting attractive alternatives.
 - Work with the agriculture sector and food industries to replace unhealthy fats with healthy fats, including adequate amounts of omega-3 fatty acids. This goal can be achieved through a combination of education, regulation, and incentives. Specific actions will depend on local sources of fat and on regional production and distribution. For example, in areas where palm oil is dominant, research could focus on developing strains that are lower in saturated fat and higher in unsaturated fat through selective breeding or genetic alteration. Labeling requirements or regulation can be used to discourage or eliminate the use of partially hydrogenated vegetable oils and to promote the use of nonhydrogenated unsaturated oils instead.
 - Require clear labeling of energy content for all packaged foods, including fast food.
 - Use tax policies to encourage the consumption of healthier foods. For example, high-sugar sodas could be fully taxed and not subsidized in the same way as healthier foods.
 - Emphasize the production and consumption of healthy food products in agriculture support and extension programs.
- Implement folic acid fortification if folic acid intake is low.
- Ensure that health providers regularly weigh both children and adult patients, track their weights over time, and provide counseling regarding diet and activity if they are already overweight or if unhealthy weight gain is occurring during adulthood. Those activities should be integrated with programs that address undernutrition. Health care providers should be encouraged to set a good example by not smoking, by exercising regularly, and by eating healthy diets.
- Promote healthy foods at worksite food services. Worksites can also promote physical activity by providing financial incentives for using public transportation or riding bicycles (and by not subsidizing automobiles by providing free parking). Providing areas for exercise during work breaks and showers may be useful.
- Set standards that restrict the promotion of foods high in sugar, refined starch, and saturated and trans fats to children on television and elsewhere.
- Set national standards for the amount of sodium in processed foods.
- National campaigns:
 - Invest in developing locally appropriate health messages related to diet, physical activity, and weight control. This effort is best done in cooperation with government agencies, nongovernmental organizations, and professional organizations so that consistent messages can be used on television and radio; at health care settings, schools, and worksites; and elsewhere. This effort should use the best social-marketing techniques available, with messages continuously evaluated for effectiveness.
 - Develop a sustainable surveillance system that monitors weight and height, physical activity, and key dietary variables.

Implementation of the recommended policies to promote health and well-being is often not straightforward because of opposition by powerful and well-funded political and economic forces, such as those involved in the tobacco, automobile, food, and oil industries (Nestle 2002). The solutions will depend on a country's specific political landscape. However, experiences in many countries indicate that alliances of public interest groups, professional organizations, and motivated individuals can overcome such powerful interests. Strategies should start with sound science and can use a mix of mass media, lobbying efforts, and lawsuits. Also, the food industry is far from monolithic, and elements can often be identified whose interests coincide with health promotion, which can create valuable partnerships. As an example, the willingness of some margarine manufacturers to invest in developing products free of trans fatty acids greatly helped the effort to reduce these fats, because these producers

then became proponents for labeling the trans fat content of foods. Protection of children can be a powerful lever because of almost universal concern about their welfare and the recognition that they cannot be responsible for the long-term consequences of their diet and lifestyle choices.

CONCLUSIONS

Many of the ongoing diet and lifestyle interventions in low- and middle-income countries are relatively recent, and few have documented reductions in the rates of major chronic diseases. However, the successes of Finland, Singapore, and many other high-income countries in reducing rates of CAD, stroke, and smoking-related cancers strongly suggest that similar benefits will emerge in the developing countries.

The Growing Burden of Risk from High Blood Pressure, Cholesterol, and Bodyweight

Anthony Rodgers, Carlene M. M. Lawes,
Thomas Gaziano, and Theo Vos

High blood pressure, cholesterol, and bodyweight are responsible for a large and increasing proportion of the global burden of disease. Although historically these risks have been regarded as “Western,” their impact is now recognized as global: they are already leading causes of disease in middle-income countries and of emerging importance in low-income countries (Ezzati and others 2004; WHO 2002). This chapter presents an evidenced-based review of the impact of high blood pressure, cholesterol, and bodyweight; the cost-effectiveness of relevant interventions; and the economic benefits of interventions. The chapter focuses on personal interventions—that is, those that are mediated largely by interpersonal actions and take place at the individual level. As such, the chapter should be considered as complementary to chapter 44 on lifestyles, which addresses populationwide interventions.

Prevention strategies have been broadly classified as individual based (also known as high risk) or population based (Rose 1985). The former typically involve screening to detect individuals above a certain threshold level of an individual risk factor—for example, people with hypertension—followed by personal interventions for those individuals. In contrast, the population-based approach aims at lowering mean risk-factor levels and shifting the population distribution of exposure in a favorable direction (Rose 1985). One example would be by reducing salt content in manufactured foods, thereby lowering blood pressure levels on a populationwide basis. Such an approach has the potential to produce large and lasting changes in disease incidence but requires substantial sociopolitical

investments. Another approach is an evolution of the individual-based strategy in which treatments are targeted to those at high absolute risk of cardiovascular disease (CVD) rather than those with single risk-factor levels above traditional thresholds, such as hypertension or obesity (Jackson and others 1993). Such an approach appears to be highly cost-effective, with the potential to substantially reduce CVD rates when combined with populationwide interventions (Murray and others 2003).

EPIDEMIOLOGY

Elevated blood pressure, cholesterol, and bodyweight are all established risk factors for CVD and, in the case of bodyweight, for other diseases, such as diabetes, certain cancers, and osteoarthritis. The associations between blood pressure (Asia Pacific Cohort Studies Collaboration 1999, 2003a; Prospective Studies Collaboration 2002); cholesterol (Asia Pacific Cohort Studies Collaboration 2003b; Law, Wald, and Thompson 1994; Prospective Studies Collaboration 1995); and body mass index (BMI) (Asia Pacific Cohort Studies Collaboration 2004; Willett and others 1995) and CVD are direct and continuous from relatively low levels, indicating that optimal levels are about 115/75 millimeters of mercury (mmHg), 3.8 millimoles per liter (mmol/l), and 21 kilograms per square meter (kg/m^2), respectively (figure 45.1).

Although some studies suggest *J*- or *U*-shaped associations (Calle and others 1999; Cruickshank 1994; D’Agostino and

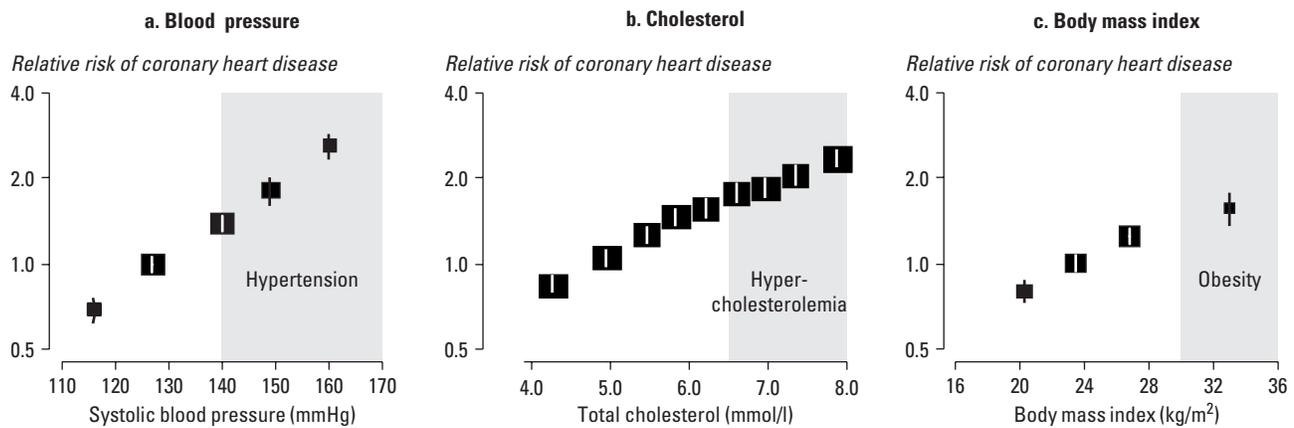

Figure 45.1 Continuous Risks of Blood Pressure, Cholesterol, and Body Mass and Coronary Heart Disease Risk

others 1991; Farnett and others 1991; Field and others 2001; Iso and others 1989; Kannel, D'Agostino, and Silbershatz 1997; Stewart 1979; Troiano and others 1996), low levels of these risk factors are unlikely to cause CVD. Rather, such associations more likely reflect incipient disease, which itself produces both a fall in risk-factor levels and an increase in CVD risk (Alderman 1996; Flack and others 1995; MacMahon and others 1997; Manson, Willett, and Stampfer 1995; Neaton and Wentworth 1992; Sleight 1997a, 1997b; Stevens and others 1998). No trial evidence points to a *J*-curve association for blood pressure, despite including patients with below average blood pressure (Hansson and others 1999; McMurray and McInnes 1992; Pfeffer 1993; Staessen and others 1997).

The continuous associations between blood pressure, cholesterol, and bodyweight and CVD demonstrate the lack of a biological justification for current threshold levels, such as those that define hypertension. Indeed, most of the disease burden resulting from these three risk factors occurs in the large majority of the population with nonoptimal levels but without hypertension, hypercholesterolemia, or obesity. Hence, this chapter avoids those terms and instead uses high blood pressure, high cholesterol, and high bodyweight, defined as nonoptimal levels of these risk factors (that is, over 115/75 mmHg, 3.8 mmol/l, or 21 kg/m², respectively).

The strength of the proportional associations of these risk factors with CVD is similar for most population subgroups. Although they attenuate with age, they remain strong and positive in the oldest age groups. Overall, in middle-aged populations, a 10 mmHg lower systolic blood pressure (SBP) is associated with a roughly 30 to 40 percent lower stroke risk and 20 to 25 percent lower ischemic heart disease (IHD) risk, a 1 mmol/l lower cholesterol level is associated with about a 15 to 20 percent lower stroke risk and 20 to 25 percent lower IHD risk, and a 2 kg/m² lower BMI is associated with an 8 to

12 percent lower stroke and IHD risk and an approximately 20 to 30 percent lower diabetes risk.

BURDEN OF THE DISEASE, CONDITION, OR RISK FACTOR

Epidemiological data on blood pressure, cholesterol, and bodyweight levels are predominantly available from developed countries; however, evidence indicates that these risk factors are important and increasing in many other countries. Surveys in developing countries suggest increases in these risks occur early in the path to industrialization (Bobak and others 1997; Evans and others 2001; Suh 2001; Wu and others 1996). Good evidence also documents risk-factor levels rising after people migrate to more urbanized settings (Poulter and Sever 1994) in Africa (Poulter 1999; Poulter, Khaw, and Sever 1988), China (He, Klag, and others 1991; He, Tell, and others 1991), and the Pacific islands (Joseph and others 1983; Salmond and others 1985; Salmond, Prior, and Wessen 1989). The World Health Organization's *Global Burden of Disease* study demonstrated that CVD was a leading cause of death in many regions and that most adults in developed and developing countries have nonoptimal blood pressure, cholesterol, and bodyweight levels (Ezzati and others 2004; WHO 2002). Indeed, even using traditional cutoff points, these risk factors are prevalent: of 140 subgroups defined by age, sex, and region, 45 percent had a mean SBP equal to or greater than 140 mmHg, 25 percent had mean cholesterol levels over 5.5 mmol/l, and 45 percent had mean BMI levels of at least 25 kg/m².

Health Burden

The *Global Burden of Disease* study assessed the burden attributable to nonoptimal levels of these risks (table 45.1) (Ezzati

Table 45.1 Global Burden of Disease Attributable to Nonoptimal Blood Pressure, Cholesterol, and BMI by Region, 2000

Condition	High-mortality developing countries ^a	Low-mortality developing countries ^b	Developed countries ^c	World total
<i>Attributable deaths (thousands)</i>				
Blood pressure	1,969	2,205	2,966	7,140 (12.8%)
Cholesterol	1,405	849	2,161	4,415 (7.9%)
BMI	399	775	1,417	2,591 (4.6%)
<i>Attributable DALYs (thousands)</i>				
Blood pressure	20,630	20,277	23,363	64,270 (4.4%)
Cholesterol	15,602	8,609	16,227	40,438 (2.8%)
BMI	6,408	11,115	15,892	33,415 (2.3%)

Sources: Ezzati and others 2004; WHO 2002b.

Note: The burden of disease estimated to be attributable to nonoptimal blood pressure (mean SBP > 115 mmHg), cholesterol (mean > 3.8 mmol/l), and body mass index (mean > 21 kg/m²) in 2000.

A, B, C and D designations in specific notes below are as follows: A = very low child mortality and very low adult mortality; B = low child mortality and low adult mortality; C = low child mortality and high adult mortality; D = high child mortality and high adult mortality; E = high child mortality and very high adult mortality.

a. The high-mortality developing countries include those in Africa, America D, the Eastern Mediterranean D, and Southeast Asia D.

b. The low-mortality developing countries include those in America B, Eastern Mediterranean B, Southeast Asia B, and the Western Pacific B.

c. The developed countries include those in America A, Europe, and the Western Pacific A.

and others 2004; WHO 2002). The burden for blood pressure was related to deaths and disability-adjusted life years (DALYs) from IHD, stroke, hypertensive disease, and other CVD; endpoints for cholesterol included IHD and stroke; and endpoints for BMI were IHD, stroke, hypertensive disease, diabetes, certain cancers, and osteoarthritis. Globally, 7.1 million deaths were attributed to high blood pressure in 2000, 4.4 million to high cholesterol, and 2.6 million to high BMI. This burden was shared approximately equally among the sexes. A large fraction occurred in middle age, especially in developing countries, and this factor, together with the frequently debilitating nature of nonfatal CVD, accounted for a large number of DALYs.

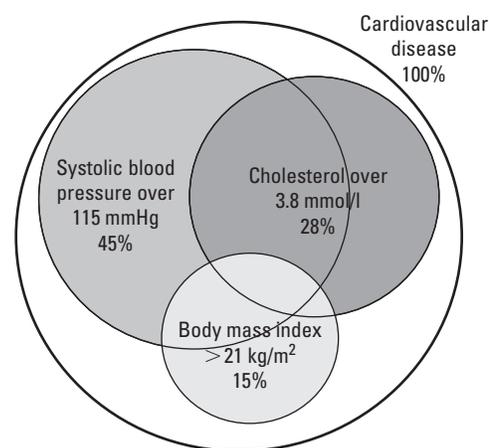

More of the DALY burden was experienced in developing countries than in developed countries, reflecting the large populations in developing countries and their already high risk-factor levels. In all regions, most CVD is attributable to the combined effects of high blood pressure, cholesterol, and body-weight levels (figure 45.2).

Table 45.2 shows the burden resulting from the overlapping or multicausal etiology of diseases. Analyses of the combined impact of these and other major cardiovascular risks indicate that the joint contribution of established risks is responsible for 83 to 89 percent of the IHD burden and 70 to 76 percent of the stroke burden worldwide (Ezzati and others 2003; Ezzati and others 2004).

Financial Burden

The economic impact of high blood pressure, cholesterol, and bodyweight levels can be estimated indirectly using the foregoing data—namely, that more than two-thirds of the CVD

burden can be attributed to those risks. In addition, more than three-quarters of type 2 diabetes is caused by high bodyweight (Ezzati and others 2004; WHO 2002). Hence the economic impact of nonoptimal levels of those risks will be at least two-thirds that due to CVD and diabetes. A recent report highlighted the economic impact of CVD in developing economies, noting that a high proportion of the CVD burden occurs among adults of working age (Leeder and others 2004). In Brazil, China, India, Mexico, and South Africa, conservative

Source: Ezzati and others 2004; WHO 2002.

Note: Individual and joint contributions of high blood pressure, cholesterol, and body weight to global cardiovascular burden are shown, with the size of each circle proportional to the size of burden (as measured in DALYs) (WHO 2002). The percentages indicate the attributable burden for each risk factor, and the overlap shows disease caused by joint or mediated effects.

Figure 45.2 Global CVD Burden Caused by High Blood Pressure, Cholesterol, and Bodyweight

Table 45.2 Individual and Joint Contributions of Seven Selected Risk Factors to the Burden of CVD by Region

Disease	Percentage of the regional disease burden	Population attributable fractions for individual risk factors (percentages)	Overall population attributable fraction (percent)
<i>High-mortality developing countries</i>			
Stroke	1.6	High blood pressure (56), high cholesterol (18), high BMI (7), low fruit and vegetable intake (12), physical inactivity (6), tobacco (7), alcohol (2)	65–71
IHD	3.0	High blood pressure (44), high cholesterol (54), high BMI (11), low fruit and vegetable intake (33), physical inactivity (21), tobacco (8), alcohol (4)	80–87
<i>Low-mortality developing countries</i>			
Stroke	4.7	High blood pressure (58), high cholesterol (13), high BMI (11), low fruit and vegetable intake (10), physical inactivity (5), tobacco (8), alcohol (7)	67–74
IHD	3.2	High blood pressure (45), high cholesterol (48), high BMI (22), low fruit and vegetable intake (31), physical inactivity (22), tobacco (8), alcohol (3)	79–87
<i>Developed countries</i>			
Stroke	6.0	High blood pressure (72), high cholesterol (27), high BMI (23), low fruit and vegetable intake (12), physical inactivity (9), tobacco (22), alcohol (0)	81–86
IHD	9.4	High blood pressure (58), high cholesterol (63), high BMI (33), low fruit and vegetable intake (28), physical inactivity (22), tobacco (22), alcohol (–0.2)	89–93
<i>World</i>			
Stroke	3.1	High blood pressure (62), high cholesterol (18), high BMI (13), low fruit and vegetable intake (11), physical inactivity (7), tobacco (12), alcohol (4)	70–76
IHD	4.0	High blood pressure (49), high cholesterol (56), high BMI (21), low fruit and vegetable intake (31), physical inactivity (22), tobacco (12), alcohol (2)	83–89

Note: See notes to table 45.1 for a breakdown of the regional groupings.

estimates indicated that at least 21 million years of future productive life are lost because of CVD each year. Although no detailed data exist on the direct economic burden of the individual risk factors, the costs of CVD treatment in developing countries are significant. In South Africa, for example, 2 to 3 percent of gross domestic product was devoted to the direct treatment of CVD, or roughly 25 percent of all health care expenditures (Pestana and others 1996). For many middle-income countries, high body mass is already an important cause of health inequities (Monteiro and others 2004).

Current expenditure in developed countries provides an indication of possible future expenditure in developing countries. For example, estimated direct and indirect costs of CVD in the United States were US\$350 billion in 2003. In 1998, US\$109 billion was spent on hypertension, or about 13 percent of the health care budget (Hodgson and Cai 2001). Studies are limited but suggest that obesity-related diseases are responsible

for 2 to 8 percent of all health care expenditures in developed countries. For example, in 1991, 2.5 percent of health care costs in New Zealand were attributable to obesity (Swinburn and others 1997), and in 1996, US\$22 billion was attributed to obesity-related CVD in the United States, equivalent to 17 percent of CVD-related health expenditures (G. Wang and others 2002).

INTERVENTIONS

Data on the choice of interventions for blood pressure, cholesterol, and bodyweight and their effectiveness are now presented.

Choice and Classification of Interventions

A variety of population-based and personal interventions could potentially be used to address the risks associated with

high blood pressure, cholesterol, and bodyweight. Of the personal interventions discussed in this section—lifestyle and dietary, pharmacological, and surgical interventions—two main strategies exist for choosing whom to treat: those above certain threshold values of *single* risk-factor levels and those above certain values of absolute cardiovascular (or global) risk, which is determined by the levels of *multiple* factors.

Targeting treatments by levels of a single risk factor (such as hypertension) does not effectively focus on overall risk of developing CVD, which is mainly determined by the net effects of other risk factors. For example, the predicted 10-year CVD risk for someone with an SBP of 140/90 mmHg can vary from 5 to 50 percent depending on the number of concomitant risk factors. The number of people who would need to be treated to prevent an event can therefore vary by an order of magnitude, even if they have the same blood pressure levels. Thus, a treatment strategy based only on individual risk-factor levels is likely to result in high-risk patients being undertreated and many patients at relatively low risk being treated with little absolute benefit, which is unlikely to be the best allocation of scarce health care resources.

The absolute-risk strategy was developed in New Zealand (Jackson and others 1993) and has been adopted extensively elsewhere, for example, by the British Hypertension Society (Ramsay and others 1999) and the Joint Task Force of European and other Societies on Coronary Prevention (Wood and others 1998). The absolute CVD risk is estimated using risk assessments such as the Framingham risk function (Anderson and others 1991) or the Prospective Cardiovascular Munster Study score (Assmann, Cullen, and Schulte 2002) on the basis of the number and severity of CVD risk factors. Targeting treatments at those at high absolute risk rather than those above arbitrary thresholds ensures a favorable ratio of benefits to risks. It can be expected to reduce events in the large proportion of people who are, for example, nonhypertensive but who still have nonoptimal blood pressure (Rose 1981). Combinations of personal interventions targeted at those at high absolute risk also have the potential of being highly cost-effective.

The simplest indicator of high absolute risk is established CVD, principally myocardial infarction, angina, stroke, or transient ischemic attack. For example, without preventive treatment, people who have had a myocardial infarction face an annual risk of death from coronary heart disease of about 5 percent (Law, Watt, and Wald 2002). That risk persists indefinitely—probably for the rest of a person's life—and varies little with age or sex.

However, many individuals with no history of CVD are at similar elevated risk for future CVD as a result of constellations of elevated risks. Thus, the distinction between primary and secondary prevention is somewhat artificial and could lead to undertreatment of many high-risk individuals. While recognizing that the distinction is somewhat arbitrary, this

chapter discusses the cost-effectiveness of efforts to manage those without previous CVD, and chapter 33 reviews the management of those with known vascular disease. A unifying system targeting treatments at those at highest risk, either with CVD or multiple risk factors, is likely to be highly cost-effective because more than 75 percent of events occur in the 5 to 10 percent of people with CVD or specific clusters of risk factors (Haq and others 1999; Tosteson and others 1997).

The limitations of the individual-risk-factor approach, together with increasing evidence that the thresholds do not have any biological justification, have motivated the adoption of strategies that take other risk factors into account. Although the most complete way of doing so is using the absolute-risk strategy outlined earlier, one intermediate strategy involves lowering the thresholds of blood pressure or lipid levels at which treatment is initiated if one or more additional CVD risk factors, such as diabetes, are present (Chobanian and others 2003).

Intervention Effectiveness

This section summarizes data on the effectiveness of population-based interventions and personal interventions (lifestyle and dietary interventions and pharmacological and surgical interventions). The studies concerned have mainly been conducted in developed countries.

Population-Based Interventions. Investigators have undertaken a variety of population-based community intervention studies, mostly in developed countries in the 1970s and 1980s (for further details see chapter 44). These studies have tended to be multifactorial projects testing whether comprehensive community programs could produce favorable changes in such risk factors as bodyweight, cholesterol, and blood pressure and in CVD morbidity and mortality (Schooler and others 1997). In general, they included a combination of populationwide and individual interventions, including messages disseminated through local associations, sports clubs, the media, and food associations; healthy food options at restaurants and worksite cafeterias; food labeling at supermarkets; face-to-face communication at meetings and distribution of educational materials; smoking restrictions; and competitions to develop healthy food. Except in Finland, the projects had mixed results, although many demonstrated significant effects with respect to individual components of the interventions. The limitations of many of the projects include inability to detect small but potentially important changes in risk factors, short duration of intervention and follow-up, and issues with outcome measures. Some have also suggested that those trials with less favorable results may have lacked adequate community support and public policy initiatives (Feinleib 1996; Mittelman and others 1993; Schooler and others 1997; Susser 1995).

A number of population-based interventions have also taken place in developing countries, including the following:

- In China, the Tianjin Project showed a significant reduction in sodium intake in men after three years of intervention, and after five years, the prevalence rates of both hypertension and obesity decreased among 45- to 65-year-olds (Schooler and others 1997).
- In Chile, the Mirame Project was a three-year intervention program designed to provide and evaluate strategies to promote healthy lifestyles among schoolchildren and their families. Nissinen, Berrios, and Puska (2001) report a significant positive effect on some risk factors for the intervention schools.
- In Mauritius, government-led initiatives resulted in a change in the composition of cooking oil from mostly palm oil, which is high in saturated fatty acids, to wholly soybean oil, which is high in unsaturated fatty acids. From 1987 to 1992, total cholesterol concentrations fell significantly, and the estimated intake of saturated fatty acids decreased, with much of this finding reportedly resulting from the change in cooking oil (Uusitalo and others 1996).

An effective populationwide intervention draws together different kinds of feasible activities that combined produce a synergistic effect (Nissinen, Berrios, and Puska 2001; Puska 1999). Even though the projects and trials were undertaken in a range of different communities and used a variety of methods and interventions, several common themes emerge. Some of the important elements of a successful program that enables individuals to adopt healthier lifestyles include the following:

- clear responsibility for coordinating prevention efforts, with credible agencies with good communication methods carrying out long-term education programs
- intersectoral collaboration, with multiple messages sourced from different organizations, including health sector entities, nonhealth government agencies, schools, workplaces, religious organizations, and voluntary agencies
- collaboration with the food industry to ensure the availability of reasonably priced healthier food options, with food labeling that presents relevant information in a clear, reliable, and standardized format
- realistic multiyear time frames.

Lifestyle and Dietary Personal Interventions. Many guidelines have concluded that lifestyle modifications, such as weight loss, healthy diet (such as one rich in potassium and low in sodium), physical activity, and moderate alcohol consumption are effective in reducing blood pressure (see, for example, Chobanian and others 2003). Trials indicate that a reduction of

salt intake lowers blood pressure, with larger blood pressure reductions in the elderly and in those with higher initial blood pressure levels (Law, Frost, and Wald 1991; Whelton and others 1998). An increase in daily fruit and vegetable intake may also lower blood pressure, and when combined with an increase in low-fat dairy products and a reduction in saturated and total fat, may lower blood pressure even more (Appel and others 1997). Weight reduction lowers blood pressure in proportion to the amount of weight lost (Whelton and others 1998), and physical activity appears to lower blood pressure in a way that may be independent of weight loss. High levels of alcohol intake are associated with blood pressure elevation, which is reversible by reducing intake (Kaplan 1995).

Dietary approaches to lowering total cholesterol and low-density lipoprotein (LDL) cholesterol typically involve reduced intake of dietary fats, particularly saturated fats. Evidence suggests a dose-response relationship between saturated fatty acid intake and LDL cholesterol levels (NCEP Expert Panel 2002). Plant sterols and stanols have recently been incorporated into foods such as margarine and can reduce LDL cholesterol by about 10 percent; however, this approach is currently relatively expensive (Law 2000). Dietary advice may also suggest increasing the intake of viscous fiber—for instance, in the form of cereal grains, fruits, and vegetables—because these dietary sources may enhance the lowering of LDL cholesterol. Maintaining bodyweight in the desirable range and engaging in moderate physical activity complement these dietary strategies (NCEP Expert Panel 2002).

Increases in obesity have been related to declines in energy expenditure (for example, reductions in physical activity and adoption of a more sedentary lifestyle) and a higher intake of energy-dense but micronutrient-poor foods, such as most processed foods (WHO 2003b). A variety of trials have recorded beneficial health effects, with weight reduction achieved by a combination of interventions (NHLBI Obesity Education Initiative Expert Panel 1998). These interventions include dietary counseling and therapy that involves a decrease in daily caloric intake and a reduction in saturated fats and total fats. An increase in physical activity is an important component of weight-loss therapy. Behavioral strategies revolving around self-monitoring of eating habits, stress management, problem solving, and social support may also complement these approaches. Overall, however, the effects of lifestyle modifications to reduce weight and maintain the weight loss are relatively poor, with many reports finding that weight returns to baseline levels after several years.

Pharmacological and Surgical Personal Interventions. Randomized trials have shown that medications to lower blood pressure effectively reduce the risk of stroke, IHD, and heart failure. Results from meta-analyses of more than 40 different trials

published in 2003 included about 210,000 participants and more than 8,000 stroke and 11,000 IHD events (Blood Pressure Lowering Treatment Trialists' Collaboration 2003; Fox and EUROPA Investigators 2003; Law, Wald, and Rudnicka 2003; Lawes and others 2004; Pepine and others 2003). The trials may be broadly classified into three groups: (a) drug versus placebo trials, (b) more intensive regimens to lower blood pressure versus less intensive regimens, and (c) drug versus drug trials.

The drug versus placebo trials achieved the greatest reductions in blood pressure, and a dose-response relationship was apparent between blood pressure reduction and reduced risk of stroke. Overall, the trials indicated that a 10 mmHg reduction in SBP would result in a 32 percent reduction in stroke risk and a 14 percent relative reduction in IHD risk. This finding is consistent with the size of associations observed in cohort studies.

Clear evidence indicates that all the major drug classes have similar effects on the risk of stroke and coronary heart disease per mmHg reduction in blood pressure (Blood Pressure Lowering Treatment Trialists' Collaboration 2003; Lawes and others 2004). The only clear evidence of clinically important, class-specific effects are with agents that block the renin-angiotensin system, which reduce diabetes incidence by about one-quarter, and with calcium channel blockers, which reduce heart failure less than other agents (although this result may be partly caused by misclassification, because a known side effect of calcium channel blockers is ankle edema, which is a diagnostic component of heart failure). Because all agents lower blood pressure by about the same modest amount and because their effects on blood pressure are additive (Law and others 2003), the key issue seems to be which combinations of two or more drugs should be provided and how long-term adherence can be maximized.

Over the past three decades, numerous trials have assessed the effect of different cholesterol-lowering interventions (Law, Wald, and Rudnicka 2003; Law, Wald, and Thompson 1994). The placebo-controlled trials can be broadly classified into those testing fibrates, statins, and other interventions (mostly dietary interventions, but also some other interventions such as resins and niacin). The statins are the most effective in lowering total and LDL cholesterol, with reductions of more than 1 mmol/l in most trials. A good correlation has been found between reduction in total cholesterol and relative risk reduction. This finding suggests, as for trials investigating blood pressure lowering, that even though some drugs are more effective in achieving greater reductions in risk factors, their effect on disease outcomes is similar per unit reduction of cholesterol. Overall, a 1 mmol/l reduction in total cholesterol is associated with a 21 percent relative risk reduction in IHD and a 17 percent reduction in risk of stroke. Again, this finding is consistent with the epidemiology, with the proviso that the vast majority of strokes in clinical trials were ischemic.

In clinical trials of statins, the relative risk reduction in cardiovascular events is similar at all levels of baseline cholesterol, extending to levels below 5 mmol/l total cholesterol, and is also consistent among patients who are and are not taking concurrent blood pressure lowering and other medications (Heart Protection Study Collaborative Group 2002). Similar findings are observed with treatments to lower blood pressure (Progress Collaborative Group 2001), indicating that these treatment effects are independent. This finding is plausible, because they act through different mechanisms and because observational studies do not suggest a large interaction (Neaton and Wentworth 1992).

The benefits of lowering blood pressure and cholesterol are achieved surprisingly rapidly: for most outcomes, risk appears to be fully reversed within 6 to 18 months of beginning treatment. For example, individuals with cholesterol lowered in the past two or more years are at approximately the same coronary heart disease risk as otherwise identical individuals whose cholesterol has been at that level for decades (Law, Wald, and Thompson 1994).

Pharmacological agents for weight loss that have been subject to randomized controlled trials include dexfenfluramine, sibutramine, orlistat, and phentermine/fenfluramine (although the last has been withdrawn because of a reported association between the drugs and valvular heart disease). Overall, trials suggest only modest weight-loss effects, with an average net weight loss of 1.5 kg after eight weeks and 2 to 3 kg after one year (NHLBI Obesity Education Initiative Expert Panel 1998). A systematic review of orlistat trials indicated a pooled net weight loss of 1.2 kg at 12 weeks, 2.9 to 3.4 kg at one year, and 2.5 to 2.4 kg at two years (O'Meara and others 2001). Results of a systematic review of trials assessing sibutramine were similar (O'Meara and others 2002), with fewer data available on long-term sustained weight loss.

Investigators have also undertaken several randomized controlled trials to assess the effects of different surgical interventions, generally in individuals with a BMI equal to or greater than 35 or 40 kg/m². Weight loss resulting from gastric bypass varied from 50 to 100 kg six months to a year following surgery (NHLBI Obesity Education Initiative Expert Panel 1998). Overall, several trials suggest that surgery resulted in about 23 to 37 kg more weight loss than conventional treatment and that this loss was maintained for eight years (Clegg and others 2002). Furthermore, gastric bypass surgery appears to be more beneficial than gastroplasty or jejunoileal bypass.

In relation to compliance and adherence with pharmacological therapy, population surveys have demonstrated that, even in industrial countries, high blood pressure is either untreated or inadequately controlled in about 70 to 75 percent of patients and that adherence to medications among patients suffering from chronic disease is only about 50 percent (WHO 2003a). The extent of poor adherence is likely to be even greater in

developing countries given the relative lack of health services and inequities in access. Pharmacotherapy faces a variety of potential barriers, including the symptomless nature of the conditions, a lack of knowledge or denial of risk, the complicated nature of drug regimens, the risk of side effects (real and perceived), and the costs of treatment.

Health providers may use multiple strategies to increase compliance and adherence. Patient-centered interventions include involving individuals in the decision-making process; providing individualized patient education and disease counseling and adapting treatment to patients' lifestyles; simplifying dosing schedules; providing drug information leaflets, medication charts, and special reminder packaging for medications; holding group sessions for education and family-oriented disease management therapies; and implementing automated telephone assessment and self-care education calls with nurse follow-up (Haynes and others 2003).

Strategies may also aim to increase physician adherence, and interventions may include the use of guidelines, peer review and audit, and prompts to remind physicians to review risks and medications (Ebrahim 1998; NCEP Expert Panel 2002). These strategies obviously do not address issues pertaining to resources and access in poor countries.

Several trials and overviews have attempted to assess the value of different interventions to improve compliance and adherence; however, issues have arisen in connection with the generalizability of the interventions, the low statistical power in many trials, the lack of description of all parts of interventions, and the assessment of complex interventions without assessment of the separate effects of the intervention components. Haynes and others' (2003) systematic review concludes that, overall, no single approach to improving adherence can be recommended. Simpler treatment regimens can sometimes improve adherence and treatment outcomes for both short- and long-term treatments. Several complex strategies, including combinations of more thorough patient instructions and counseling, easier access to care, reminders, close follow-up, supervised self-monitoring, family therapy, and rewards for success can improve adherence and treatment outcomes in some patients. However, even the most effective interventions did not lead to large improvements in adherence or treatment outcomes and were relatively resource intensive. By contrast, Connor, Rafter, and Rodgers's (2004) systematic review indicates improved adherence and clinical outcomes with fixed-dose combination treatment or unit-of-use packaging.

Few good, evidence-based strategies to improve obesity management are currently available, although reminder systems, brief training interventions, shared care, inpatient care, and dietitian-led treatments may all be worth further investigation (Harvey and others 2003). Thus, a clear need for innovations still exists to help people follow medication prescriptions as well as dietary and lifestyle advice.

COST-EFFECTIVENESS OF INTERVENTIONS

Costs include expenditures required to identify and treat risk factors as well as expenditures for treating CVD when it is not prevented. Where possible, this chapter deals with the separate sources of costs for several reasons. First, the costs for identifying those requiring treatment vary significantly by level of economic development and by urban versus rural location. In many situations in developing countries, such costs will make most or all forms of screening beyond a determination of CVD history unaffordable. Second, in some countries, such as India, that are large producers of generic drugs, prices are reported to be lower than in most other drug-producing or -importing countries. Third, this approach allows researchers and policy makers to understand the constituent costs so that they can examine where cost reductions may be most beneficial. Fourth, it clarifies what expenditures may be required as a result of changes in decisions about the treatment of risk factors. Finally, many people in developing countries do not have access to hospitals for acute management of CVD events. Nonetheless, increased expenditure on treating risk factors may lead to significant reductions in the costs of treating subsequent CVD events for many countries. Ultimately, the net effect is reflected in cost-effectiveness analyses. Unless otherwise stated, costs are in 2001 U.S. dollars.

The costs of personal interventions include the costs of patient screening (identifying high-risk patients), drugs and their acquisition, clinic visits, health care workers' time, laboratory tests, and travel. Annual drug costs for medications to lower blood pressure and cholesterol vary widely by country and depend on whether generics are available and used. For example, according to the *International Drug Price Indicator Guide* (Management Sciences for Health 2004), annual costs in 2002 of generic 40 mg lovastatin ranged from US\$14 in Barbados to US\$217 in Costa Rica, and on-patent statins can cost almost a US\$1,000 a year in the United States. Because drug costs vary by up to two orders of magnitude across countries, results of cost-effectiveness analyses are particularly sensitive to their input prices. Table 45.3 presents some sample prices. The costs of these medications have dropped considerably in recent years, and now the annual costs for hydrochlorothiazide (25 mg), atenolol (50 mg), and captopril (50 mg), are US\$2, US\$4, and US\$9, respectively (Management Sciences for Health 2004). Statins will become increasingly affordable as simvastatin joins lovastatin in coming off patent (2006 in the United States and already off patent in Germany and the United Kingdom).

The estimated number of visits to manage high blood pressure and cholesterol, under traditional paradigms, ranges from two to six per year at costs ranging from US\$3 to US\$20 per visit across the six regions assessed, but note that generally many fewer tests and less follow-up is required with a strategy

Table 45.3 Annual Costs of Selected Cardiovascular Medications

Medication	United States (2002 US\$) ^a	Average international price (2002 US\$)	Projected polypill ^b
Beta-blocker	32–365	3–15	n.a.
Diuretic	6–37	1–3	n.a.
Statin	180–864	11–147	n.a.
Aspirin	2	1–6	n.a.
Angiotensin-converting enzyme inhibitor	65–365	1–19	n.a.
Total	285–1,633	17–190	20–40

n.a. = not applicable.

a. Based on average wholesale prices.

b. Based on a moderate increase from the sum of the lowest-cost generic components.

based on absolute risk. Diagnostic testing for cholesterol in the United States using a general laboratory is reimbursed at US\$6 for total cholesterol, US\$16 for a complete lipoprotein cholesterol fractionation analysis, and US\$6 for triglycerides (Xact Medicare Services 2003). Point-of-care one-step enzymatic strips that require only a few drops of blood from a finger stick and that can process total cholesterol in minutes cost less than US\$3 per test (Greenland and others 1987). A basic metabolic panel for those on diuretics or for measuring renal function is US\$12. The costs attributed to patient time and travel for visits have not been estimated for many countries, but they were recently estimated at US\$12 to US\$26 per visit in the United States, depending on age and sex (Prosser and others 2000).

A review of studies to date highlights several issues regarding cost-effectiveness analyses, including the significant variations in terms of calculations of cost per life year saved. The two most important aspects of the cost-effectiveness of any primary intervention are the future risk for CVD of the population treated and the costs of the medications.

Population-Based Interventions

Given the strong association between CVD and high blood pressure, cholesterol, and body mass, most guidelines for those risk factors begin by recommending lifestyle modifications. Although these benefits can lead to changes in risk factors, their effect on CVD events is not well documented. However, on the basis of assumptions about cholesterol and blood pressure reduction from population-based lifestyle education programs and given the relatively low cost of the interventions—US\$5 to US\$17 per person per year (Tosteson and others 1997)—the cost-effectiveness of such programs may be reasonable. However, the cost-effectiveness ratios of these interventions were sensitive to the cost of the intervention as well as to the expected reduction in the risk factor. For example, a commu-

nity intervention that expects a 4 percent reduction in total serum cholesterol and costs US\$5 per person annually targeted would save more than US\$2 billion over 25 years of the program. When the North Karelia (Puska 1999) estimates were used in a cost-effectiveness analysis in the United States (Tosteson and others 1997), the cost-effectiveness ratios ranged from being cost saving to US\$88,000 (in 1985 U.S. dollars) per life year saved, depending on the percentage reduction in cholesterol (1 to 4 percent).

Personal Interventions to Lower Blood Pressure or Cholesterol in Developed Countries

A common finding of cost-effectiveness analyses of primary prevention of CVD by means of lowering blood pressure and cholesterol is the wide variability in cost-effectiveness ratios, depending on underlying risk, age, and costs of medications. For personal interventions using drug treatment for lowering blood pressure and cholesterol levels, no single cost-effectiveness analysis adequately summarizes experience in the developed countries. Collectively, the studies evaluating hypertension treatment in Australia, New Zealand, the United States, and the Scandinavian countries suggest a range of cost-effectiveness ratios from US\$4,600 to more than US\$100,000 per life year gained when applied to the entire adult population without further risk stratification (Kupersmith and others 1995). Compared with the entire population, for those at high risk with diastolic blood pressures over 105 mmHg and older than 45, hypertension treatment can cost as little as a few hundred dollars per life year gained or can even be cost saving (Johannesson and others 1991).

Investigators have reported that primary prevention with cholesterol-reducing medications is less attractive overall than other interventions, such as hypertension treatment, from a cost-effectiveness perspective, although once again this finding is likely to differ considerably now that statins are off patent.

Reported cost-effectiveness ratios have ranged from US\$10,000 to US\$2 million per life year gained (Hay, Yu, and Ashraf 1999), whereas dietary interventions for cholesterol reduction are more favorable, with ratios of around US\$2,000 per quality-adjusted life year (QALY) (Prosser and others 2000). For cholesterol treatment, Prosser and others (2000) find cost-effectiveness ratios of US\$50,000 per QALY for on-patent statins among those at highest risk (high cholesterol levels and multiple risk factors) and up to US\$1.4 million per QALY among low-risk females when compared with dietary strategy alone. The cost per life year gained in the primary prevention trial of the West of Scotland Coronary Prevention Study among high-risk individuals treated with pravastatin was about US\$30,000 (Caro and others 1997). Using the same criteria, Downs and others (1998) find that the cost per life year saved in the Air Force/Texas Coronary Atherosclerosis Prevention Study cohort with average cholesterol levels was more than US\$100,000. In general, younger and older age groups tend to have the least favorable cost-effectiveness ratios. For younger groups, this finding probably reflects their overall lower risk and the many years of treatment required before realizing a benefit. For the elderly, high cost-effectiveness ratios may reflect other competing causes of death and the delay of up to two years between treatment and benefit seen in most primary prevention trials.

Personal Interventions to Lower Blood Pressure or Cholesterol in Developing Countries

No trials of blood pressure, cholesterol, or body mass lowering have been conducted solely in developing countries. As a result, we have derived assessments of cost-effectiveness by extrapolating from results in developed countries presented earlier. Goldman and others (1991) report that a decline in the cost of lovastatin by 40 percent, once generic, would result in a roughly 30 percent reduction in the cost-effectiveness ratio. However, this finding does not take into account that both the underlying epidemiology and the costs can be quite different across and within countries and regions.

Murray and others (2003) compare 17 nonpersonal and personal health service interventions or combinations of interventions in the 14 epidemiological subregions defined by the World Health Organization (WHO) as part of its Choosing Interventions That Are Cost-Effective (WHO-CHOICE) initiative. The nonpersonal interventions included health education through the mass media and legislative efforts to reduce salt intake, improve blood pressure generally, and reduce cholesterol and obesity levels. The personal interventions included treatment with statins of those above two different cholesterol-level thresholds (greater than 6.2 mmol/l or greater than 5.7 mmol/l), treatment with beta-blockers and diuretics of those above two different hypertension thresholds (greater than 160 mmHg or greater than 140 mmHg), and treatment of individuals with

both hypertension and increased cholesterol with all three medications. Finally, the effects of combination treatment with a beta-blocker, diuretic, statin, and aspirin were modeled for four groups defined on the basis of absolute risk (10-year probability of a cardiovascular event of 5, 15, 25, or 35 percent).

Intervention effects were based on systematic reviews of randomized trials or meta-analyses. Population health effects caused by the interventions were based on stochastically simulating populations on the basis of age, sex, and risk factor distribution of smoking, hypertension, cholesterol, BMI, and smoking in the 14 subregions, both with and without the various treatments to determine the effect. The effects of the intervention were then translated into DALYs using a standard multistate modeling tool. Costs include both program-level costs (media, training, and administration) and patient-level costs (medicines, health care visits, diagnostic tests). All costs were based on a standard ingredients approach and on regional estimations. The costs of CVD events were not included.

The results are summarized in table 45.4. The incremental cost-effectiveness ratios for the strategy assessing absolute risk and using the triple combination of beta-blocker, statin, and aspirin with or without the addition of health education and salt legislation ranged from US\$138 per DALY saved (absolute risk greater than 35 percent) in the Africa E region to US\$4,319 per DALY saved (absolute risk greater than 5 percent) in the Latin America and the Caribbean B region. These estimates are in international or purchasing-power parity dollars (see chapter 15 for an explanation). Table 45.4 also shows the approximate equivalent costs in U.S. dollars and explains the conversion from the WHO-CHOICE estimates. The nonpersonal interventions, including efforts to reduce salt intake in processed foods, were less costly than the personal interventions. Personal interventions based on treatment guidelines were cost-effective; however, when the strategies for treating high cholesterol or hypertension were compared with the absolute-risk approach, they were not favorable and were dominated by the latter, meaning that the absolute-risk approach of treating those with a greater than 35 percent risk averted more DALYs and cost less than either the blood pressure or cholesterol strategies. For an example of a country-specific analysis, see box 45.1.

Several recent publications have suggested that combination treatments of medications to lower blood pressure, statin, aspirin, and perhaps other agents such as folate could more than halve cardiovascular risk (Wald and Law 2003; WHO 2002; Yusuf 2002). This suggestion is especially relevant for developing countries, given that suitable components are all now off patent. Good evidence indicates that single-pill combinations increase adherence to drug regimens (Connor, Rafter, and Rodgers 2004) and reduce supply and transport costs. We used a Markov model to evaluate the cost-effectiveness of such a hypothetical pill or combination packaging of the individual medications. We modeled the effect of a pill that included half

Table 45.4 Comparison of the Cost-Effectiveness of Absolute Risk with Treatment According to Either Blood Pressure or Lipid Targets Alone in Addition to Population-Based Strategies, Selected WHO Regions

Source: Murray and others 2003.

B = low child mortality and low adult mortality; E = high child mortality and very high adult mortality; HE = health education through the mass media to reduce cholesterol; SL = legislation to decrease the salt content of processed foods, including appropriate labeling and enforcement; TRI = treatment with aspirin, beta-blockers, and a statin.

a. Costs of prevention and nondrug costs for treatment according to absolute risk are converted at an estimated regional average ratio of exchange rate to purchasing-power parity rate; drug costs are not converted, assuming drugs to be imported at world prices. The share of drug costs in total treatment cost, as a function of risk, is taken from the estimates for India in table 45.6 and assumed to be the same for all regions.

b. Dominated strategies were both less effective and more costly than comparator strategies.

c. Treating SBP greater than 140 mmHg or 160 mmHg or total cholesterol greater than 5.7 mmol/l or 6.2 mmol/l (220 or 240 mg/dL).

d. Risk refers to 10-year risk of CVD greater than or equal to the number listed.

of the standard doses of hydrochlorothiazide, atenolol, lisinopril, lovastatin, and aspirin on overall morbidity and mortality in treating those without prior CVD. We did not include folate because no randomized trials had shown that it reduced CVD events at the time of the analysis. The assumptions of the relative risk reductions were based on those of Wald and Law (2003). The strategies compared were for treating various high-risk populations (absolute risk for CVD greater than 15, 25, and 35 percent over 10 years). We applied the model to a population of 1 million adults over the age of 35, with the costs and bene-

fits seen from a societal perspective and with the intervention run for 10 years. We calculated estimates for one representative country from each region where demographic and risk factor data existed. Unlike the WHO-CHOICE analysis, this analysis separated use of the intervention according to those with and without established CVD. Table 45.5 presents the results.

Table 45.6 shows the breakdown of events averted and costs for India. Even though the absolute numbers differ for other countries, the relative differences between the different groups receiving the “polypill” compared with the groups not receiving

Box 45.1

Example of Country-Specific Analysis: South Africa

In another analysis, researchers (Gaziano 2001) compared the approach based on absolute risk with blood pressure guidelines in South Africa. The analysis used country-specific epidemiology and, where available, applied local cost data. The study compared six strategies for initiating drug treatment—two different blood pressure levels (160/95 mmHg and 140/90 mmHg) and four different levels of absolute CVD risk over 10 years (40, 30, 20, and 15 percent)—to a strategy of no treatment. The methodology differed from the WHO-CHOICE study because of the availability of local data. Data on diabetes prevalence were included to further refine risk estimates. Also the actual mix of medications was used to assess costs with actual current drug-use patterns, which included the use of some nongeneric medications.

The table displays the results. The four absolute-risk strategies had the four lowest incremental cost-effectiveness ratios. The strategy of initiating antihypertensive therapy for those individuals with a predicted 10-year CVD risk greater

than 40 percent had an incremental cost-effectiveness ratio of US\$700 per QALY gained compared with no treatment. The absolute risk of CVD greater than 30, 20, and 15 percent had larger and increasing cost-effectiveness ratios. Treatments based on the 1995 South African guidelines and the Joint National Commission VI guidelines were both more costly and resulted in fewer QALY gains than the 15 percent absolute-risk strategy and were therefore dominated by the less costly absolute-risk treatment strategies.

Furthermore, the results showed that the cost-effectiveness ratios were quite sensitive to the costs of treatment for hypertension, especially medication costs. Further analysis revealed a threshold point for an annual treatment cost of US\$53. Below this threshold, the 40 percent absolute-risk strategy cost less and increased the number of life years gained compared with the no primary prevention strategy and is therefore cost saving. In South Africa, annual treatment with diuretics and beta-blockers could be provided for less than US\$40.

Incremental Cost-Effectiveness Ratios for Selected Hypertension Management Strategies over 10 Years, South Africa

Treatment	Incremental cost-effectiveness ratio ^a	
	US\$/QALY	US\$/life year saved ^b
No treatment	n.a.	n.a.
Absolute risk of CVD > 40 percent	700	900
Absolute risk of CVD > 30 percent	1,600	2,100
Absolute risk of CVD > 20 percent	4,900	6,700
Absolute risk of CVD > 15 percent	11,000	18,000

a. Each strategy compared with no polypill.

it are similar for all countries. Although the total costs for treating lower-risk patients increase, so do the benefits, and the overall incremental cost-effectiveness ratio remains relatively favorable. The proportion of costs shifts away from those attributable to hospital care when no primary prevention is initiated to costs attributable to ambulatory care and pharmaceuticals when more lower-risk patients are treated.

Interventions to Reduce Bodyweight

No large-scale randomized trials of weight reduction as an isolated intervention are available on which to base estimates of the benefits of weight loss in lowering the risk of coronary heart disease. Thus, costs per life year saved would have to be modeled to project benefits. In one such analysis, a school-based educational program to reduce obesity among middle school students reported a cost of US\$4,300 per QALY (L. Wang and others 2003). However, this analysis assumed that the weight loss would be maintained throughout adulthood, but the high relapse rates found in weight reduction studies do not bear out this assumption (Serdula and others 1999). Further research is needed to evaluate the benefits of weight reduction in relation to reducing CVD events and the long-term sustainability of weight loss before reliable cost-effectiveness estimates can be made.

Distributional and Equity Consequences

Failing to translate available evidence from industrial countries about CVD prevention strategies into practicable solutions for developing countries would have clear equity implications, especially when CVD is a large and growing problem in developing countries and when safe and effective interventions that were once extremely expensive are now available for a few cents a day. Because access to cardiovascular health care in developing countries often depends on patients' ability to pay, the poor would stand to benefit the most from a low-cost intervention such as a polypill.

Some see CVD as exclusively a disease of the affluent in developing countries; however, in many developing countries, the transition of CVD to becoming a disease of the poor has already begun—a transition already seen in developed countries around the world. A recent analysis of the distribution of major cardiovascular risks by poverty levels has shown that many cardiovascular risks already affect the poor in the world's poorest countries (Ezzati and others 2004; WHO 2002). Combating the trend requires highly effective, low-cost solutions relevant for most or all of those at risk in developing countries, in contrast to the investments in high-tech treatment interventions that have commonly occurred to date.

ECONOMIC BENEFITS OF INTERVENTION

In the cost-effectiveness analyses, most of the gains are reported in cost savings either from particular interventions, such as decreased hospitalizations resulting from the improved combination therapy of the polypill, or from a more efficient means of screening those at highest risk through an absolute-risk approach. Those who do not die from the sequelae of poorly controlled risk factors for CVD suffer from serious chronic illness, such as stroke and congestive heart failure. Those chronic diseases can result in significant impairments, thereby preventing those affected from continuing to work and sometimes also requiring the services of other family members, who themselves end up having to leave the workforce. Further losses resulting from disability include the loss of wages for major wage earners and their families and the state's losses in terms of disability compensation. Leeder and others (2004) estimate that in 2000 the cost of CVD disability payments in South Africa equaled US\$70 million.

However, many other indirect economic gains or losses are not included in the economic analysis, such as gains or losses in productivity. Leeder and others (2004) report that, at current CVD mortality rates, the potential productive years of life lost (defined as those years between the ages of 35 and 64) will nearly double by 2030. Those later adult working years are particularly important, given the many years of investment in skills through formal education and experience that would be lost. Preventing CVD would therefore improve the size and skills of the workforce and would therefore aid economic development. For those reasons, the Commission for Macroeconomics and Health has recommended that any intervention that costs less than triple a country's per capita gross domestic product be regarded as cost-effective (WHO 2001). Many of the combination cardiovascular preventive approaches outlined in this chapter comfortably satisfy that criterion.

RESEARCH AND DEVELOPMENT AGENDA

The cost-effectiveness data reviewed in this chapter indicate that the best use of resources for personal-level interventions for preventing CVD mediated by high blood pressure, cholesterol, and bodyweight would be combination medications targeted to those at high absolute risk. This strategy represents a considerable departure from existing paradigms, such as hypertension treatment. Research and development is therefore required in several areas to develop, implement, and evaluate this strategy. This research could include several themes as follows:

- Refine absolute risk-based treatment in developing country settings:
 - Evaluate optimal communications to the public and to health professionals that explain the rationale for this

new paradigm and its advantages over traditional paradigms, such as hypertension treatment. One barrier to adopting preventive therapy based on absolute risk has been its relative complexity compared with dichotomous diagnosis-based strategies, such as hypertension–no hypertension.

- Develop simple methods for predicting absolute risk using straightforward, inexpensive, direct measures, such as physical examination, clinical history, and on-site tests. These methods would likely involve low-cost algorithms completed by a multipurpose health care worker involving, for example, the collection of data on age, sex, tobacco use, blood pressure, waist circumference, and urine dipstick results. The development of different levels of screening protocol may also be needed in certain settings.
- Calibrate existing algorithms for different disease rates and cardiovascular profiles in developing countries.
- Develop treatment algorithms that can easily be adopted in resource-poor settings by, for example, multipurpose health care workers.
- Develop methods for predicting absolute risk on the basis of the probability of lost healthy life years as well as the probability of a clinical event. This strategy could mean developing an index of healthy life years at risk from a cardiovascular event in the next five years, which would require taking case fatalities into consideration and discounting. A major barrier to adopting a strategy based on absolute risk has been the absence of a time-based measure and, hence, the equal value placed on preventing an event at a young and at an old age.
- Develop and evaluate combination treatments:
 - Carry out new research on the ideal combinations for different patient groups and populations at different stages of the health transition. Local initiatives would be needed to determine the ideal combination of medications based principally on cost, tolerability, and ability to lower risk-factor levels. One default set of interventions could be an angiotensin-converting enzyme inhibitor (for example, enalapril or lisinopril); a diuretic (such as hydrochlorothiazide or chlorthalidone); a statin (for instance, simvastatin or lovastatin); and low-dose aspirin.
 - Measure the potential costs and benefits of adding other active agents, such as vitamins or diabetic medications.
 - Quantify the extent of improved access, acceptability, and tolerability for people with symptomatic vascular disease who have established indications for those medications.
 - Evaluate the benefits and costs in developing countries with large-scale clinical trials and demonstration projects, both among patients who have established indications (compared with usual care) and among those

who do not have clear indications but are still at high risk (compared with a placebo).

- Evaluate the advantages and disadvantages of a polypill versus unit-of-use packs and other novel delivery strategies.
- Investigate weight-loss initiatives:
 - Develop strategies to improve the effectiveness of personal interventions to reduce bodyweight in developing countries.
 - Evaluate the use of gastric surgery for weight loss in the extremely obese in selected settings.
- Assess technology:
 - Screen which technologies should be transferred to developing countries on the basis of cost-effectiveness criteria.
 - Design new technologies specifically for use by community health workers (for example, point-of-care devices).
- Review public and personal health services:
 - Carry out a critical evaluation of community health workers versus trained health professionals in delivering simplified screening and treatment regimens.
 - Provide guideline assistance for CVD prevention and management to regional and country-specific ministers of health and policy makers.
 - Support demonstration projects to determine the limitations for managing chronic conditions in resource-poor settings.

CONCLUSIONS

The analyses presented in this chapter indicate that providing off-patent blood pressure and cholesterol-lowering medications targeted at those at high absolute risk seems to be a cost-effective strategy. Currently available personal interventions to prevent or reduce high BMI are likely to be much less cost-effective.

An approach based on absolute risk will still involve choosing some level below which people are not recommended for personal treatments, which will leave some people at risk of progression of vascular disease. This issue exists with current paradigms and underscores the need for parallel improvements in population-based prevention. The strategy based on absolute risk must be regarded as complementary to populationwide initiatives that address the root causes of CVD—in particular, the societal determinants that lead to high salt and saturated fat in the diet in relation to high blood pressure and cholesterol and high-energy diets coupled with decreasing physical activity in relation to high bodyweight. Preventing and reducing those risks in developing countries will reduce the need for medication-based prevention strategies in the coming decades.

Chapter 46

Tobacco Addiction

Prabhat Jha, Frank J. Chaloupka, James Moore, Vendhan Gajalakshmi, Prakash C. Gupta, Richard Peck, Samira Asma, and Witold Zatonski

Cigarette smoking and other forms of tobacco use impose a large and growing global public health burden. Worldwide, tobacco use is estimated to kill about 5 million people annually, accounting for 1 in every 5 male deaths and 1 in 20 female deaths of those over age 30. On current smoking patterns, annual tobacco deaths will rise to 10 million by 2030. The 21st century is likely to see 1 billion tobacco deaths, most of them in low-income countries. In contrast, the 20th century saw 100 million tobacco deaths, most of them in Western countries and the former socialist economies.

Hundreds of millions of premature tobacco deaths could be avoided if effective interventions were widely applied in low- and middle-income countries. Numerous studies from high-income countries and a growing number from low- and middle-income countries provide robust evidence that tobacco tax increases, timely dissemination of information about the health risks of smoking, restrictions on smoking in public and workplaces, comprehensive bans on advertising and promotion, and increased access to cessation therapies are effective in reducing tobacco use and its consequences. Cessation by the 1.1 billion current smokers is central to meaningful reductions in tobacco deaths over the next five decades. New analyses presented here find that higher tobacco taxes could prevent 3 million tobacco deaths by 2030 among smokers alive today. Reduced uptake of smoking by children would yield benefits chiefly after 2050. Price and non-price interventions are, for the most part, highly cost-effective.

This chapter begins with an overview of smoking trends and tobacco's health consequences, followed by a discussion of the economic rationale for government intervention, with a focus

on the uniquely addictive properties of nicotine. A review of the effectiveness of tobacco-control policies in reducing tobacco initiation and in increasing cessation follows. A cost-effectiveness analysis of these interventions is provided. Finally, the constraints to implementing tobacco-control policies are discussed.

SMOKING TRENDS

Tobacco use, in both smoked and nonsmoked forms, is common worldwide. This chapter focuses on smoked tobacco, chiefly cigarettes and *bidis* (tobacco hand rolled in the leaf of another plant, *temburi*, which is popular in India and parts of Southeast Asia), because smoked tobacco is more common—accounting for about 65 to 85 percent of all tobacco produced worldwide (WHO 1997)—and causes more disease and more diverse types of disease than does oral tobacco use.

Prevalence

A systematic review of 139 studies on adult smoking prevalence (Jha and others 2002) found that more than 1.1 billion people worldwide smoke, with about 82 percent of smokers residing in low- and middle-income countries. Table 46.1 provides an update of these estimates for the population in 2000. Globally, male smoking far exceeds female smoking, with a smaller gender difference in high-income countries. Smoking prevalence is highest in Europe and Central Asia, where 35 percent of all adults are smokers.

While overall smoking prevalence continues to increase in many low- and middle-income countries, many high-income countries have witnessed decreases, most clearly in men. A

Table 46.1 Estimated Smoking Prevalence (by Gender) and Number of Smokers, 15 Years of Age and Older, 2000

World Bank region	Smoking prevalence (percent)			Total smokers	
	Males	Females	Overall	Millions	Percentage of all smokers
East Asia and the Pacific	63	5	34	429	38

Source: Authors.

study in 36 mostly Western countries, from early 1980 to the mid 1990s, suggested that the decrease in smoking prevalence observed among men was caused by the higher prevalence in younger age groups of those who have never smoked. Among women, there was little overall change in smoking prevalence because the increasing prevalence of smokers in younger cohorts counterbalanced increasing cessation in older age groups (Molarius and others 2001).

Cessation

Ex-smoking rates are a good measure of cessation at a population level. In *some* high-income countries, the prevalence rates of ex-smokers have increased over the past two to three decades. For example, in the United Kingdom, smoking prevalence among males over age 30 fell from 70 percent in the 1950s to 30 percent in 2000; female smoking prevalence fell from 40 to 20 percent over the same period. Much of the decrease arose from cessation. Today, two times as many ex-smokers as smokers exist among those age 50 or over. Currently, 30 percent of the U.K. male population is made up of former smokers (Peto and others 2000). Polish male cessation rates have also increased, partly because of control programs. One of every four adult Polish males described himself as an ex-smoker (Zatonski and Jha 2000). In contrast, the prevalence of male ex-smokers in most developing countries is low: 10 percent in Vietnam, 5 percent in India, and 2 percent in China (Jha and others 2002). Even those low figures may be falsely elevated because they include people who quit because either they were too ill to continue or they had early symptoms of tobacco-related illness (Martinson and others 2003).

HEALTH CONSEQUENCES OF SMOKING

The health consequences of smoking are often assumed to be widely understood. In fact, ignorance of the magnitude of tobacco hazards is widespread in terms of both individual

health and population policy. Thus, the salient aspects of tobacco epidemiology are outlined in this section.

Key Messages for the Individual Smoker

More than 50 years of epidemiology on smoking-related diseases have led to three key messages for individual smokers worldwide (Doll and others 2004; Peto and others 2003).

- The eventual risk of death from smoking is high, with about one-half to two-thirds of long-term smokers eventually being killed by their addiction.
- These deaths involve a substantial number of life years forgone. About half of all tobacco deaths occur at ages 35 to 69, resulting in the loss of about 20 to 25 years of life, compared with the life expectancy of nonsmokers.
- Cessation works: those adults who quit before middle age avoid almost all the excess hazards of continued smoking.

Worldwide, about 80 percent of deaths among the 2.7 billion adults over age 30 involve vascular, respiratory, or neoplastic disease. Smoking is associated with an increase in the frequency of many of these diseases, although important differences exist between and across populations. The following discussion focuses on the consequences of smoking on adult mortality. Detailed epidemiological reviews of worldwide mortality from smoking are found elsewhere (C. Gajalakshmi and others 2000; V. Gajalakshmi and others 2003; Gupta and Mehta 2000; Liu and others 1998; Niu and others 1998; Peto and others 1994).

Current Mortality and Disability from Smoking

Recent updates of indirect estimates of global tobacco mortality (Ezzati and Lopez 2003; M. Ezzati, personal communication, November 2004) indicate that in 2000, 5.0 million premature deaths were caused by tobacco. About half (2.6 million) of those deaths were in low-income countries. Males accounted

Note: The terms *high-income* and *former socialist economies* as used in the text correspond roughly to high-income and Europe and Central Asia regions using the World Bank classification. *Low-income countries* corresponds roughly to East Asia and the Pacific, Latin America and the Caribbean, Middle East and North Africa, South Asia, and Sub-Saharan Africa.

for 3.7 million deaths, or 72 percent of all tobacco deaths. About 60 percent of male and 40 percent of female tobacco deaths were of middle-aged persons (ages 35 to 69).

In high-income countries and former socialist economies, the 1 million middle-aged male tobacco deaths were largely composed of cardiovascular disease (0.45 million) and lung cancer (0.21 million). In contrast, in low-income countries, the leading causes of death among the 1.3 million male tobacco deaths were cardiovascular disease (0.4 million), chronic obstructive pulmonary disease (0.2 million), other respiratory disease (chiefly tuberculosis, 0.2 million), and lung cancer (0.18 million). The specific numbers of deaths from tobacco and of total disability-adjusted life years (DALYs) by gender and World Bank region are shown in table 46.2. Disability estimates are not discussed here; however, disability is highly correlated with mortality in most settings.

Past and Future Trends in Mortality

In high-income and former socialist economies with more complete and reliable mortality statistics, one can measure the effects of increased smoking prevalence and subsequent decreases that have been observed among large numbers of adults. These changes are best documented by examining lung cancer mortality rates among young adults because lung cancer is not often misclassified with other causes of death at young ages and it is almost entirely attributable to smoking.

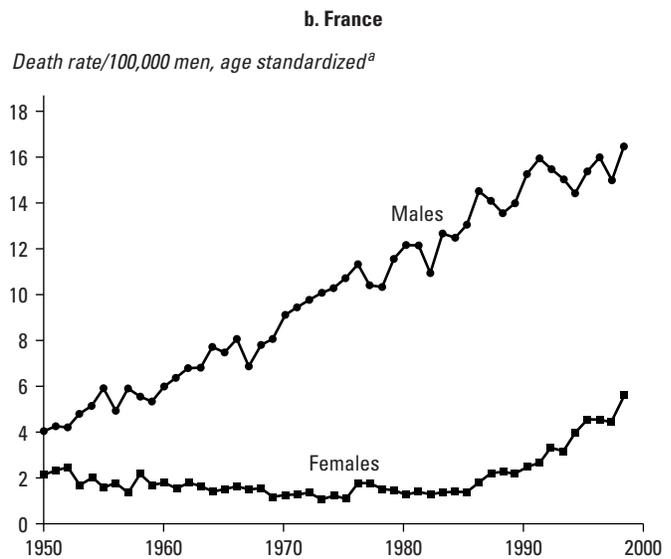

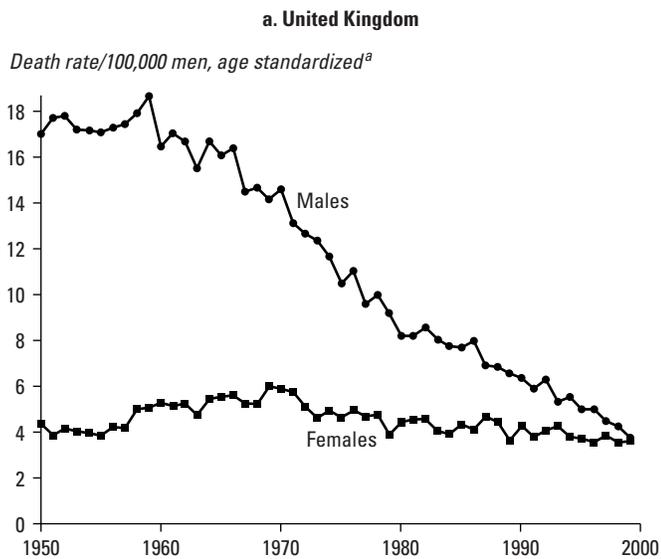

Age-Standardized Lung Cancer Mortality Rates

Age-standardized male lung cancer rates at ages 35 to 44 per 100,000 men in the United Kingdom had fallen from 18 in 1950 to 4 by 2000. In contrast, comparable French male lung cancer rates show the reverse pattern (Peto and others 2003; figure 46.1). In France, the increase in smoking occurred some decades later than in the United Kingdom, and declines in smoking began only after

1990. Similarly, a large increase in female lung cancer at young ages was avoided in the United Kingdom, but female lung cancer at young ages continues to rise in France.

Future increases in tobacco deaths worldwide are expected to arise from increased smoking by males in developing countries and by women worldwide. Such increases are a product of population growth and increased age-specific tobacco mortality rates, the latter relating to both smoking duration and the amount of tobacco smoked. Peto and others (1994) have made the following calculation: if the proportion of young people taking up smoking continues to be about half of men and one-tenth of young women, there will be about 30 million new long-term smokers each year. As previously noted, epidemiological studies in developed and developing countries suggest that half of these smokers will eventually die from smoking. However, if we conservatively assume that “only” about one-third of smokers die as a result of smoking, then smoking will eventually kill about 10 million people a year. Thus, for the 25-year period from 2000 to 2025, there would be about 150 million tobacco deaths, or about 6 million deaths per year on average; from 2025 to 2050, there would be about 300 million tobacco deaths, or about 12 million deaths per year.

Further estimations are more uncertain, but current smoking trends and projected population growth indicate that from 2050 to 2100 there will be an additional 500 million tobacco deaths. These projections for the next three to four decades are comparable to retrospective and early prospective epidemiological studies in China (Liu and others 1998; Niu and others 1998), which suggest that annual tobacco deaths will rise to 1 million before 2010 and to 2 million by 2025, when the young adult smokers of today reach old age. Similarly, results from a large retrospective study in India suggest that 1 million annual deaths can be expected from male smokers by 2025 (V. Gajalakshmi and others 2003). With other populations in Asia, Eastern

a. Mean of annual rates in component five-year age groups (35–39, 40–44).

Figure 46.1 Changes in Lung Cancer Mortality at Age 35 to 44 in the United Kingdom and France, 1950–99

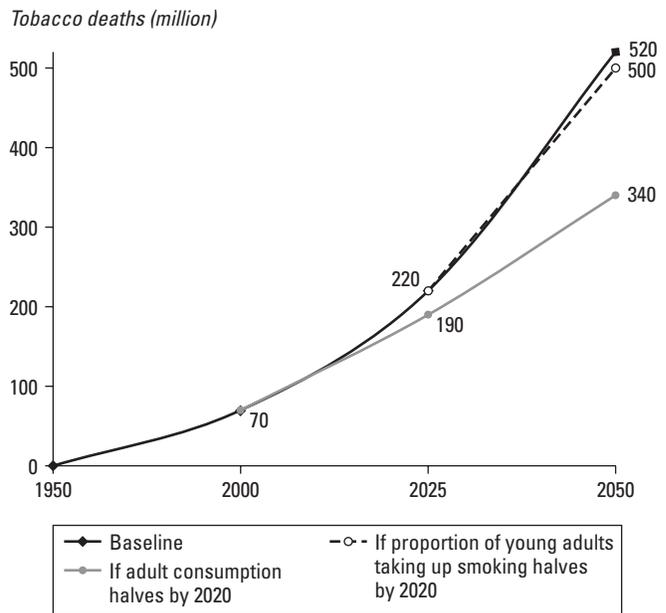

Europe, Latin America, the Middle East, and (less certainly) Sub-Saharan Africa showing similar growth in population and age-specific tobacco death rates, the estimate of some 450 million tobacco deaths over the next five decades appears plausible. Almost all of these deaths will be among current smokers.

Benefits of Cessation

Current tobacco mortality statistics reflect past smoking behavior, given the long delay between the onset of smoking and the development of disease. The prevention of a substantial proportion of these tobacco deaths before 2050 requires adult cessation. For example, halving the per capita adult consumption of tobacco by 2020 (akin to the declines in adult smoking in the United Kingdom) would avert about 180 million tobacco deaths. Continuing to reduce the percentage of children who start to smoke will prevent many deaths, but its main effect will be on mortality rates in 2050 and beyond (figure 46.2; Jha and Chaloupka 2000a; Peto and Lopez 2001).

Substantial evidence indicates that smoking cessation reduces the risk of death from tobacco-related diseases. Among doctors in the United Kingdom, those who quit smoking before the onset of major disease avoided most of the excess hazards of smoking (Doll and others 2004). The benefits of quitting were largest in those who quit before middle age (between ages 25 and 34 years) but were still significant in those who quit later (between ages 45 and 54 years).

Cessation before middle age avoids more than 90 percent of the lung cancer risk attributable to tobacco, with quitters possessing a pattern of survival similar to that of persons who

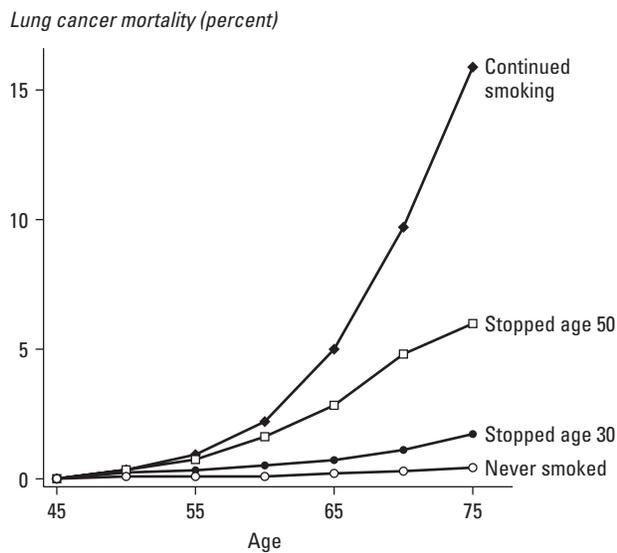

Source: Jha and Chaloupka 2000a; Peto and Lopez 2001.

Note: Peto and others (1994) estimate 60 million tobacco deaths between 1950 and 2000 in industrial countries. This figure estimates an additional 10 million tobacco deaths between 1990 and 2000 in developing countries. The figure also assumes no tobacco deaths before 1990 in developing countries and minimal tobacco deaths worldwide before 1950. Projections for deaths from 2000 to 2050 are based on Peto and Lopez (2001).

Figure 46.2 Tobacco Deaths in the Next 50 Years under Current Smoking Patterns

have never smoked. In the United Kingdom, among those who stopped smoking, the risk of lung cancer fell steeply with time since cessation. For men who stopped at ages 60, 50, 40, and 30, the cumulative risks of lung cancer by age 75 were

Source: Peto and others 2000.

Figure 46.3 Stopping Works: Cumulative Risk of Lung Cancer Mortality in U.K. Males, 1990 rates

10 percent, 6 percent, 3 percent, and 2 percent, respectively (Peto and others 2000; figure 46.3). These results have been supported by a recent multicenter study of men in four European countries; for men who quit smoking at age 40, the study found that the excess lung cancer risk avoided was 85 percent, 91 percent, and 80 percent in the United Kingdom, Germany, and Italy, respectively (Crispo and others 2004). Smoking cessation is uncommon in most developing countries, but some evidence exists that, among Chinese men, quitting also reduces the risks of total and vascular mortality (Lam and others 2002).

RATIONALE FOR GOVERNMENT INTERVENTION

In addition to the public health burden caused by tobacco, an economic rationale exists for government to intervene to reduce tobacco use:

- Consumers have inadequate information about the health consequences of tobacco use (Jha and others 2000; Warner and others 1995). Specifically, the decision to initiate smoking is made primarily by youths, whose ability to make fully informed, appropriately forward-looking decisions is questioned by society in many different contexts (minimum ages for drinking, driving, and voting, for instance). In industrial countries, about 80 percent of adult smokers begin smoking before age 20. Even if children and young adults have information on future risks, they tend to discount that future risk greatly.

- The addictive nature of tobacco is underappreciated and poorly understood. Although general awareness of risks is better in high-income countries, many people still underestimate tobacco's danger relative to other health risks, and many smokers fail to fully internalize these risks (Weinstein 1998).
- Smokers may impose costs on others from passive tobacco smoke or, more controversially, from higher health care costs (Lightwood and others 2000; Warner 2003).

The reader is referred to more detailed discussions on the welfare economics of tobacco (Barnum 1994; Jha and others 2000; Peck and others 2000; Warner and others 1995; and several background papers in the Disease Control Priorities Project Working Paper Series). We discuss nicotine addiction because this newer evidence has profound implications for explaining smoking behavior and for devising control policies.

Nicotine Addiction

Before the landmark 1988 U.S. Surgeon General's report, which suggested that cigarettes and other forms of tobacco are addictive and that nicotine is the major agent in tobacco responsible for addiction, the prevailing view was that tobacco use was largely a voluntary behavior or personal choice (Koop 2003). Since that time, clinicians, behavioral scientists, researchers, and public health experts have increasingly recognized manufactured tobacco products as some of the most addictive and deadly dependence-producing substances available. Although numerous factors have been identified that can contribute to the reinforcement of the smoking habit—for example, the synergistic and independent effects of other compounds in tobacco smoke (such as tar and acetaldehyde) or the sensory and environmental stimuli associated with smoking (such as tobacco advertising)—little debate exists that nicotine is a significant contributor to the development and maintenance of the smoking habit (Markou and Henningfield 2003). In most aspects of dependence, nicotine is on par with other powerfully addictive drugs, such as heroin and cocaine. Newer evidence has converged on the following key points.

Biological Aspects. Nicotine is a psychoactive drug that triggers a cascade of neurobiological events in the reward areas of the brain and throughout the body that can, in turn, act in concert to reinforce tobacco use (Markou and Henningfield 2003). Even a short-term exposure to nicotine has been shown to induce long-lasting changes of the excitatory input into the brain's reward system, which may be an important early step in the path to addiction (Laviolette and van der Kooy 2004). Notably, in some experimental models, if nicotine's neurobiological effects are blocked pharmacologically, or if nicotine is removed from cigarette smoke, smoking eventually ceases

(Jarvis 2004). The overwhelming property of nicotine that leads to its frequent use is the occurrence of nicotine withdrawal, for which cigarette smoke provides rapid relief. Though each individual differs greatly in his or her sensitivity to nicotine dependence, evidence suggests that most adults are susceptible to the biological effects of nicotine and tobacco (Picciotto 2003).

Psychological Aspects. In addition to the unique neurobiology of nicotine, the ready availability of tobacco influences the uptake of smoking as well as the development and maintenance of dependence. With illicit drugs, legal and social barriers constantly test a user's drive to consume the drug. In contrast, a smoker is presented with nearly ubiquitous opportunities and frequent cues to both purchase and use tobacco because of mass marketing and promotion of tobacco (Shiffman and West 2003). Young people, who are attracted to many risk behaviors, such as fast driving or binge drinking, do not "learn" from early smoking in the way that most young people become safer drivers and moderate drinkers as adults (Jha and others 2000; O'Malley, Bachman, and Johnston 1988).

Economics. The traditional economic formulation of costs and benefits tends not to take into account the unique properties of addiction (see Chaloupka, Tauras, and Grossman 2000 for a review). Newer models have begun to incorporate factors such as lack of information, regret, and addiction itself. One key innovation by Gruber and Koszegi (2001, 2002) permits smokers to be time inconsistent, meaning that, given preferences, smokers would make different decisions at different points in time. This approach, now widely used within the new field of behavioral economics, admits conflict between what smokers would like for themselves today and what they would like for themselves in the future.

Implications for Control Programs. These newer economic models have several implications for control programs. First is the need for much more aggressive tobacco taxation to deter the development of tobacco smoking. Estimates suggest that, in the United States, optimal taxation taking into account smoking initiation and nicotine addiction would be at least US\$1 higher per pack (Gruber 2003; Gruber and Koszegi 2002; Gruber and Mullainathan 2002). The second implication is that the usual assumption that higher taxes reduce the welfare or satisfaction of continuing smokers may not be true. Higher taxes enhance welfare by acting like an external control device over the time-inconsistent preferences of smokers, which would reduce the likelihood of smoking initiation.

The third implication is that the overall economic benefits of tobacco control, taking into account addiction, are likely to be substantially positive. Earlier cost-benefit analyses have shown that if even modest costs are assigned to uninformed

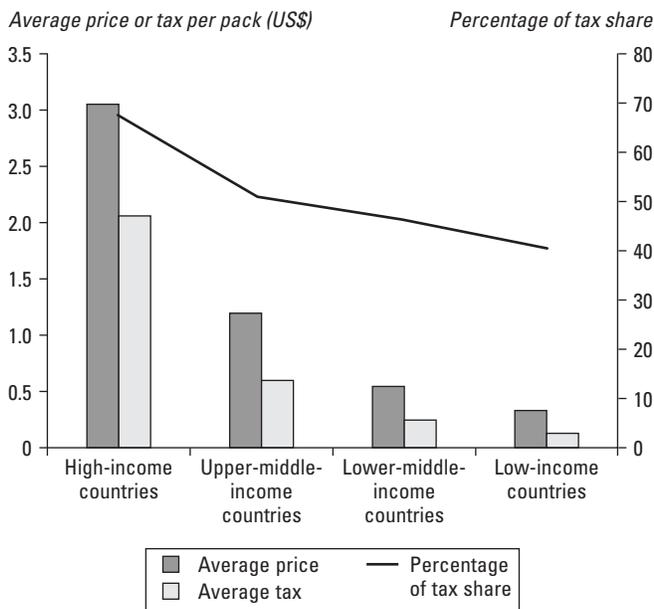

smoking choices, the net economic costs of tobacco are profoundly negative (Barnum 1994; Peck and others 2000). While some of the methods for such costing have been disputed, newer economic evidence supports the idea that widespread hazards of tobacco use lead to major economic costs. Jamison, Lau, and Wang (2005) have outlined that male survival explains income growth independent of changes in physical capital, education, fertility, economic openness, and technical progress. Thus, if adult male survival in the former socialist economies of Europe had been that of high-income countries, annual growth rates over the past three decades would have been about 1.4 percent rather than 1 percent, making 1990 per capita income about 12 percent higher, or an absolute value of US\$140 billion. The chief determinant of the mortality gap between the former socialist economies and high-income countries from 1960 to 1990 is smoking (Peto and others 1994; Zatonski and Jha 2000). More recent economic studies that have put a value on "statistical life" suggest that smoking cessation generates huge benefits. For example, Murphy and Topel (2003) find that in the United States, the value of reduced mortality from all causes between 1970 and 1998 amounted to US\$2.6 trillion per year, or half of gross domestic product (GDP) growth during the period. Fully US\$1.1 trillion per year arose from reduced heart disease, of which at least one-third was from reduced smoking and saturated fat in diets (Cutler and Kadiyala 2003; see chapter 15 for a fuller discussion on the economic benefits of disease control).

INTERVENTIONS TO REDUCE DEMAND FOR TOBACCO

Numerous studies, mostly from high-income countries, have examined the effect of interventions aimed at reducing the demand for tobacco products on smoking and other kinds of tobacco use. The small but growing number of studies from low- and middle-income countries provide useful lessons about differences in the effect of these interventions between these countries and high-income countries. The following is a review of the effect of price and non-price interventions in reducing demand for smoking, including a discussion of each intervention's effect on initiation and cessation. A more complete study of the effectiveness of various interventions is available elsewhere (Jha and Chaloupka 2000b).

Tobacco Taxation

Nearly all governments tax tobacco products. However, significant differences exist across countries in levels of tobacco taxation. Some of these taxes are specific or per unit taxes; others are expressed as a percentage of wholesale or retail prices (ad valorem taxes). As illustrated in figure 46.4, taxes tend to be absolutely higher and account for a greater share of the retail price (two-thirds or more) in high-income countries. In

Source: Authors.

Figure 46.4 Average Cigarette Price, Tax, and Percentage of Tax Share per Pack, by Income Group, 1996

low- and middle-income countries, taxes are generally much lower and account for less than half of the final price of cigarettes. In the United States, federal and state excise taxes on cigarettes were one-third lower, in real terms, in 1995 than their peak level of the mid 1960s. However, taxes rose sharply over the next eight years and stood at US\$1.12 per pack as of 2002.

Well over 100 studies from high-income countries clearly demonstrate that increases in taxes on cigarettes and other tobacco products lead to significant reductions in cigarette smoking and other tobacco use (Chaloupka, Hu, and others 2000). These reductions reflect the combination of increased smoking cessation, reduced relapse, lower smoking initiation, and decreased consumption among continuing tobacco users.

Studies from Canada, the United Kingdom, the United States, and many other high-income countries generally estimate that the price elasticity of cigarette demand ranges from -0.25 to -0.50 , indicating that a 10 percent increase in cigarette prices will reduce overall cigarette smoking by 2.5 to 5.0 percent (Chaloupka, Hu, and others 2000; U.S. DHHS 2000). Estimates from a limited number of studies from low- and middle-income countries suggest a greater price elasticity of -0.8 in such countries. Recent studies using survey data have concluded that half or more of the effect of price on overall cigarette demand results from reducing the number of current smokers (CDC 1994; Wasserman and others 1991). Higher taxes increase both the number of attempts at quitting smoking and the success of those attempts (Tauras 1999; Tauras and Chaloupka 2003). A study in the United States (Tauras 1999) suggested that a 10 percent increase in price would result in 11

to 13 percent shorter smoking duration or a 3.4 percent higher probability of cessation.

Many recent studies from the United States have used individual-level data to explore differences in the price elasticity of cigarette demand by age, with a particular emphasis on youth and young adults (Chaloupka, Hu, and others 2000; U.S. DHHS 2000). Given that most smoking behavior becomes firmly established during teenage years and young adulthood, interventions that are effective in preventing smoking initiation and the transition to regular, addicted smoking will have significant long-term public health benefits. Estimates from these recent studies conclude that an inverse relationship exists between price elasticity and age, with estimates for youth price elasticity of demand up to three times those obtained for adults (Gruber 2003; Ross, Chaloupka, and Wakefield 2001). Several recent studies have begun to explore the differential effect of cigarette prices on youth smoking uptake, concluding that higher cigarette prices are particularly effective in preventing young smokers from moving beyond experimentation into regular, addicted smoking (Emery, White, and Pierce 2001; Ross, Chaloupka, and Wakefield 2001).

In the United Kingdom and the United States, increases in the price of cigarettes have had the greatest effect on smoking among the lowest-income and least educated populations (CDC 1994; Townsend, Roderick, and Cooper 1998). Furthermore, it was estimated that smokers in U.S. households below median income level are four times more responsive to price increases than smokers in households above median income level. In general, estimates of price elasticity for low- and middle-income countries are about double those estimated for high-income countries, implying that significant increases in tobacco taxes in these countries would be effective in reducing tobacco use.

Restrictions on Smoking

Over the past three decades, as the quantity and quality of information about the health consequences of exposure to passive smoking have increased, many governments, especially in high-income countries, have enacted legislation restricting smoking in a variety of public places and private worksites. In addition, increased awareness of the consequences of passive smoke exposure, particularly to children, has led many workplaces and households to adopt voluntary restrictions on smoking. Although the intent of those restrictions is to reduce nonsmokers' exposure to passive tobacco smoke, the policies also reduce smokers' opportunities to smoke. Additional reductions in smoking, especially among youths, will result from the changes in social norms that are introduced by adopting these policies (U.S. DHHS 1994).

In Western populations, comprehensive restrictions on cigarette smoking have been estimated to reduce population

smoking rates by 5 to 15 percent (see review by Woolery, Asma, and Sharp 2000) and can also lead to changes in social norms regarding smoking behavior, especially among youths. As with higher taxes, these restrictions reduce both the prevalence of smoking and cigarette consumption among current smokers. Smoking bans in workplaces generally reduce the quantity of cigarettes smoked by 5 to 25 percent and reduce prevalence rates by up to 20 percent (Levy, Friend, and Polishchuk 2001). No-smoking policies were most effective when strong social norms against smoking helped make smoking restrictions self-enforcing.

Health Information and Counteradvertising

The 1962 report by the British Royal College of Physicians and the 1964 U.S. Surgeon General's Report were landmark tobacco-control events in high-income countries. These publications resulted in the first widespread press coverage of the scientific links between smoking and lung cancer. The reports were followed, in many countries, by policies requiring health warning labels on tobacco products, which were later extended to tobacco advertising.

Research from high-income countries indicates that these initial reports and the publicity that followed about the health consequences of smoking led to significant reductions in consumption, with initial declines of between 4 and 9 percent and longer-term cumulative declines of 15 to 30 percent (Kenkel and Chen 2000; Townsend 1993). Efforts to disseminate information about the risks of smoking and of other tobacco use in low- and middle-income countries have led to similar declines in tobacco use in those countries (Kenkel and Chen 2000). In addition, mass media antismoking campaigns, in many cases funded by earmarked tobacco taxes, have generated reductions in cigarette smoking and other tobacco use (Kenkel and Chen 2000; Saffer 2000). Decreases in smoking prevalence were largest in Western countries, where the public is constantly and consistently reminded of the dangers of smoking by extensive coverage of issues related to tobacco in the news media (Molarius and others 2001).

In many low- and middle-income countries, a lack of awareness continues to exist about the risks of mortality and disease posed by smoking. For example, a national survey in China in 1996 found that 61 percent of smokers thought that tobacco did them "little or no harm" (Chinese Academy of Preventive Medicine 1997). In high-income countries, smokers are aware of the risks, but a recent review of psychological studies found that few smokers judge the size of these risks to be higher and more established than do nonsmokers, and that smokers minimize the personal relevance of these risks (Weinstein 1998).

Bans on Advertising and Promotion

Cigarettes are among the most heavily advertised and promoted products in the world. In 2002, cigarette companies

spent US\$12.5 billion on advertising and promotion in the United States alone, the highest spending level reported to date (U.S. Federal Trade Commission 2004). Tobacco advertising efforts worldwide include traditional forms of advertising on television, radio, and billboards and in magazines and newspapers as well as favorable product placement; price-related promotions, such as coupons and multipack discounts; and sponsorship of highly visible sporting and cultural events.

Numerous econometric studies, largely from the United Kingdom and the United States, have explored the relationship between cigarette advertising and promotional expenditure and cigarette demand. In general, these studies have resulted in mixed findings, with most studies concluding that advertising has a small positive effect on demand (Chaloupka, Hu, and others 2000; Townsend 1993). However, critics of these studies note that econometric methods, which estimate the effect of a marginal change in advertising expenditures on smoking, are ill suited for studying the effect of advertising (Chaloupka, Hu, and others 2000; U.S. Federal Trade Commission 2004; Townsend 1993). Approaches used by other disciplines, including survey research and experiments that assess reactions to and recall of cigarette advertising, do support the hypothesis that increases in cigarette advertising and promotion directly and indirectly increase cigarette demand and smoking initiation (U.S. DHHS 1994; U.K. Department of Health 1992). These studies conclude that cigarette advertising is effective in getting and retaining children's attention, with the strength of the association strongly correlated with current smoking behavior, smoking initiation, and smoking intentions.

Comprehensive advertising and promotion bans on cigarettes provide more direct evidence on the effect of advertising these products (Saffer 2000). One study using data from 22 high-income countries for the period 1970 through 1992 provides strong evidence that comprehensive bans on cigarette advertising and promotion led to significant reductions in cigarette smoking. The study predicts that a comprehensive set of tobacco advertising bans in high-income countries could reduce tobacco consumption by more than 6 percent, taking into account price and non-price control interventions (Saffer and Chaloupka 2000). However, the study concludes that partial bans have little effect on smoking behavior, given that the tobacco industry can shift its resources from banned media to other media that are not banned.

Smoking Cessation Treatments

Near-term reductions in smoking-related mortality depend heavily on smoking cessation. Numerous behavioral smoking cessation treatments are available, including self-help manuals, community-based programs, and minimal or intensive clinical interventions (U.S. DHHS 2000). In clinical settings, pharmacological treatments, including nicotine replacement

therapies (NRT) and bupropion, have become much more widely available in recent years in high-income countries through deregulation of some NRT from prescription to over-the-counter status (Novotny and others 2000; U.S. DHHS 2000). The evidence is strong and consistent that pharmacological treatments significantly improve the likelihood of quitting, with success rates two to three times those when pharmacological treatments are not used (Novotny and others 2000; Raw, McNeill, and West 1999; U.S. DHHS 2000). The effectiveness of all commercially available NRT seems to be largely independent of the duration of therapy, the setting in which the therapy is provided, regulatory status (over-the-counter versus prescribed therapy), and the type of provider (Novotny and others 2000). Over-the-counter NRT without physician oversight have been used in many countries for a number of years with good success.

Although NRT are successful in treating nicotine addiction, the markets for NRT and other pharmacological therapies are more highly regulated and less affordable than are nicotine-containing tobacco products. Recent evidence indicates that the demand for NRT is related to economic factors, including price (Tauras and Chaloupka 2003). Policies that decrease the cost of NRT and increase availability—such as mandating private health insurance coverage of NRT, including such coverage in public health insurance programs, and subsidizing NRT for uninsured or underinsured individuals—would likely lead to substantial increases in the use of these products. Given the demonstrated efficacy of NRT in treating smoking, these policies could generate significant increases in smoking cessation.

INTERVENTIONS TO REDUCE THE SUPPLY OF TOBACCO

The key intervention on the supply side is the control of smuggling. Recent estimates suggest that 6 to 8 percent of cigarettes consumed globally are smuggled (Merriman, Yurekli, and Chaloupka 2000). Of note, the tobacco industry itself has an economic incentive to smuggle, in part to increase market share and decrease tax rates (Joossens and others 2000; Merriman, Yurekli, and Chaloupka 2000). Although differences in taxes and prices across countries create a motive for smuggling, a recent analysis comparing the degree of corruption in individual countries with price and tax levels found that corruption within countries is a stronger predictor of smuggling than is price (Merriman, Yurekli, and Chaloupka 2000). Several governments are adopting policies aimed at controlling smuggling. In addition to harmonizing price differentials between countries, effective measures include prominent tax stamps and warning labels in local languages, better methods for tracking cigarettes through the distribution chain, aggressive enforce-

ment of antismuggling laws, and stronger penalties for those caught violating these laws (Joossens and others 2000). Recent analysis suggests that, even in the presence of smuggling, tax increases will reduce consumption and increase revenue (Merriman, Yurekli, and Chaloupka 2000).

In contrast to the effectiveness of demand-side interventions, there is much less evidence that interventions aimed at reducing the supply of tobacco products are as effective in reducing cigarette smoking (Jha and Chaloupka 1999, 2000a). The U.S. experience provides mixed evidence about the effectiveness of limiting youth access to tobacco products in reducing youth tobacco use (U.S. DHHS 2000; Woolery, Asma, and Sharp 2000). In addition, the effective implementation and enforcement of these policies may require infrastructure and resources that do not exist in many low- and middle-income countries. A preliminary discussion is occurring in Canada about reducing its number of retail outlets for tobacco from the current 65,000. Neither the effect of such a move nor its enforcement costs are well known. Crop substitution and diversification programs are often proposed as a means of reducing the supply of tobacco. However, little evidence exists that such programs would significantly reduce the supply of tobacco, given that the incentives for growing tobacco tend to attract new farmers who would replace those who abandon tobacco farming (Jacobs and others 2000). Similarly, direct prohibition of tobacco production is not likely to be politically feasible, effective, or economically optimal. Finally, although trade liberalization has contributed to increases in tobacco use (particularly in low- and middle-income countries), restrictions on trade in tobacco and tobacco products that violate international trade agreements or draw retaliatory measures (or both) may be more harmful (Taylor and others 2000).

EFFECTIVENESS AND COST-EFFECTIVENESS OF TOBACCO-CONTROL INTERVENTIONS

Using a static model of the cohort of smokers alive in 2000, we estimate the number of deaths attributable to smoking over the next few decades that could be averted by (a) price increases, (b) NRT, and (c) a package of non-price interventions other than NRT. Cost-effectiveness of these policy interventions was calculated by weighing the approximate public sector costs against the years of healthy life saved, measured in DALYs. The details of an earlier version of this model have been published previously (Ranson and others 2002).

Results of Model Projections

The following is an updated analysis, using higher price increases and a greater effectiveness for NRT than did the

Table 46.3 Reductions in Future Tobacco Deaths among Smokers Alive in 2000 from Price Increases of 10 Percent, 33 Percent, 50 Percent, and 70 Percent by World Bank Region

original (Ranson and others 2002). This analysis is conservative in its assumptions about effectiveness and generous in its assumptions about the costs of tobacco control.

Potential Effect of Price Increases. With a price increase of 33 percent, the model predicts that 22 million to 65 million smoking-attributable deaths will be averted worldwide, which is approximately equivalent to 5 to 15 percent of all smoking-attributable deaths expected among those who smoke in 2000 (see table 46.3). Low- and middle-income countries account for about 90 percent of averted deaths. East Asia and the Pacific alone will account for roughly 40 percent of averted deaths. Total smoking-attributable deaths averted worldwide range from 33 million to 92 million for a 50 percent price increase and 46 million to 114 million for a 70 percent price increase. A 70 percent price increase would avert 10 to 26 percent of all smoking-attributable deaths worldwide.

Of the tobacco-related deaths that would be averted by a price increase, 80 percent would be male, reflecting the higher overall prevalence of smoking in men. The greatest relative effect of a price increase on deaths averted is among younger cohorts. Note that these projections use conservative price increases. In certain countries, such as Poland and South

Africa, recent tax increases have doubled the real price of cigarettes (Guindon, Tobin, and Yach 2002).

Potential Effect of Nicotine Replacement Therapies.

Provision of NRT with an effectiveness of 1 percent is predicted to result in the avoidance of about 3.5 million smoking-attributable deaths (table 46.4). NRT of 5 percent effectiveness would have about five times the effect. Again, low- and middle-income countries would account for roughly 80 percent of the averted deaths. The relative effect of NRT (of 2.5 percent effectiveness) on deaths averted is 2 to 3 percent among individuals age 15 to 59 and lower among those age 60 and older (results not shown).

Potential Effect of Non-price Interventions Other Than NRT.

A package of non-price interventions, other than NRT, that decreases the prevalence of smoking by 2 percent is predicted to prevent about 7 million smoking-attributable deaths (more than 1.6 percent of all smoking-attributable deaths among those who smoked in 2000; see table 46.4). A package of interventions that decreases the prevalence of smoking by 10 percent would have an effect five times greater. Low- and middle-income countries would account for approximately four-fifths

of quitters and averted deaths. The greatest relative effect of non-price interventions on deaths averted would be among younger cohorts.

Figure 46.5 summarizes the potential effect of a set of independent tobacco-control interventions, using 33 and 70 percent price increases (using a high elasticity of -1.2 for low- and middle-income regions and -0.8 for high-income regions), a 5 percent effectiveness of NRT, and a 10 percent reduction from non-price interventions other than NRT. In this cohort of smokers alive in 2000, approximately 443 million are expected to die in the next 50 years in the absence of interventions. A substantial fraction of these tobacco deaths are avoidable with interventions. Price increases have the greatest effect on tobacco mortality, with the most aggressive price increase of 70 percent having the potential to avert almost one-quarter of all tobacco deaths. Even a modest price increase of 33 percent could potentially prevent 66 million tobacco deaths over the course of the next 50 years. Although NRT and other non-price interventions are less effective than price increases, they can still avert a substantial number of tobacco deaths (18 million and 35 million deaths, respectively). The greatest effect of these tobacco-control interventions would occur after 2010, but a substantial number of deaths could be avoided even before then.

Source: Authors.

Note: Price increases assume a high price elasticity (-1.2 for low- and middle-income countries and -0.8 for high-income countries).

Figure 46.5 Potential Effect of Tax Increases, NRT, and Non-price Interventions on Tobacco Mortality, 2000–50

Note that no attempt has been made in this analysis to examine the effect of combining the various packages of interventions (for example, price increases with NRT, or NRT and other non-price interventions). A number of studies have compared the effect of price and non-price interventions; few empirical attempts have been made to assess how these interventions might interact. Although price increases have been found in this analysis to be the most cost-effective antismoking intervention, policy makers should use both price and non-price interventions to counter smoking. Non-price measures may be required to affect the most heavily dependent smokers, for whom medical and social support in stopping will be necessary. Furthermore, these non-price measures may be effective in increasing social acceptance and support of tobacco price increases.

Cost-Effectiveness of Antismoking Interventions. In general, price increases are found to be the most cost-effective antismoking intervention. A 33 percent price increase (our base case scenario) could be achieved for a cost of US\$13 to US\$195 per DALY saved globally, or US\$3 to US\$42 in low-income countries and US\$85 to US\$1,773 in high-income countries. Wider access to NRT could be achieved for between US\$75 and US\$1,250 per DALY saved, depending on which assumptions are used. Non-price interventions other than NRT could be implemented for between US\$233 and US\$2,916 per DALY saved (table 46.5). Thus, NRT and other non-price measures are slightly less cost-effective than price increases but remain cost-effective in many settings. The cost-effectiveness of NRT is

highly sensitive to the actual price of the NRT. NRT with a price of US\$25 have a cost-effectiveness of US\$75 per DALY compared with US\$329 for an NRT price of US\$150 (data not shown).

For a given set of assumptions, the variation in the cost-effectiveness of each intervention between low- and middle-income regions is relatively small and sensitive to the discount rate (data not shown). All three interventions are most cost-effective in South Asia and Sub-Saharan Africa. The difference between low- and middle-income countries and high-income countries is more pronounced. For NRT, the cost per year of healthy life gained is 3 to 10 times higher in high-income countries than elsewhere. For non-price interventions other than NRT, the cost in high-income countries is 22 times higher, and for price increases, almost 42 times higher. Of note, the estimates of cost-effectiveness are given as wide ranges, which reflect the range of assumptions used.

For price increases, the high-end estimates are roughly 25 times the low-end estimates, and this difference is consistent among the regions. For NRT, the high-end estimates are 2.5 to 10 times the low-end estimates, varying among the regions. For non-price interventions other than NRT, the high-end estimates are 20 times the low-end estimates, and this difference is consistent among the regions.

The cost-effectiveness results can be compared against existing studies only for high-income countries because of a lack of studies situated elsewhere. Our estimates of deaths avoided for a 10 percent price increase are conservative compared with those of Moore (1996) and Warner (1986).

COMPREHENSIVE TOBACCO-CONTROL PROGRAMS

In recent years, several governments, mostly in high-income countries, have adopted comprehensive programs to reduce tobacco use, often funded by earmarked tobacco tax revenues. The programs generally have similar goals for reducing tobacco use:

- preventing initiation among youths and young adults
- promoting cessation among all smokers
- reducing exposure to passive tobacco smoke
- identifying and eliminating disparities among population subgroups (U.S. DHHS 1994).

Furthermore, the programs have one or more of four key components: community interventions engaging a diverse set of local organizations; countermarketing and health information campaigns; program policies and regulations (such as taxes, restrictions on smoking, bans on tobacco advertising, and access to better cessation treatments); and surveillance and evaluation of potential issues, such as smuggling (U.S. DHHS 1994). Programs have placed differing emphasis on these four components, with substantial diversity among the types of activities supported within each component. Disaggregating current tobacco-control program spending reveals that the greatest effect can be achieved through a focus on macro-level changes, such as policy change. Recent analyses from the United Kingdom and United States clearly indicate that these comprehensive efforts have been successful in reducing tobacco

use and in improving public health (Farrelly, Pechacek, and Chaloupka 2003; Townsend, Roderick, and Cooper 1998; U.S. DHHS 1994). In California, for example, the state's comprehensive tobacco-control program has produced a rate of decline in tobacco use double that seen in the rest of the United States.

The cost of implementing control programs is low. Table 46.6 provides the estimated total costs of implementing price and NRT interventions by World Bank region. Current estimates of the costs of implementing a comprehensive tobacco-control program range from US\$2.50 to US\$10 per capita in the United States. The U.S. Centers for Disease Control and Prevention recommends spending US\$6 to US\$16 per capita for a comprehensive tobacco-control program in the United States (CDC 1999). Canadian spending on tobacco-control programs was approximately US\$1.70 per capita in 1996 (Pechmann, Dixon, and Layne 1998). At the highest recommended spending level (US\$16 per capita) in the United States, annual funding for a comprehensive tobacco program would equal only 0.9 percent of U.S. public spending, per capita, on health.

Evidence from the United States demonstrates that states with the greatest prevalence of smoking have a greater marginal effect with their tobacco-control spending, suggesting that the potential gains from modest investments in comprehensive tobacco-control measures are large. Each US\$10 spent per capita on tobacco control annually has resulted in a 55 percent reduction (variation of 20 to 70 percent) in per capita cigarette consumption (Tauras and others 2005). In the United States, US\$10 translates into 0.03 percent of per capita GDP in 2003.

Table 46.6 Estimated Cost of Price Intervention and NRT Programs (2002 U.S. dollars)

CONSTRAINTS TO EFFECTIVE TOBACCO-CONTROL POLICIES

Although substantial evidence exists concerning the effectiveness of numerous policy interventions to reduce tobacco use, the use of these interventions globally is uneven and limited (see a more formal analysis in Chaloupka and others 2001). World Bank data reveal that ample room exists to increase tobacco taxes. In 1995, the average percentage of all government revenue derived from tobacco tax was 0.63 percent. Middle-income countries averaged 0.51 percent of government revenue from tobacco taxes, while lower-income countries averaged only 0.42 percent. An increase in cigarette taxes of 10 percent globally would raise cigarette tax revenues by nearly 7 percent, with relatively larger increases in revenues in high-income countries and smaller increases in revenues in low- and middle-income countries (Sunley, Yurekli, and Chaloupka 2000). Despite this evidence, price increases have been underused. Guindon, Tobin, and Yach (2002) studied 80 countries and found that the real price of tobacco, adjusted for purchasing power, fell in most developing countries from 1990 to 2000.

Why does so much variation exist in tobacco-control policies? The political economy of tobacco control has been inadequately studied. A few plausible areas of interest are outlined here. First, the recognition of tobacco as a major health hazard appears to be the impetus for most of the tobacco-control policies in many high-income countries. Some evidence shows that improved national capacity and local needs assessment could increase the likelihood that tobacco-control measures will be adopted. For example, econometric analyses in South Africa geared to local policy requirements substantially increased the willingness of the government to implement tobacco-control policies (Abedian and others 1998). Second, tobacco-control budgets are only a fraction of what is required. Funding is needed not so much to implement programs as to fight off tobacco industry tactics and to build popular support for control. Third, the most obvious constraint to tobacco control is political opposition, which is difficult to quantify. Opposition from the tobacco industry is well organized and well funded (Pollock 1996).

A key tool for addressing political opposition is earmarking tobacco taxes. Earmarking has been successfully used in several countries, including Australia, Finland, Nepal, and Thailand. Of the 48 countries currently in the World Health Organization's European region, 12 earmark taxes for tobacco control and other public health measures. The average level of allocation is less than 1 percent of total tax revenue (WHO 2002). Earmarking does introduce clear restrictions and inefficiencies on public finance, and for this reason alone most macroeconomists do not favor earmarking, no matter how worthy the cause. However, analysis suggests that the efficiency

or “dead-weight losses” from earmarking tobacco taxes are minimal (Hu, Xu, and Keeler 1998). Furthermore, earmarking tobacco taxes can be justified if governments use the funds to benefit those who pay (the *benefits principle*), provide assured funding for tobacco-control policies and programs, and secure public support for new or higher tobacco taxes. Earmarked taxes also have a political function in that they help concentrate political winners of tobacco control and thus influence policy. Earmarked funds that support broad health and social services (such as other disease programs) broaden the political and civil society support base for tobacco control. In Australia, broad political support from the Ministries of Sports and Education helped convince the Ministry of Finance that raising tobacco taxes was possible. Indeed, after an earmarked tax was passed, the Ministry of Finance went on to raise tobacco taxes further without earmarking (Galbally 1997). Additionally, targeting revenue from tobacco taxes to other health programs for the poorest socioeconomic groups could produce double health gains—reduced tobacco consumption combined with increased access to and use of health services. In China, a 10 percent increase in cigarette taxes would decrease consumption by 5 percent and would increase government revenue by 5 percent. The increased earnings could finance a package of essential health services for one-third of China's poorest 100 million citizens in 1990 (Saxenian and McGreevey 1996).

Finally, a key pillar in tobacco control that can help overcome some of these constraints is the Framework Convention on Tobacco Control (FCTC). The World Health Assembly of the World Health Organization adopted the FCTC in May 2003. It consists of a series of negotiated protocols within a general framework. The first three protocols are negotiations covering smuggling, advertising, and treatment of tobacco addiction. Countries agreeing to the negotiated protocols are to adopt appropriate legislation and, if necessary, implement the appropriate measures. As of February 2005, 168 countries had signed the FCTC, 57 had ratified it, and it had come into force on February 27, 2005.

CONCLUSION

Worldwide, only two large and growing causes of death exist. One is HIV-1 infection, and the other is tobacco. On current consumption patterns, about 1 billion people in the 21st century will be killed by their addiction to tobacco. Strong evidence shows that tobacco tax increases, the dissemination of information about health risks from smoking, restrictions on smoking in public places and workplaces, comprehensive bans on advertising and promotion, and increased access to cessation therapies are effective both in reducing tobacco use and in improving the health of populations. Despite this evidence, these policies, especially higher taxes, have been

applied aggressively only in a few high-income countries, covering a small proportion of the world's smokers. Limited implementation of effective tobacco control in developing countries is due to political constraints as well as the lack of awareness of the unique effectiveness and cost-effectiveness of these interventions.

Chapter 47

Alcohol

Jürgen Rehm, Dan Chisholm, Robin Room, and Alan D. Lopez

This chapter provides an overview of epidemiology of alcohol use and health consequences as well as introducing cost-effectiveness interventions to reduce alcohol-related harm.

EPIDEMIOLOGY OF ALCOHOL USE AND ALCOHOL-RELATED DISEASE CONDITIONS

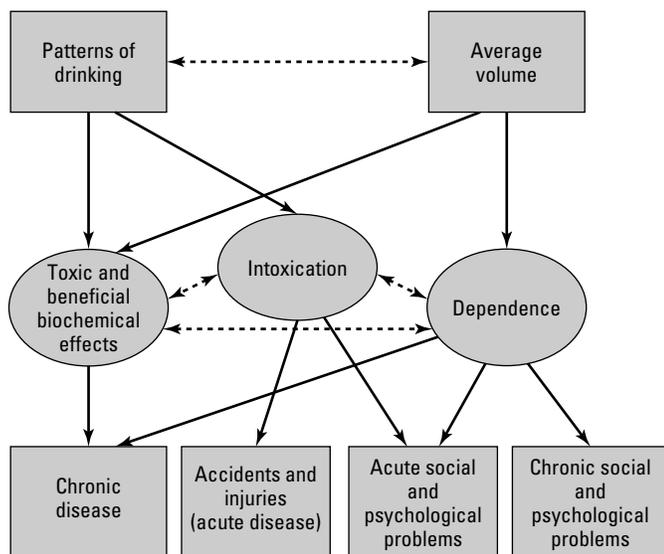

Alcoholic beverages and the problems they engender have been familiar fixtures in human societies since the beginning of recorded history. Because alcohol is causally related to more than 60 International Classification of Diseases codes (Rehm, Room, Graham, and others 2003), disease outcomes are among the most important alcohol-related problems. Depending on the pattern of consumption, alcohol is also protective against diseases, most important among them, coronary heart disease (Rehm, Sempos, and Trevisan 2003). However, the net effect is negative, and 4 percent of the global burden of disease is attributable to alcohol, or about as much death and disability globally as is attributable to tobacco and hypertension (Ezzati and others 2002; WHO 2002). Alcohol thus constitutes a serious public health problem (Room, Babor, and Rehm 2005). Evidence-based preventive measures are available at both the individual and the population levels, with alcohol taxes, restrictions on alcohol availability, and drinking-and-driving countermeasures among the most effective policy options (Babor and others 2003). This chapter reviews the cost-effectiveness of different interventions in developing regions of the world.

Dimensions of Alcohol Related to Disease

The relationship between alcohol consumption and health and social outcomes is complex and multidimensional (Rehm and

others 2004). As figure 47.1 shows, alcohol consumption is linked to acute and long-term health and social consequences through three intermediate mechanisms—toxic and beneficial biochemical effects, intoxication, and dependence (Babor and others 2003; Rehm, Room, Graham, and others 2003)—as follows:

- *Toxic and beneficial biochemical effects.* These effects of alcohol consumption may influence chronic disease in either beneficial or harmful ways. Accepted beneficial effects include the influence of moderate drinking on coronary heart disease through reduction of plaque deposits in arteries, protection against blood clot formation, and promotion of blood clot dissolution (Zakhari 1997). Examples of harmful effects include increased risk for high blood pressure and for liver damage (Rehm, Room, Graham, and others 2003) and direct toxic effects on acinar cells triggering pancreatic damage (Apte, Wilson, and Korsten 1997) or hormonal disturbances (Emanuele and Emanuele 1997). These are just examples, because alcohol exposure is associated with a multitude of toxic effects on different organs.
- *Intoxication.* Alcohol intoxication is a powerful mediator for acute health outcomes, such as accidental or intentional injuries or deaths, although intoxication can also be implicated in chronic health and social problems and in certain forms of heart disease. The subjective feeling of intoxication is mainly caused by the effects of alcohol on the central nervous system, and these effects are felt and can be measured even at light to moderate consumption levels (Eckardt and others 1998).
- *Dependence.* Alcohol dependence is a clinical disorder in its own right, but it is also a powerful mechanism sustaining alcohol consumption and mediating its impact on both

Source: Adapted from Babor and others 2003.

Figure 47.1 Model of Alcohol Consumption, Intermediate Outcomes, and Long-Term Consequences

chronic and acute physiological and social consequences of alcohol (Drummond 1990). In the quantitative analyses reported in this chapter, alcohol dependence—and alcohol-use disorders (AUDs) in general—will be considered only as a health outcome related to high-risk alcohol use.

This chapter, including the section on the cost-effectiveness of interventions, focuses primarily on health consequences, although later it briefly discusses the social consequences of high-risk drinking and recommended interventions. The epidemiological calculations are taken from Ezzati and others' (2002) comparative risk analysis (CRA) and the World Health Organization (WHO) assessment of the global burden of disease (WHO 2002). (For further information, see Mathers and others 2003; Rehm, Rehn, and others 2003; Rehm, Room, Graham, and others 2003; Rehm, Room, Monteiro and others 2003; Rehm and others 2004). The CRA defines alcohol exposure using two measures: the average volume of alcohol consumption and patterns of drinking (figure 47.1). It then relates these exposure measures to disease outcomes.

The average volume of consumption has been the conventional measure of exposure in alcohol epidemiology (Bruun and others 1975) and has been linked to many disease categories following the seminal work of English and others (1995; see also Rehm, Room, Graham, and others 2003). Patterns of drinking have been linked mainly to two categories of disease outcome: acute effects of alcohol (such as accidental and intentional injuries) and cardiovascular outcomes (mainly coronary heart disease). The CRA defines patterns of drinking primarily

in terms of high-risk drinking occasions and also in terms of drinking in public settings and the proportion of drinking that occurs outside of meals (for further details, see Rehm and others 2004).

Epidemiology of High-Risk Alcohol Use

The intervention analyses presented in this chapter focus on average high-risk drinking, although patterns of drinking were also incorporated into the disease burden calculations. High-risk drinking is defined in sex-specific terms as drinking 20 grams per day or more of pure alcohol on average for females and 40 grams per day or more of pure alcohol on average for males (a bottle of table wine contains about 70 grams of pure alcohol). This definition of high-risk drinking is fairly standard in alcohol epidemiology and was first introduced by English and others (1995) on the basis of Australian guidelines. Originally, English and others (1995) used two categories: *hazardous drinking* (defined as drinking between 20 and 40 grams per day of pure alcohol on average for females and between 40 and 60 grams per day of pure alcohol for males) and *harmful drinking* (defined as drinking 40 grams per day or more of pure alcohol on average for females and 60 grams per day or more of pure alcohol on average for males). These categories have been used in almost every comprehensive meta-analysis on alcohol and disease since 1995 (see Rehm, Room, Graham, and others 2003 for an overview). However, critics asserted that the terms *hazardous drinking* and *harmful drinking* were not neutral; thus, the CRA uses drinking categories II and III, referring to the term *high-risk drinking* when both categories are considered together. High-risk drinking thresholds differ by sex because the risk for chronic disease is related to lower volumes of drinking for women than for men; thus, the thresholds for high-risk drinking were set to reflect an approximately similar risk of chronic disease.

Table 47.1 shows the distribution of high-risk drinking by age and by World Bank region. The table excludes the Middle East and North Africa because prevalence rates of high-risk drinking are considerably lower than 1 percent and this situation is unlikely to change in the near future.

Calculating the burden of high-risk alcohol use that is avertable by means of effective interventions requires additional epidemiological data—in particular, rates of incidence to and remission from high-risk alcohol use and the relative fatality of high-risk alcohol users compared with non-high-risk alcohol users. We derived remission rates from studies of natural recovery from alcohol problems, which found an average of 10.9 years to remission (Sobell, Ellingstad, and Sobell 2000), with an adjustment of plus 20 percent for older age groups and minus 20 percent for younger age groups. We set the relative risk of mortality for high-risk alcohol users age 15 to 44 at 2.5 and the relative risk for older age groups at 1.3 for men and 1.4 for women (Gmel, Gutjahr, and Rehm 2003; Rehm, Gutjahr, and Gmel

Table 47.1 Prevalence of High-Risk Drinking by Gender, Age Group, and Region, 2000
(percentage of the population)

Region	Gender	Age group (years)				
		15–29	30–44	45–59	60–69	70+

Note: The criteria for high-risk drinking were set sex specific (for details see text).

2001). Using WHO disease-modeling software, we derived an internally consistent epidemiological profile of current high-risk alcohol use in each region, including specifications of incidence and the relative risk of mortality, with currently observed rates of prevalence, remission, and risk of mortality as inputs. A final input parameter is the disability level for high-risk alcohol use, which we estimated at 0.154 (where zero equals no disability); this is a weighted average based on the severity breakdown of high-risk drinkers from the CRA (80 percent category II, or hazardous; 20 percent category III, or harmful). The preference values for these health states of 0.11 and 0.33, respectively, are derived from Stouthard, Essink-Bot, and Bonsel (2000).

Relationship between High-Risk Drinking and AUDs

Assessing the relationship between high-risk drinking and AUDs is not a straightforward exercise. Even though high-risk drinking over a long period entails the risk of AUDs, that all people with AUDs are also high-risk drinkers does not automatically follow. First, neither the definition of alcohol dependence nor WHO's (1993) definition of harmful use includes actual consumption levels. An individual is considered dependent if at least three of the following criteria apply:

- strong desire or compulsion to take the substance
- impaired control and physiological withdrawal if the substance is reduced or ceased
- tolerance to the effects of the substance
- preoccupation with use of the substance
- persistent use despite clear evidence of harmful consequences.

By contrast, harmful alcohol use is defined as a pattern of use that is causing damage to physical or mental health. Thus,

whereas many of these criteria are associated with high-risk alcohol use, no strict classificatory rule indicates that people with AUDs are a subcategory of high-risk drinkers.

Second, the prevalence of AUDs is often derived from surveys, where the operationalization usually requires that three symptoms be present in a lifetime and at least one of these criteria be present within the past 12 months (see, for example, Demyttenaere and others 2004, table 2). Thus individuals may be categorized as alcohol dependent even if they are currently abstaining from alcohol.

Third, qualitative studies across a wide range of cultures have found that the criteria used for diagnosing AUDs often have different meanings and implications in different cultural settings (Room and others 1996; Schmidt and Room 1999). For instance, in the United States over the past decade, the level of reported AUDs increased despite decreases in high-risk drinking (Grant and others 2004). This fact has been explained in terms of changes in drinking norms and social attitudes during a period when the United States has become a “drier” culture. Thus, the measurement of AUDs is quite complex and culturally dependent. Moreover, AUDs are only one outcome of alcohol consumption and, in many parts of the world, not the most important one. As a result, we decided to focus on high-risk alcohol consumption rather than AUDs.

Relationship between Alcohol Use and Disease Categories

The exact procedures for quantifying the risk of disease attributable to alcohol are described in detail elsewhere (Rehm, Room, Graham, and others 2003; Rehm and others 2004). For most chronic disease categories, investigators have derived alcohol-attributable fractions of disease by combining

prevalence and relative risk estimates based on meta-analyses (Corrao and others 2000; English and others 1995; Gutjahr, Gmel, and Rehm 2001; Ridolfo and Stevenson 2001; Single and others 1996, 1999). For depression, we drew alcohol-attributable fractions from mental health surveys, looking at the rates of comorbidity and the order of onset of depression and alcohol disorders. For coronary heart disease, we modeled the interaction of average volumes and patterns of drinking based on multilevel analyses that include temporal information as covariates (Gmel, Rehm, and Frick 2003; Rehm and others 2004). For the final estimates, we based alcohol-attributable fractions on these multilevel results for all countries, except for developed countries with relatively favorable drinking patterns (Australia, Japan, and countries in North America and Western Europe), which are not discussed here because the focus is on developing countries. For injuries, we took a similar multilevel approach to quantify the interaction of the average volume of consumption and patterns of drinking in determining alcohol-attributable fractions (Rehm and others 2004).

Thus the analysis includes the following major disease categories:

- chronic disease
 - cancer (mouth and oropharyngeal, esophageal, liver, female breast)
 - neuropsychiatric diseases (AUDs, unipolar major depression, epilepsy)
 - diabetes
 - cardiovascular diseases (hypertensive diseases, coronary heart disease, stroke)
 - gastrointestinal diseases (cirrhosis of the liver)
 - conditions arising during the perinatal period (low birthweight)
- injury
 - unintentional injury (motor vehicle accidents, drowning, falls, poisonings, other unintentional injuries)
 - intentional injury (self-inflicted injuries, homicide, other intentional injuries).

We did not include other disease categories that are clearly alcohol-related, such as fetal alcohol syndrome, because the current analysis was based on the CRA and was, thus, limited to the global burden-of-disease categories.

Social Determinants of Exposure and Risk

Alcohol-specific risks to health are in part determined and modified by social determinants. For example, Harrison and Gardiner (1999) find that for men age 25 to 69 in England and Wales in 1988–94, those in the lowest socioeconomic status category, unskilled labor, had a 15-fold greater risk for alcohol-related mortality than professionals in the highest category

had. These differences cannot be explained by the overall volume of drinking, which actually tended to be greater for those in higher socioeconomic groups. Rather, the differences can be explained by the fact that more of the drinking of those in lower socioeconomic status categories is in high-risk patterns; that is, depending on the use values for drinking in the culture, poor drinkers may see little point in wasting resources on drinking that is not to intoxication. Poorer drinkers are also likely to be less protected physically and socially from possible harm arising from drinking, such as injuries and chronic and infectious diseases. Mäkelä (1999) finds that multiple dimensions of socioeconomic status are required to capture all the adverse interactions of socioeconomic status with alcohol-related mortality.

A critical macroeconomic question is how a country's level of economic development is related to alcohol-related risks to health. The impact of alcohol on disease and mortality may be more potent in countries with greater poverty and nutritional deficiencies (Isichei, Ikwuagu, and Egbuta 1993; Room and others 2002, 119–30). However, most of the risk relationships between alcohol and disease have been derived from studies in established market economies, and the extent of systematic research is currently insufficient to allow quantification of this phenomenon. As a result, the estimated disease burden cited here may be considered as a lower-bound estimate of the actual alcohol-attributable disease burden in developing countries.

BURDEN OF DISEASE RELATED TO HIGH-RISK ALCOHOL USE

In the following sections, the procedures to estimate alcohol-related burden of disease are described, as well as the limitations of the used approach.

Determining the Alcohol-Related Burden of Disease

Table 47.2 breaks down alcohol-attributable disability-adjusted life years (DALYs) by disease category and World Bank region using a constant 3 percent per year discount rate, but with no age weighting. Results differ from those of the CRA (Ezzati and others 2002; Rehm and others 2004; WHO 2002) because of the use of non-age-weighted DALYs.¹

Determining the Burden of Disease Related to High-Risk Alcohol Consumption

In determining the burden of disease related to high-risk alcohol consumption, we first divided the burden of disease between chronic and acute disease. For chronic disease, we assume that almost the entire disease burden reported in the CRA is associated with high-risk alcohol use. Indeed, the overall disease burden in the CRA is an underestimate, because drinking up to 20 grams per day of pure alcohol by females and

Total DALYs attributable to alcohol	12,460	9,139	6,151	326	14,836	5,956	6,850	56,008
Total DALYs from all diseases	116,502	104,287	344,754	65,570	346,225	408,655	149,161	1,535,871
Proportion of DALYs attributable to alcohol (percent)	10.7	8.8	1.8	0.5	4.3	1.5	4.6	3.6

Source: Authors' calculations based on Rehm and others 2004 and WHO 2002.

Note: Negative DALYs can occur because certain patterns of alcohol have cardio-protective effects.

up to 40 grams per day of pure alcohol by males is globally associated with a net beneficial effect in relation to chronic disease. However, this effect occurs mainly in countries with moderate drinking patterns (Rehm, Sempos, and Trevisan 2003), which tend to be high-income countries (Rehm, Rehn, and others 2003). Although high-risk but regular drinking patterns may also have some beneficial effects, such effects are not important in countries with binge drinking patterns. (For the association between alcohol and coronary heart disease, see McKee and Britton 1998; Puddey and others 1999; Rehm, Sempos, and Trevisan 2003; for consequences on modeling the regional burden of disease, see Rehm and others 2004.)

For injuries, which are considered to be acute outcomes, we started by separating out the proportion of injury not caused by high-risk drinking, which we accomplished by assuming that injuries are linearly related to per capita consumption (Rehm and others 2004).² This assumption is probably conservative, because high-risk drinkers in countries with binge drinking patterns are likely to have more frequent and intensive drinking occasions, and the risk of injury usually rises logarithmically with the amount of drinking on a specific occasion (see, for example, National Highway Traffic Safety Administration 1992). Following this initial calculation, we

could calculate the proportion of per capita consumption related to high-risk drinking in each region, thereby determining the proportion of injury caused by high-risk drinking (table 47.3). Together with our calculation of the chronic disease burden attributable to high-risk alcohol use, this percentage enabled us to estimate the overall disease burden attributable to high-risk alcohol use: whereas 3.6 percent of the global burden was attributable to alcohol drinking generally, 2.8 percent was attributable to high-risk drinking.

Limitations of the CRA Approach

The CRA's estimates of the global and regional alcohol-related burden of disease are based on a number of assumptions, of which the following are the most crucial:

- The estimates of per capita consumption and unrecorded consumption for different countries do not contain substantial measurement error.
- The distribution of consumption as derived from surveys is similar to actual distribution in the population.
- The relationships between alcohol and chronic disease derived from meta-analyses of cohort and case-control studies are stable among countries and regions.

Table 47.3 DALYs Attributable to High-Risk Average Alcohol Consumption by Disease Category and Region, 2001 (thousands of DALYs)

Disease category	Europe and Central Asia	Latin America and the Caribbean	Sub-Saharan Africa	East Asia and the Pacific	South Asia	High-income countries	World
Total chronic disease	6,510	5,283	2,770	10,296	3,167	4,526	33,634
Total injury	3,149	1,500	1,693	1,532	514	1,092	9,207
Total DALYs attributable to high-risk alcohol consumption	9,659	6,783	4,463	11,828	3,681	5,618	42,841
Total DALYs from all diseases	116,502	104,287	344,754	346,225	408,655	149,161	1,535,871
Proportion of DALYs attributable to high-risk alcohol consumption	8.3	6.5	1.3	3.4	0.9	3.8	2.8

Source: Authors' calculations based on Rehm and others 2004 and WHO 2002.

Some evidence indicates that per capita consumption can be reliably estimated, and information on this indicator is available for the vast majority of countries (Rehm, Rehn, and others 2003). With respect to survey information, reliability and worldwide coverage are lower. However, because the overall volume of consumption and, thus, the average volume per capita are based on production and sales estimates, the measure of the volume of drinking overall can be considered reliable. These factors leave the stability of relationships between alcohol and chronic disease as the most crucial part of our estimates. Some indications suggest that relative risks may not be the same in developing countries as in developed countries (for example, for tobacco and lung cancers, see Liu and others 1998). Thus, the CRA's estimates may be biased, most likely toward an overestimation of the impact of alcohol.

One additional problem pertains to the usual epidemiological approach as applied to alcohol. Most information about alcohol and chronic disease is derived from cohorts. Because cohorts are frequently not representative of the population as a whole, specific patterns of consumption such as binge drinking are often not represented, and thus their influence cannot be analyzed (Rehm, Gmel, and others 2003). Unfortunately, the patterns most often missing are those that are the most detrimental with respect to health; thus, the impact of alcohol on chronic diseases that are influenced by patterns of drinking other than average volumes is underestimated.

INTERVENTIONS FOR REDUCING HIGH-RISK DRINKING

The next two sections estimate the burden of disease attributable to high-risk alcohol consumption that is currently being averted or could be averted by a range of personal and nonpersonal intervention strategies and calculate the expected costs

and cost-effectiveness of such interventions. Methods and analyses draw on Chisholm and others (2004), adjusted as necessary to conform to the analytical standards of this volume, including the specification of all costs in U.S. dollars rather than international dollars.

Population Model

We determined intervention effectiveness using a state transition population model (Lauer and others 2003), which traces the development of a regional population taking into account births, deaths, and the specified risk factor—in this case, high-risk alcohol use. In addition to population size and structure, the population model uses a number of epidemiological parameters (incidence and prevalence, remission, and cause-specific and residual rates of mortality) and assigns age- and gender-specific health state valuations to both the disease in question and to the nondiseased population. The output of the model is an estimate of the total healthy life years experienced by the population over a lifetime period (100 years).

We ran the model for a number of possible scenarios, including no intervention at all (natural history), current intervention coverage, and scaled-up coverage of current and possible new interventions. For the intervention scenarios, we used an implementation period of 10 years for an intervention program (after which epidemiological rates return to their natural history levels), from which we derived the number of additional DALYs averted each year compared with the case for no intervention at all. We discounted DALYs at 3 percent but did not age weight them.

Effectiveness

A number of interventions have been evaluated and shown to be effective in reducing alcohol use, yet their level of

implementation remains low in all but a handful of countries and their potential effect on population-level health has rarely been assessed. By contrast, some interventions without clearly established effects continue to be widely used, including, for example, mass media public information campaigns and school-based education aimed at reducing alcohol consumption. Recent reviews of measures to reduce alcohol misuse have assessed the quality of the evidence for four types of interventions specifically aimed at reducing high-risk alcohol use (Babor and others 2003; Ludbrook and others 2002):

- policy and legislative interventions, including taxation of alcohol sales, laws on drunk driving, restrictions on retail outlets, and controls on advertising
- measures to better enforce these interventions, such as random breath testing of drivers
- mass media and other awareness campaigns
- brief interventions with individual high-risk drinkers.

On the basis of these reviews, we included the following strategies and intervention effects in our analysis: drinking-and-driving legislation and random breath testing, taxation of alcoholic beverages, reduced hours of sale in retail outlets, and advertising bans (included as population-based interventions) and so-called brief interventions (included as interventions aimed at personal behavior). We considered including one other intervention strategy—mass media or school-based awareness campaigns—but omitted it in the final analysis on the grounds that evidence for its effectiveness was weak, both in terms of methodological quality and in terms of its effect on consumption (as opposed to transfer of information or knowledge alone) (Babor and others 2003; Edwards and others 1994; Foxcroft and others 2003; Foxcroft, Lister-Sharp, and Lowe 1997; Ludbrook and others 2002).

Drunk-Driving Legislation and Random Breath Testing.

Drunk-driving laws and reinforcement policies, such as random breath testing of drivers, influence fatal and nonfatal traffic injuries among both high-risk alcohol users and other members of the population, such as passengers and pedestrians. We assessed two independent effects on alcohol-related traffic injuries, but note that evidence for these effects comes from the developed countries, where road infrastructures and driving patterns may differ significantly from those in the developing world. The first intervention was drunk-driving laws, estimated to reduce traffic fatalities by 7 percent if widely implemented across a region. The second was enforcement by random breath testing, estimated to reduce fatalities by 6 to 10 percent in regions partially implementing such a strategy and by 18 percent with wide implementation. The effect on non-fatal injuries was estimated to be a reduction of 15 percent (Peek-Asa 1999; Shults and others 2001). In each region, we

applied these estimated effects to the proportion of total deaths and of years lived with a disability attributed to alcohol-related traffic accidents (table 47.4).

Taxation on Alcoholic Beverages. Excise taxation on alcoholic beverages primarily affects the incidence of drinking through reduced consumption. Effects are measured in terms of price elasticity, which relates the change in consumption to the size of the price increase (table 47.5). We derived price elasticities, adjusted downward by one-third to reflect possible reduced price responsiveness among high-risk drinkers, with reference to preferred type of alcoholic beverage (beer, wine, or spirits) by region, built up from country-level data (WHO 2003b). This downward adjustment of price elasticities for high-risk drinkers is a conservative approach; most of the literature found similar effects on high-risk and dependent drinkers as on social users (Babor and others 2003; see also Farrell, Manning, and Finch 2003).

Price elasticities ranged from -0.3 for the most preferred beverage category to -1.5 for the least preferred (Babor and others 2003; Levy and Ornstein 1983). For a beer-drinking region where wine is the second-most preferred beverage type, for example, elasticities were set as follows: beer -0.3 , wine -1.0 , distilled spirits -1.5 . We performed sensitivity analysis around these elasticities. We evaluated three rates of excise tax on alcoholic beverages: the current rate of tax, a 25 percent increase over the current rate, and a 50 percent increase over the current rate. We adjusted estimated reductions in the incidence of high-risk alcohol use by the observed or expected level of unrecorded consumption resulting from illicit production and smuggling (for instance, an estimated 35 percent of alcohol consumption in Eastern Europe and Central Asia is unrecorded, a proportion that was modeled to increase by 10 to 15 percent with the tax increases). In regions with rates of unrecorded consumption already greater than 50 percent (South Asia and Sub-Saharan Africa), tax increases can actually have a regressive impact on incidence if accompanied by a rise in the already high level of unrecorded (and therefore untaxed) consumption.

Reduced Hours of Sale in Retail Outlets. Access to and availability of alcohol can be dramatically reduced by prohibition or rationing, but implementing and sustaining such strategies without adverse effects, such as black markets and poisonings from home-produced alcohol, present considerable challenges. A more modest strategy is to reduce the hours of sale of retail outlets selling alcoholic beverages (for example, no sales for off-premise consumption for a 24-hour period at the weekend), which in Scandinavia has reduced consumption and alcohol-related harm (Leppänen 1979; Nordlund 1984; Norström and Skog 2003). On the basis of these studies, we modeled a modest reduction of 1.5 to 3.0 percent in the incidence of high-risk drinking and 1.5 to 4.0 percent in alcohol-related traffic

Table 47.4 Effectiveness of Drinking-and-Driving Legislation and Its Enforcement

a. Percentages for all age groups combined shown here.

fatalities, depending on the regional pattern of drinking, with the largest effects in regions with the highest levels of high-risk drinking occasions.

Advertising Bans. Public health specialists are becoming increasingly interested in the effect of a comprehensive ban on alcohol advertising, including advertising on television and through radio and billboards. However, available evidence from econometric studies suggests a modest effect on consumption at best, even for a comprehensive ban, arguably because of the continuing presence of other alcohol marketing strategies, such as product placement or event sponsorship (Grube and Agostinelli 2000; Saffer 2000; Saffer and Dave 2002). Here we consider the potential effects of a comprehensive advertising ban (television, radio, and billboards) by modeling a 2 to 4 percent reduction in the incidence of high-risk alcohol use, depending on regional drinking patterns.

Brief Interventions. We modeled brief interventions (such as physician advice provided in primary health care settings), which involve a small number of education sessions and psychosocial counseling, to influence the prevalence of high-risk drinking by increasing remission and reducing disability. Efficacy reviews of brief interventions reveal an estimated 13 to 34 percent net reduction in consumption among high-risk drinkers (Higgins-Biddle and Babor 1996; Moyer and others 2002; Whitlock and others 2004), which, if applied to the total population at risk, would reduce the overall prevalence of high-risk drinking by 35 to 50 percent, equivalent to a 14 to 18 percent improvement in the rate of recovery over no treatment at all. After taking into account adherence (70 percent) and potential treatment coverage in the population (50 percent of high-risk drinkers), however, we estimated remission rates to be between 4.9 and 6.4 percent higher than natural history rates.

Table 47.5 Effect of Taxation on the Incidence of High-Risk Alcohol Use

a. B = low child mortality, low adult mortality; C = low child mortality, high adult mortality; D = high child mortality, high adult mortality; E = high child mortality, very high adult mortality.

b. Price rise caused by tax = (percentage of tax/(1 + percentage of tax)) × elasticity × 2/3 (high-risk drinkers less responsive).

c. Effect = sum of (prevalence × price increase) for each beverage × (1 - percentage of unrecorded consumption).

d. Lower-range elasticities = -0.2, -0.7, -1.2.

e. Upper-range elasticities = -0.4, -1.3, -2.0.

Costs

Costs covered in the analysis include program-level costs associated with running the intervention (such as administration, training, and media costs) and patient-level costs (such as costs of primary care visits). Program-level costs include resource inputs used in the production of an intervention at a level above that of the patient or providing facility, such as central planning, policy, and administration functions, as well as resources devoted to preventive programs, such as the enforcement of drunk-driving legislation by police officers (Johns and others 2003). We derived estimated quantities of resources required to implement each intervention for 10 years at the national, provincial, and district levels with reference to the region's prevailing characteristics—for example, the stability and efficiency of tax systems, the volume of traffic (for breath testing), and the strength of antidrinking sentiment as indicated by existing alcohol controls (advertising bans, restricted sales). In this analysis, patient-level resource inputs used in the provision of a given health care intervention (for example, hospital inpatient days, outpatient visits, medications, and laboratory tests) are relevant only to brief interventions. We estimated an average of four primary care visits per year for the intervention itself, plus an additional 0.33 outpatient visits (20 percent \times 1.67 visits) and 0.25 inpatient days (5 percent \times 5 days) (see, for example, Fleming and others 2000). We applied these patient-level resource inputs to the 50 percent of prevalent high-risk alcohol users in receipt of brief advice in year 1 and (because we model an enduring effect for 10 years) year 6 and to the 50 percent of incident cases in years 2 to 5 and 7 to 10. Note that, throughout, the costing does not include possible offsetting revenues for the government, for instance, from drunk-driving convictions and, in particular, from the revenues likely to result from increased alcohol taxes.

Unit costs and prices of program- and patient-level resource inputs include the salaries of central administrators; the capital costs of vehicles, offices, and furniture; and the cost per outpatient visit (see chapter 7 for an overview of the costing methodology, plus prices by World Bank region). All costs are expressed in U.S. dollars for 2001 and are discounted at an annual rate of 3 percent.

COST-EFFECTIVENESS OF INTERVENTIONS

In the following section, we provide results relating to the population-level health effects, costs, and cost-effectiveness of the evidence-based interventions previously reviewed.

Population-Level Effects

Except for random breath testing, two-thirds of the total population-level health gain from these interventions was among

males (the proportion for random breath testing rises to 80 to 90 percent because of the higher proportion of deaths and injuries attributed to traffic accidents among men). A clear difference is also apparent between regions with relatively high rates of high-risk alcohol use (that is, prevalence in the total population greater than 5 percent) and regions with generally low levels of high-risk drinking (that is, less than 2 percent).

As shown in table 47.6, in the three regions with a higher prevalence of high-risk alcohol use—Europe and Central Asia, Latin America and the Caribbean, and Sub-Saharan Africa—the most effective interventions were taxation and brief physician advice to individual high-risk drinkers, with each averting more than 500 DALYs per million population per year. The remaining control strategies—random breath testing, reduced access to alcoholic beverage retail outlets, and a comprehensive advertising ban—mainly produced effects in the range of 200 to 400 DALYs averted per million population per year. In the two regions with lower rates of high-risk drinking (particularly among the female population), by contrast, the burden that is avertable through taxation is very much reduced (10 to 100 DALYs averted per million population per year). In South Asia, the most effective intervention is enforcement of drinking-and-driving laws by means of random breath testing, because of the higher rate of traffic-related injuries than elsewhere as well as the low levels of high-risk drinking.

Population-Level Costs

Table 47.7 summarizes the costs and cost-effectiveness of each intervention and of two combination strategies by region. The most costly interventions to implement in all regions were random breath testing and brief physician advice in primary care. The higher costs of brief advice stem from a combination of patient-level costs in the provision of the intervention itself (an average annual cost of US\$7 to US\$20 per treated case), plus program costs associated with administration and training primary care providers (15 to 40 percent of total costs). Random breath testing is also a relatively resource-intensive intervention to implement because of the need for regular sobriety checkpoints administered by law enforcement officers. Other interventions, including taxation, had a per capita cost in the range US\$0.02 to US\$0.13, depending in part on the efficiency of the tax collection system and the degree of antidrinking sentiment.

Population-Level Cost-Effectiveness

Compared with doing nothing, taxation is the most cost-effective population-level strategy in Europe and Central Asia, Latin America and the Caribbean, and Sub-Saharan Africa, the three regions with a relatively high prevalence of high-risk drinking (table 47.7). At the current rate of tax, for example, each DALY averted costs US\$104 to US\$225, equivalent to 4,435 to 9,633 DALYs averted per US\$1 million expenditure.

Source: Chisholm and others 2004.

a. Refers to the modeled percentage of all high-risk drinkers exposed to the intervention.

Advertising bans had a cost per unit of effect similar to that of reduced access to sales outlets, US\$134 to US\$380, equivalent to 2,631 to 7,442 averted DALYs per US\$1 million dollars expenditure, whereas random breath testing had the highest estimated cost per DALY averted: US\$973 to US\$1,856 per

DALY, approximately 500 to 1,000 DALYs averted per US\$1 million dollars expenditure. Brief physician advice provided in primary care settings had an average cost-effectiveness in the range of US\$204 to US\$502 per DALY averted, or close to 2,000 to 5,000 averted DALYs for every US\$1 million expenditure.

Source: Chisholm and others 2004.

a. Refers to the modeled percentage of all high-risk drinkers exposed to the intervention.

Starting from the current situation in these regions, the most efficient strategies for reducing high-risk alcohol use would be tax increases (additional gains are obtained at virtually no extra cost because the costs of tax administration and enforcement remain relatively constant whatever the rate of tax), followed by the introduction or escalation of comprehensive advertising bans on alcohol products, reduced access to retail outlets, and the provision of brief interventions such as

physician advice in primary care. Even a multifaceted strategy made up of an increase in taxation plus full implementation of the other interventions considered here has a favorable ratio of costs to health benefits.

In East Asia and the Pacific and South Asia, the two regions with lower rates of high-risk alcohol use, a comparison of intervention costs and effects to a no-intervention scenario reveals that current practice—namely, excise taxes on alcoholic

beverages—is not the most efficient response to the existing burden of alcohol use. The reduced efficiency of taxation in these lower-prevalence regions is related both to the distribution of the fixed costs of administering and enforcing alcohol tax legislation across a smaller target population of drinkers and to underlying drinking patterns: more than 85 percent of all alcohol consumption falls into a single preferred drink category, spirits, which therefore diminishes the scope for reducing the consumption of less preferred but more elastic categories of alcoholic beverages. In South Asia, targeted strategies such as brief physician advice and random breath testing have the lowest cost per DALY averted (around US\$500), while taxation policies are the most expensive at more than US\$2,500 per DALY averted. In East Asia and the Pacific, the most cost-effective interventions are brief physician advice, a comprehensive ban on advertising, and reduced access to retail outlets (below US\$250 per DALY averted).

Implications and Limitations of Sectoral Cost-Effectiveness Analyses

This cost-effectiveness analysis offers a new approach to generating economic evidence that can inform public health policy on alcohol in a wide range of cultural and epidemiological settings (Chisholm and others 2004). Resulting estimates of cost-effectiveness can inform policy makers not only by determining the efficiency of existing resource allocation and practices, but also by identifying priorities for future alcohol control strategies. Furthermore, use of a common methodology enables comparison with cost per DALY estimates for other risk factors or disease entities, which may constitute an important argument when considering priorities for the allocation of scarce health care resources. However, the application of a broad sectoral approach using entire regions as the unit of analysis clearly limits the approach's use in specific country contexts, where demographic or epidemiological characteristics, as well as treatment costs and coverage, may not coincide with estimates for the region as a whole. In addition, extrapolation of the extent of intervention effects from relatively information-rich countries to other sociocultural settings lessens the precision of derived estimates of population-level health gains.

Although an ongoing analytical step is to calibrate results at the country level, the primary purpose and utility of the sectoral approach is to identify interventions that are clearly cost-effective as opposed to those that clearly do not seem to offer good value for money. In this respect, the primary conclusion to be drawn from the analysis is that in regions with high or moderate rates of high-risk alcohol use, a number of intervention strategies can have a notable effect on population health, including both individual-based interventions, such as brief physician advice at the primary care level, as well as

population-wide measures, such as taxation of alcoholic beverages. Of these, taxation has the most sizable and least resource-intensive effect on reducing the avertable burden of high-risk alcohol use. In regions where high-risk alcohol use represents less of a public health burden, targeted approaches such as brief physician advice as well as other intervention strategies that restrict the supply or promotion of alcoholic beverages appear to be the most cost-effective mechanisms, although greater empirical support for the efficacy of these interventions in these localities is clearly needed before considering their widespread implementation.

Even though sectoral cost-effectiveness analysis pursues a societal perspective, considerable challenges remain in relation to the appropriate measurement of certain societal costs and effects that fall outside the boundaries of the health system. Therefore, this analysis has not been able to successfully capture potential reductions in workforce and household productivity losses among high-risk drinkers, nor does it incorporate the economic costs associated with alcohol-related crime, violence, and harm reduction. It also does not value the time spent by patients and informal caregivers in seeking or providing care and support. Including these modest additional costs and substantial incremental effects is likely to improve the cost-effectiveness ratios of all interventions, but to a variable and currently unknown extent.

ECONOMIC BENEFITS OF INTERVENTIONS

By design, estimates of the burden of alcohol do not include most social harm and harm to people other than the drinker; however, the burden of social problems from drinking can be at least as significant as the health burden. The burden attributable to alcohol in the CRA estimates is actually a substantial underestimate of the full harm alcohol imposes on human welfare. The estimates reported earlier reflect primarily the chronic disease and injury effects of drinking. Because the CRA focused on disease and disability, the estimates were not designed to take account of the social harm and problems that are particular to alcohol and that result for the drinker and for others as a consequence of a person's drinking (Klingemann and Gmel 2001). These problems are quite prevalent in many populations (Room and others 2003) and are also affected by the interventions listed earlier.

Some information on the relative burden of alcohol for social services versus health services is available for a handful of societies. In an estimate of the staffing and service costs attributable to alcohol in different service systems in Scotland for fiscal year 2001/02, for instance, health services accounted for only 21 percent of the estimated costs, whereas social services accounted for 19 percent, and criminal justice and fire services accounted for 60 percent (Catalyst Health Consultants 2001, 3).

If those estimates are used as a rough gauge of the burden to society, the illness and disability burden of alcohol may thus constitute half or less of the total burden when social problems are also taken into consideration.

Thus, policies that affect the levels of alcohol-related health and social harm not only are a matter of intervening to save people from the detrimental effects of their own behavior, but also potentially have a broader effect on the health and well-being of families and of associates of drinkers. This issue is especially relevant for women: even though men predominate among high-risk drinkers worldwide (Rehm and others 2004; Room and others 2002), women bear much of the burden of harm from others' drinking, not only in such forms as domestic violence, but also in such forms as diversion of family resources from greater needs.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

The following paragraphs provide a few concrete examples of interventions or policy changes that illustrate the actual implementation and effects of control strategies in developing societies (the examples are taken from Room and others 2002).

Tax Rate Reduction and the Resulting Disease Burden in Mauritius

Mauritius, an island nation in the Indian Ocean, has a population of about 1 million. These people are of Indian, African, European, and Chinese origin. By religious affiliation, 53 percent are Hindu, 29 percent are Christian, and 17 percent are Muslim. Tourism is the third-ranked industry in terms of hard currency earnings. In June 1994, the government drastically lowered customs duties on imported alcoholic beverages to 80 percent from rates that had ranged from 200 percent for wine to 600 percent for whisky and other spirits (Abdool 1998). The government made the change under pressure from the hotel industry, which claimed that tourists were not purchasing enough alcohol because of its high prices (Lee 2001). Other reasons given for the change were to reduce unofficial imports from abroad and to make better, more refined alcoholic beverages available to the local population. Despite little evidence to support the view, there were claims in the public discussion that better-quality alcohol would result in fewer health problems.

The effects of the change were felt mainly by Mauritians rather than tourists, as follows:

- Arrests for driving with blood alcohol over the legal limit made primarily in connection with traffic crashes increased by 23 percent between 1993 and 1997.
- Admissions of alcoholism cases to the island's psychiatric hospital shot up in 1994. The 1995 rate was more than twice

the 1993 rate, and the rate rose again slightly in 1996 and 1997. Medical specialists in Mauritius agree that patients with alcohol problems account for an increasing portion of admissions in general medical wards and now represent between 40 and 50 percent of bed occupancy (Abdool 1998).

- Age-adjusted death rates per 100,000 population for chronic liver disease and cirrhosis rose from 32.8 for males and 4.0 for females in 1993 to 42.7 for males and 5.3 for females in 1996 (WHO 1999, 2000).

Even though available statistics are limited, the reduction in alcohol import taxes clearly had a substantial negative effect on the health of Mauritians. Thus, the government's 1997 call for control measures for alcohol—specifically, new permits for licensed premises, increased excise duties on alcohol, and limitations on bars' opening hours—was not surprising. Alcohol taxes were increased somewhat in the 1999/2000 budget (U.S. Department of State 1999). However, an analysis by World Bank staff that did not take health effects into account called for further reductions in maximum tariff rates, identifying Mauritius as having an antitrade bias on the basis of the structure of its alcohol and tobacco taxes (Hinkle and Herrou-Aragon 2001).

Wallace and Bird (2003) suggest the following general principles for setting and collecting alcohol taxes in the context of developing societies from the perspective of revenue generation rather than public health (see also Tax Policy Chief Directorate 2002):

- Countries around the world need revenues they can raise relatively efficiently, but this need is probably more critical in the case of developing nations. That said, alcohol taxes are probably a good bet for future revenues.
- Excise taxes on alcohol should be set by alcohol content, rather than as a percentage of the price.
- Tax rates should be logically defined so that alcoholic beverages with similar alcohol content are treated similarly, with stronger alcohol beverages taxed more heavily.
- Analyses of revenue-maximizing rates should be conducted to determine a range of tax rates that is likely to maximize government revenues.
- Tax systems should be designed to be as simple as possible to allow for the maximum efficiency of tax administration.

Reduced Access through Locational Prohibition in Brazil

The second example involves the institution of a new control on alcohol availability in an environment where it is likely to be combined with driving. Although we have modeled the effects of another, better studied availability control (namely, closing on a weekend day), a wide variety of possible

measures is available to control the time and place of alcohol purchase or drinking (Babor and others 2003; Room and others 2002). Even though in this case the particular control was extremely limited in scope, it appears to have had measurable effects.

Traffic deaths are an important source of mortality in Brazil, amounting to 3.6 percent of overall mortality. The few available studies suggest that alcohol plays a significant role in traffic casualties. For instance, one study in São Paulo found positive blood alcohol levels in 72 percent of pedestrian deaths and 32 percent of driver and passenger deaths of persons age 13 and older (Carlini-Cotrim and Chasin 2000).

In 1985, motivated by concern about alcohol and impaired driving and about the lax enforcement of drinking and driving laws, a conservative party politician from the state of São Paulo introduced legislation to prohibit alcohol sales in commercial facilities that had access to state highways. Even though the bill passed in the legislature, its implementation was delayed by the state's alcohol producers and commercial and industrial federations, which claimed that the law would be a barrier to improved facilities for travelers, would encourage people to carry bottles in their cars, and would restrict individual freedoms. Discussion in the press was also generally unsympathetic. In August 1988, however, a new state governor from the same party implemented the law. At that time, the press was slightly more supportive. Since then, the law has been on the books, although site visits to restaurants and snack bars along a state highway in 1997 suggested a low level of compliance. In 1995, another legislator from the same party proposed repealing the law on the grounds that no studies proved that it lowered traffic accidents. The repeal passed the legislature without significant public debate, but the state governor vetoed it. Undaunted, the same legislator then proposed a law to criminalize buying as well as selling alcohol along state highways. That law passed but has not yet been implemented.

A study by Carlini-Cotrim, Pinsky, and Serrano Barbosa (1998) assesses the effects of the intervention. Finding data for a controlled study comparing traffic casualties on state highways with casualties on federal highways, which were unaffected by the law, proved impossible. The best data available were on crashes and crashes resulting in injuries per 10,000 vehicles traveling on three short highway systems administered by a private agency. Linear regressions on those data for 1983–93 showed that the law had made a significant difference in the number of accidents resulting in injuries on all three roads and a significant difference in all accidents on two of the roads. A separate analysis on estimated accidents and accidents with injuries per 10,000 vehicles in two geographic areas of the state did not show significant effects of the law. Overall, the analyses do provide some support for the law having a beneficial effect on the rate of traffic casualties.

Drunk-Driving Enforcement in South Africa

No published studies are available of the implementation of random breath testing in a developing country. However, some data are available on a campaign to increase drunk-driving enforcement in South Africa, a strategy that has often shown some effects, although weaker and less lasting than those of random breath testing.

The minister of finance launched a short-term campaign, ARRIVE ALIVE, for the period October 1997 to January 1998, in response to the high rate of traffic fatalities and injuries. The campaign's main aim was to mobilize all available traffic policing, control, and education resources to reduce traffic accidents on South African roads by at least 5 percent, especially in the Western Cape, Gauteng, and KwaZulu Natal provinces, because 75 percent of all accidents occurred in those provinces. The ARRIVE ALIVE campaign targeted, in turn, what were considered the three critical factors having the greatest impact on injuries: failing to wear seat belts, drinking and driving, and speeding. Unofficially, the campaign came to be called "belts, booze, and bats out of hell."

As many of the parties interested in road safety as possible were involved, with funding drawn from a variety of government and business sources. The campaign included a number of components particularly relevant to alcohol use. New equipment purchased by the provinces included alcohol screening devices, alcohol evidentiary units, and so-called booze buses (vehicles containing all the technology needed to check breath and blood alcohol levels). Sentences were increased to underline the point that traffic violations are serious offenses, with a three-month suspension of a driver's license and an increased maximum fine for a first conviction for drunk driving and with license suspension for one to five years for second offenders. Traffic supervisors underwent intensive training courses before the start of the campaign.

Because the aim of the campaign included educating road users, advertisements covering aspects of the campaign were run on the radio, on television, and in movie theaters throughout the country. Supplements were published in national and provincial newspapers. Private companies, such as a supermarket chain and an automobile manufacturer, also promoted the campaign. A national transportation center, established to collect and collate data from local and provincial authorities, operated for 12 hours every day throughout the campaign. Traffic authorities staffed an additional 80 roadside communications points, and at selected points on certain routes, road signs were erected and updated to display the percentage of speed limit and drinking-and-driving violations and the rate of seat belt use in that area.

A total of 776 enforcement points were set up on 195 strategic routes in the selected provinces. Posters, pamphlets, key rings, and license decals were produced for distribution and

display at roadblocks in the three provinces. Between October 1, 1997, and January 17, 1998, 6,674 notices of prosecution were issued for alcohol-related traffic offenses, 83 percent of which were issued in the intervention provinces.

Comparison studies showed a decrease in the drinking rate of drivers in the three provinces, whereas the other six provinces, as a group, showed an increase. KwaZulu Natal had the lowest drinking rate of all drivers throughout the campaign (3 to 7 percent), and the Western Cape had the most dramatic decrease (from 12.0 to 9.3 percent in October). Except for in Gauteng, the drinking rates for pedestrians decreased from more than 15 percent to less than 7 percent. Overall, during the months targeted, drinking-and-driving rates decreased by 2 to 4 percent, as measured by breath testing. The total number of crashes decreased by 8 percent, and fatalities dropped by 9 percent. The ratio of benefits to costs for the intervention was estimated as 4 to 1, based on an investment in the campaign of R50 million, or about US\$4.4 million at 2002 rates (ARRIVE ALIVE Campaign 2000).

Despite the potential inconvenience of roadblocks and other enforcement activities, the public generally perceived the campaign positively. The liquor retail and hospitality industries complained about decreased sales, and tow truck operators complained about reduced business.

Even though driver behavior improved during the focus months, violations often increased after the focus was changed, for example, from drunk driving to seat belt use. This finding emphasizes the need for sustained enforcement as opposed to ad hoc campaigns. (This example was summarized from ARRIVE ALIVE Campaign 2000 and Cerff and Plüddemann 1998.)

Implementation of Brief Interventions in Several Developing Countries

In the first phase of the WHO Collaborative Project on Identification and Management of Alcohol Related Problems (Saunders and Aasland 1987), a screening measure suitable for use in both developing and developed countries—the alcohol-use disorders identification test—was developed to identify people at risk for alcohol problems among those attending primary health care services. In the second phase, a multicenter clinical trial of brief intervention procedures designed to reduce the health risks associated with hazardous alcohol use was carried out in primary health care settings in Australia, Bulgaria, Costa Rica, Kenya, Mexico, Norway, the Soviet Union, the United Kingdom, the United States, and Zimbabwe (Babor and others 1994).

The project's aims were to study the influence of simple advice and brief counseling, to examine the moderating role of reduced consumption on the prevention of alcohol-related problems, and to evaluate the cross-national generalizability of

brief intervention techniques. The project's hypothesis was that the amount of change in alcohol consumption over a nine-month period would be proportional to the intensity of the intervention provided by a trained primary health care professional. The results showed a significant effect of interventions on both consumption and intensity of drinking among males, but the intensity of the intervention was not related to the amount of change in drinking behavior; 5 minutes of simple advice turned out to be as effective as 20 minutes of brief counseling (Babor and Grant 1992). The female sample was too small for the results to attain significance, and the intervention did not significantly affect men's frequency of dependence symptoms, problems related to alcohol, or concern expressed by others (WHO Brief Intervention Study Group 1996).

The findings suggest that in a population of high-risk drinkers, behavior change is more a function of motivational factors and social influence than of the moderation skills and social learning techniques that behavioral self-control training packages typically use. Changes in drinking were not attributable solely to the small number of patients who achieved an abstinence goal, nor to the small number who gave up daily or almost daily drinking. Rather, changes seem to have been distributed across a broad spectrum of the drinkers who reduced their consumption by small, but clinically meaningful, amounts.

RESEARCH AND DEVELOPMENT AGENDA

Research and development needs in the area of alcohol consumption are large and multidimensional. The work reported in this chapter represents best estimates from the available data, some of which were developed to fill the needs of the analysis; however, we cite few figures for the developing world for which we can say that the underlying data are so good that they could not usefully be improved. Nevertheless, more and better data are available on alcohol than on many other health topics.

The health and social burdens of alcohol are clearly extremely large in most developing societies. Thus, the most urgent focus should be on development and evaluation projects to study the outcomes of various policy and program interventions. The projects must necessarily be attuned to what is politically feasible in a particular time and place. They are likely to include natural experiment studies, where the research tracks the effects of changes that governments undertake, whether those changes are expected to increase or to decrease the extent of alcohol problems. Where possible, the projects should include experimental and quasi-experimental studies, whereby the effects of a change at intervention sites are studied in comparison to outcomes at control sites, with random

assignment where possible. Costing data should be included to permit cost-effectiveness analysis.

Also important are process studies—that is, research on how policy makers decide on policy changes, how they implement them, and what the reactions and sequelae are. For example, deciding to introduce a new alcohol tax may be the easiest part of an initiative, but actually implementing it in a developing society with a great deal of unrecorded alcohol in the informal market and with poorly guarded borders may be much more difficult. Currently, no international mechanism or nexus exists for developing and disseminating practical knowledge about implementing effective alcohol control strategies between developing countries.

At this time, nearly all studies of alcohol interventions come from a limited range of developed countries. Extending knowledge and experience in and between developing societies is urgently needed.

A secondary need, but one that is also important, is to extend the epidemiological database in developing societies on levels and patterns of drinking and on the health and social consequences of drinking. To this end, better estimation of unrecorded alcohol consumption is needed. Which dimensions of drinking patterns matter for what kinds of outcomes needs to be studied in the context of different kinds of developing societies. Studies of the effects that the interaction of drinking levels and patterns with poverty and social exclusion have on the extent of alcohol-related problems are also necessary. Because most of our knowledge about the health effects of drinking concerns mortality, studies of alcohol's role in various kinds of morbidity should be emphasized. Another area where data are lacking is the social harm arising from drinking, for which we cannot presently make the kinds of estimates that are possible to make for harm to health. Developing and reaching consensus on ways to measure the social harm caused by drinking is a substantial agenda for both the developed and the developing world.

Developing the epidemiological database can provide clues to etiology to be pursued further by biomedical and social researchers and, thus, offers hope for the development of new treatments or preventive interventions. It can provide information on the distribution of drinking patterns and problems in subpopulations that can be used to guide targeting and prevention and treatment priorities. However, from a short-term policy perspective, the most important function of developing the epidemiological database in a particular country may be providing a base for creating political will for action. For example, the development of devices to measure blood and breath alcohol and the collection of data on drinking and driving that they made possible were prerequisites for developing the political will and support for implementing drinking-and-driving countermeasures in industrial countries.

CONCLUSION

The burden of disease attributable to alcohol in the developing world is considerable, and the social harm not accounted for in this analysis increases the costs. However, known interventions can reduce the burden by up to 25 percent, depending on the region of the world. Compared with other interventions in the health care field, these interventions are quite cost-effective, but given the nature of many of the interventions, caution is needed. In particular, the following recommendations can be given:

- Interventions and research about their effectiveness are based mostly on experiences from established market economies; thus, the levels of effectiveness estimated in our analysis should be treated as broad indications. Depending on actual methods of implementation, individual interventions could be more or less effective.
- Interventions should ideally be modeled on the basis of the specific environment (that is, countries or provinces) and on the harm distribution in the respective environment, including social harm.
- General principles, such as restricting access to alcohol, should be attuned to local cultures and traditions when interventions are formulated.
- Population measures must take into account the complex interplay of public opinion and balance the interests of different groups and stakeholders with conflicting values. One of these stakeholders is, of course, the alcohol industry.

If policy makers keep these principles in mind, reducing the alcohol-related health burden could be one of the most cost-effective targets of population-level health programs in developing countries. This target is even more attractive because the measures discussed will also reduce the alcohol-related social burden, thereby further contributing to development.

NOTES

1. The global burden of disease attributable to alcohol is 4.0 percent using age-weighted DALYs and 3.6 percent using non-age-weighted DALYs. This difference can be explained by the many alcohol-attributable outcomes occurring during adolescence and young adulthood, when age weights are higher.

2. The CRA defined *per capita consumption* as average consumption of pure alcohol per person 15 years old or older.

Chapter 48

Illicit Opiate Abuse

Wayne Hall, Chris Doran, Louisa Degenhardt, and Donald Shepard

Illicit drugs are those banned by international drug control treaties. They include cannabis products (for example, marijuana, hashish, and bhang); stimulant drugs (such as cocaine and methamphetamine); so-called dance-party drugs (such as 3, 4-methylenedioxymethamphetamine, also known as *ecstasy* or *MDMA*); and illicit opioids (for instance, heroin and opium) and diverted pharmaceutical opioids (such as buprenorphine, methadone, and morphine) (see annex 48.A).

Worldwide, 185 million people were estimated to have used illicit drugs during 1998–2002 (UNODC 2004; UNODCCP 2002). Cannabis was the most widely used illicit drug, with 146.2 million users in 2002, or 3.7 percent of the global population over age 15. The stimulant drugs were the next most widely used illicit drugs: 29.6 million people worldwide used amphetamines; 13.3 million used cocaine; and 8.3 million used ecstasy. An estimated 15.3 million, or 0.4 percent of the world population age 15 to 64, used illicit opioids; more than half used heroin and the remainder used opium or diverted pharmaceutical opioids. Illicit opioids continue to be the major illicit drug problem in most regions of the world in terms of impact on public health and public order (UNODC 2004).

Even though cannabis use accounts for about 80 percent of illicit drug use worldwide, the mortality and morbidity attributable to its use are not well understood, even in developed countries (W. Hall and Pacula 2003; Macleod and others 2004; WHO Programme on Substance Abuse 1997). The same is true of the morbidity and mortality attributable to cocaine and amphetamine-type stimulants (Macleod and others 2004). Dance-party drugs have been used for too short a time in most developed societies to enable a good assessment of their potential for harm (Boot, McGregor, and Hall 2000; Macleod and others 2004). The remainder of this chapter is concerned with

disease control priorities for illicit opioid dependence, because dependent users account for most of the illicit opioids consumed and experience most of the harm such dependence causes (W. Hall, Degenhardt, and Lynskey 1999).

NATURE, CAUSES, AND HEALTH CONSEQUENCES OF ILLICIT OPIOID USE

Before considering interventions, we briefly summarize what is known about the antecedents, causes, and health consequences of illicit opioid use.

Antecedents of Heroin Use

Law enforcement efforts to reduce the availability of heroin aim to increase its price, deter illicit drug use, and promote social values that discourage heroin use (Fergusson, Horwood, and Lynskey 1998; Hawkins, Catalano, and Miller 1992; Newcomb and Bentler 1988). These gains may be at the cost of increasing harm among the minority who use opioids despite the prohibition—for example, by encouraging injecting use as the most efficient way to use an expensive drug and increasing needle sharing because clean injecting equipment is not freely available (Rhodes and others 2003; Strathdee and others 2003).

Two aspects of the family environment are associated with increased rates of both licit and illicit drug use in young people in developed countries. The first is exposure to a disadvantaged home environment, with parental conflict and poor discipline and supervision; the second is exposure to parents' and siblings' use of alcohol and other drugs (Hawkins, Catalano, and Miller 1992). In developed countries, children who perform

poorly in school because of impulsive or problem behavior and those who are early users of alcohol and other drugs are most likely to use illicit opioids (Fergusson, Horwood, and Swain-Campbell 2002). Affiliation with drug-using peers is a risk factor for drug use that operates independently of individual and family risk factors (Fergusson, Horwood, and Lynskey 1998; Hawkins, Catalano, and Miller 1992).

Health Consequences of Heroin Use

The following sections describe the major health consequences of heroin use. They include dependence, increased mortality and morbidity attributable to drug overdoses, and bloodborne viruses.

Heroin Dependence. In household surveys, 1 to 2 percent of adults in Australia, the United States, and Europe report using heroin at some time in their lives (Australian Institute of Health and Welfare 1999; EMCDDA 2002; SAMHSA 2002). The highest rates are typically among adults age 20 to 29. Self-reported heroin use in population surveys probably underestimates rates of use because heroin users are undersampled and those who are sampled underreport their use (W. Hall, Lynskey, and Degenhardt 1999).

In developed countries, one in four of those who report heroin use become dependent on it (Anthony, Warner, and Kessler 1994). People who are heroin dependent continue to use heroin in the face of problems that they know (or believe) to be caused by its use. These problems include being arrested or imprisoned, having interpersonal and family problems, catching infectious diseases, and suffering from drug overdoses. Many heroin users who seek treatment have typically been daily heroin injectors, although in Europe (EMCDDA 2002), North America (Office of National Drug Control Policy 2001), and parts of Asia, illicit opioid users also smoke or “chase” the drug (inhale the fumes released when heroin is heated) (UNODC 2004).

The American Psychiatric Association defines *drug dependence* as “a cluster of cognitive, behavioral, and physiologic symptoms indicating that the individual continues use of the substance despite significant substance-related problems” (American Psychiatric Association 1994, 176). In the fourth edition of the association’s *Diagnostic and Statistical Manual of Mental Disorders* (1994), a diagnosis of substance dependence requires that three or more of the following occur together:

At any time in the same 12-month period:

1. tolerance, as defined by either of the following:
 - a. need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - b. markedly diminished effect with continued use of the same amount of the substance;

2. withdrawal, as manifested by either of the following:
 - a. the characteristic withdrawal syndrome for the substance
 - b. the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms;
3. the substance is often taken in larger amounts or over a longer period than was intended;
4. there is a persistent desire or unsuccessful efforts to cut down or control substance use;
5. a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors, driving long distances), use the substance (e.g., chain smoking), or recover from its effects;
6. important social, occupational, or recreational activities are given up or reduced because of substance use;
7. the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.

Indirect estimation methods suggest that in Australia, the United Kingdom, and the European Union fewer than 1 percent of adults age 15 to 54 are heroin dependent (EMCDDA 2002; W. Hall and others 2000). Research in the United States indicates that dependent heroin users who seek treatment or who come to the attention of the legal system may use heroin for decades (Goldstein and Herrera 1995; Hser, Anglin, and Powers 1993), with periods of use punctuated by abstinence (Bruneau and others 2004; Galai and others 2003), drug treatment, and imprisonment (Gerstein and Harwood 1990). When periods of abstinence are included, dependent heroin users use heroin daily for 40 to 60 percent of the 20 years that they typically are addicts (Ball, Shaffer, and Nurco 1983; Maddux and Desmond 1992).

Illicit opioid use increased in Asia, Europe, and Oceania and, to a lesser extent, in Africa and South America in the 1990s, but it has stabilized or declined since 2000 (UNODC 2004). Most illicit opioid users (7.8 million) live in Asian countries that surround the major opium-producing countries, Afghanistan and Myanmar. Europe accounts for about 25 percent of illicit opioid use (4 million users or 0.8 percent of the adult population age 15 to 64). Two-thirds of users are in Eastern Europe, which reported large increases in illicit opioid use during the second half of the 1990s (Atlani and others 2000; Hamers and Downs 2003; Kelly and Amirkhania 2003; Rhodes and others 1999; Uuskula and others 2002).

Illicit opioid use stabilized in much of Asia between 2000 and 2002 (UNODC 2004) as a result of decreased opium production after the rapid expansion during the 1990s (Dorabjee and Samson 2000; Reid and Crofts 2000). After 2000, India and Pakistan reported stabilizing rates of illicit opioid use but increased injection of pharmaceutical opiates (Ahmed and others 2003; Dorabjee and Samson 2000; Strathdee and others

2003). China has reported a steady rate of growth in illicit opiate use in its southern and northern provinces (Beyrer 2003; Beyrer and others 2000; Yu and others 1998) and a 15-fold increase in the number of registered opioid addicts between 1990 and 2002, bringing the total to about 1 million (UNODC 2004).

Oceania experienced a marked rise in heroin use in the late 1990s, largely driven by a dramatic increase in the availability of heroin in Australia (Darke, Topp, and others 2002; W. Hall, Degenhardt, and Lynskey 1999). In late 2000, an abrupt heroin shortage resulted in a large reduction in fatal and nonfatal overdoses (Day and others 2004; Degenhardt, Day, and Hall 2004).

Mortality, Morbidity, and Heroin Dependence. In developed countries, dependent heroin users have an increased risk of premature death from drug overdoses, violence, suicide, and alcohol-related causes (Darke and Ross 2002; Goldstein and Herrera 1995; Vlahov and others 2004). Heroin users treated before the HIV epidemic were 13 times more likely to die prematurely than their peers (Hulse and others 1999), with opioid overdose the most frequent cause of death (W. Hall, Degenhardt, and Lynskey 1999). In countries with a high prevalence of HIV infection, AIDS is a major cause of premature death among drug users (EMCDDA 2002; UNAIDS and WHO 2002). Fatal opioid overdose deaths increased in many developed countries during the 1990s before declining after 2000 (UNODC 2004).

In parts of Asia, Eastern Europe, and the United States, the sharing of contaminated injecting equipment accounts for a substantial proportion of new HIV infections (EMCDDA 2002; UNAIDS and WHO 2002; UNODC 2004). Injecting opioid use has been a major driver of HIV epidemics in China (Yu and others 1998), Myanmar (Beyrer and others 2000), the Russian Federation and former Soviet republics (Hamers and Downs 2003), and Vietnam (Beyrer and others 2000; Hien and others 2001).

The prevalence of infection with hepatitis B and C viruses among injecting drug users is greater than 60 percent in Australia (National Centre in HIV Epidemiology and Clinical Research 1998), Canada (Fischer and others 2004), China (Ruan and others 2004), the United States (Fuller and others 2004), and the European Union (EMCDDA 2002). Chronic infection occurs in 75 percent of infections, and 3 to 11 percent of chronic hepatitis C virus carriers develop liver cirrhosis within 20 years (Hepatitis C Virus Projections Working Group 1998).

Heroin-related deaths primarily occur among young adults and account for a large number of life years lost in developed societies. In Australia in 1996, for example, such deaths accounted for 2.2 percent of life years lost, with each death accounting for 22 years of life lost (Mathers, Vos, and Stephenson 1999). In Scotland and Spain, opiate-related deaths

account for 25 to 33 percent of deaths of young adult males (EMCDDA 2002).

Economic Costs of Illicit Opioid Use. In Canada, Xie and others (1996) calculate the costs of illicit drugs as 0.2 percent of gross domestic product (GDP). In Australia, Collins and Lapsley (1996) estimate the economic costs of illicit drug abuse at 2 percent of GDP.

CONTRIBUTION OF OPIOID DEPENDENCE TO THE GLOBAL BURDEN OF DISEASE

Degenhardt, Hall, and others (2004) estimate the contribution of illicit opioid dependence to the global burden of disease using data on deaths caused by opioid and other drug overdoses, suicides and accidents, and HIV/AIDS. When estimates of morbidity attributable to illicit drug use were added in, illicit opioid use accounted for 0.7 percent of global disability-adjusted life years (DALYs) in 2000 (WHO 2003).

These estimates suggest that illicit opioid use is a significant global cause of premature mortality and disability among young adults. Even so, they probably underestimate the disease burden attributable to illicit opioids, because they omit differences across subregions in the quality of data on causes of mortality and estimates of mortality and morbidity attributable to hepatitis and violence (Degenhardt, Hall, and others 2004).

INTERVENTIONS FOR ILLICIT OPIOID DEPENDENCE

Methods adopted to control the problems arising from illicit opioid dependence include source-country control; interdiction of supply into end-use countries; enforcement by the police force and the criminal justice system of legal prohibitions on the supply, possession, and use of opioids; treatment of those who are opioid dependent, both voluntarily and under legal coercion from the criminal justice system; school-based and mass media preventive educational programs; and regulatory policies restricting the prescription of opioids (Manski, Pepper, and Petrie 2001).

Prevention of Heroin Use

Countries use a variety of interventions in attempts to prevent the initiation of use of illicit drugs such as cannabis (Manski, Pepper, and Petrie 2001; Spooner and Hall 2002), in the belief that early initiation of cannabis use leads to an increased risk of using illicit opioids (Fergusson, Horwood, and Swain-Campbell 2002). These interventions include legal prohibitions on the manufacture, sale, and use of opioid drugs

for nonmedical purposes; enforcement of these sanctions by law enforcement officials by means of fines and imprisonment; and enforcement of restrictions on medically prescribed opioids to prevent their diversion (Manski, Pepper, and Petrie 2001). Preventive measures also include mass media and school-based educational campaigns about the health risks of opioid and other illicit drug use (Spooner and Hall 2002). It is unclear how effective these interventions are in preventing cannabis use and even less clear whether they reduce the initiation of opioids (Caulkins and others 1999; Manski, Pepper, and Petrie 2001).

The most popular interventions against illicit opioid use in many developed societies have been the interdiction of drug supply and the enforcement of legal sanctions against the possession, use, and sale of opioid drugs (Manski, Pepper, and Petrie 2001). As a consequence, imprisonment is the most common intervention to which many illicit opioid users have been exposed (Gerstein and Harwood 1990). In Asia and Eastern Europe, high rates of imprisonment of drug users have been a factor in HIV transmission, because drug users engage in high-risk injecting while imprisoned (Beyrer and others 2000).

Interventions to Reduce Heroin-Related Harm

The most effective intervention to reduce bloodborne virus infection arising from illicit injecting of opioids and other drugs is the provision of clean injecting equipment to reduce users' risks of contracting or transmitting bloodborne viruses. This intervention has been widely supported in most developed countries, but it has been incompletely adopted in developing countries that have problems with the concept of facilitating the injection of illicit drugs (UNAIDS and WHO 2002). Vaccinations are available against hepatitis B but not hepatitis C. These important interventions are covered in chapter 18.

A number of strategies can potentially reduce deaths from opioid overdoses (Darke and Hall 2003; Sporer 2003). First, injecting drug users can be educated about the dangers of combining the use of opioids with alcohol and benzodiazepines (McGregor and others 2001), both of which heighten the risk of a fatal opioid overdose (Darke and Zador 1996; Warner-Smith and others 2001). Heroin users also need to be discouraged from injecting in the streets or alone, thereby denying themselves assistance in the event of an overdose. These interventions have yet to be evaluated.

A second strategy is to encourage drug users who witness overdoses to seek medical assistance and to use simple resuscitation techniques until help arrives. A more controversial option is to distribute the opioid antagonist naloxone to high-risk heroin users (Darke and Hall 1997; Strang and others 1996). Neither of these interventions has been evaluated.

A third strategy is to provide supervised injecting facilities in areas with high rates of injecting opioid use (Dolan and

others 2000; Kimber and others 2003). Supervised injecting facilities have been introduced in Germany, the Netherlands, and Switzerland (Dolan and others 2000; Kimber and others 2003), but their effect on overdose deaths has not been rigorously evaluated to date. A supervised injecting facility was evaluated in Australia, but the evaluation was limited by the concurrent onset of a heroin shortage that resulted in a 40 percent decline in overdose deaths (Kaldor and others 2003).

A fourth strategy is to increase methadone maintenance among older, high-risk opioid-dependent people, because individuals enrolled in methadone maintenance treatment (MMT) are substantially less likely to suffer from a fatal overdose (Caplehorn and others 1994; Gearing and Schweitzer 1974; Langendam and others 2001).

Treatment Interventions for Dependent Opioid Users

The range of treatment interventions includes voluntary programs such as detoxification, abstinence-oriented treatments, and oral Methadone maintenance treatment, as well as involuntary options imposed by criminal justice systems.

Detoxification. Detoxification is supervised withdrawal from a drug of dependence that attempts to minimize withdrawal symptoms. It is not a treatment for heroin dependence; it provides a respite from opioid use and may be a prelude to abstinence-based treatment (Mattick and Hall 1996).

Naltrexone is a longer-acting opiate antagonist than naloxone; it can be used to accelerate the opioid withdrawal process. Ultra-rapid opioid detoxification accelerates withdrawal by giving the patient naltrexone under general anesthetic. There is no evidence that accelerated withdrawal in itself reduces the high rate of relapse to heroin use in the absence of further treatment (W. Hall and Mattick 2000).

Abstinence-Oriented Treatments. Abstinence-oriented treatments aim to achieve enduring abstinence from all opioid drugs by providing some type of intervention after withdrawal to reduce the high rate of relapse to opioids (Mattick and Hall 1996). The interventions may include social and psychological support only or such support supplemented by pharmacological methods.

Residential treatment in therapeutic communities and outpatient drug counseling may entail encouraging patients to become involved in self-help groups such as Narcotics Anonymous. These approaches share a commitment to achieving abstinence from all opioids, using group and psychological interventions to help dependent heroin users remain abstinent. Therapeutic communities and drug counseling are usually provided through specialist addiction or mental health services. The former are residential, and the latter are provided on an outpatient basis.

No randomized controlled trials of therapeutic communities or outpatient drug counseling have been carried out. Observational studies in the United Kingdom (Gossop, Marsden, and Stewart 1998; Gossop and others 1997) and the United States (Hubbard and others 1989; Simpson and Sells 1982) have found that therapeutic communities and drug counseling were less successful than MMT in attracting and retaining dependent heroin users, but they substantially reduced heroin use and crime among those who remained in treatment for at least three months (Gerstein and Harwood 1990; Gossop, Marsden, and Stewart 1998; Gossop and others 1997). Some evidence indicated that therapeutic communities may be more effective if they are used in combination with legal coercion to ensure that heroin users are retained in treatment long enough to benefit from it (Gerstein and Harwood 1990).

Recovering drug users run Narcotics Anonymous groups using an adaptation of the 12-step philosophy of Alcoholics Anonymous. Some individuals use these groups as their sole form of support for abstinence, whereas for others these groups complement therapeutic communities that are based on the same principles. Such groups are usually not open to people who are in opioid substitution treatment programs.

The most extensive research on self-help has been in the treatment of alcohol dependence. Treated alcoholics who participate in Alcoholics Anonymous groups have higher rates of abstinence than those who do not (see, for example, Tonigan, Connors, and Miller 2003; Tonigan, Toscova, and Miller 1996). The good outcome in those who attend Alcoholics Anonymous meetings may reflect the self-selection of motivated participants into self-help groups. Recent studies that have attempted to control for this possibility using sophisticated statistical methods have produced mixed results, with some showing the persistence of an effect of self-help after correction (Tonigan, Connors, and Miller 2003) while others do not (Fortney and others 1998).

Shepard and others (forthcoming) evaluate the effect of self-help participation on substance abuse 24 months after treatment for members of a mixed population of substance abusers treated at two treatment facilities in the United States, some of whom had problems with heroin. They find that participation in self-help groups was associated with longer abstinence from all drugs. Correction for self-selection did not eliminate the association in one treatment setting, but it made the results much more equivocal in the other.

Oral Methadone Maintenance Treatment. This treatment substitutes a long-acting, orally administered opioid for the shorter-acting heroin, with the aim of stabilizing dependent heroin users so that they are amenable to rehabilitation (Marsh and others 1990; Ward, Hall, and Mattick 1998). When given in high or blockade doses, methadone blocks the euphoric effects

of injected heroin, allowing the individual to take advantage of psychotherapeutic and rehabilitative services.

Every one of the small number of randomized controlled trials of MMT compared with placebo or no treatment has produced positive results (W. Hall, Ward, and Mattick 1998; Mattick and others 2003). Large observational studies show that MMT decreases heroin use and criminal activity and reduces HIV transmission while patients remain in treatment (Gerstein and Harwood 1990; Simpson and Sells 1990; Ward, Hall, and Mattick 1998). MMT is the best-supported form of opioid maintenance treatment (Farre and others 2002; Marsch 1998; Mattick and others 2003).

Buprenorphine is a mixed agonist-antagonist that also blocks the effects of heroin. When given in high doses, its effects can last for up to three days, while its antagonist effects substantially reduce overdose and abuse (Oliveto and Kosten 1997; Ward, Hall, and Mattick 1998). Meta-analyses have found that buprenorphine is effective in the treatment of heroin dependence (Mattick and others 2003) and is of equivalent efficacy to MMT when delivered in primary health care and specialist treatment settings in Australia (Gibson and others 2003).

Bammer and others (2003) have proposed injectable heroin maintenance as a way of attracting into treatment those heroin users who are not interested in or have failed to respond to MMT. This method has recently been evaluated in the Netherlands (Central Committee on the Treatment of Heroin Addicts 2002) and Switzerland (Perneger and others 1998; Uchtenhagen, Gutzwiller, and Dobler-Mikola 1998). Perneger and others (1998) report a randomized controlled trial of injectable heroin maintenance in people who had failed at MMT. Stabilizing and safely maintaining heroin addicts on injectable heroin (self-administered on-site in a comprehensive health and social service) proved feasible for six months and substantially improved their health and social well-being. The Swiss trials showed that it was possible to maintain opioid addicts on injectable heroin for up to two years (Rehm and others 2001; Uchtenhagen, Gutzwiller, and Dobler-Mikola 1998). A recent randomized controlled trial in the Netherlands (Central Committee on the Treatment of Heroin Addicts 2002) confirms the findings of Perneger and others (1998).

Criminal Justice Interventions for Dependent Illicit Opioid Users. The most common intervention for illicit opioid dependence in most developed societies is imprisonment (EMCDDA 2003; Gerstein and Harwood 1990). Imprisonment is not intended to be a health intervention. Nonetheless, it is an ineffective way of reducing opioid dependence, when judged by the high recidivism in longitudinal studies of dependent heroin users (see, for example, Hser, Anglin, and Powers 1993; Manski, Pepper, and Petrie 2001).

Legally coerced treatment is treatment that is legally forced on those who have been charged with or convicted of an

offense to which their drug dependence has contributed (W. Hall 1997). It is most often provided as an alternative to imprisonment, under the threat of imprisonment if the person fails to comply with the treatment (W. Hall 1997; Manski, Pepper, and Petrie 2001; Spooner, Hall, and Mattick 2001). Its major justification is that it is an effective way of treating offenders' drug dependence that reduces the likelihood of their offending again (Gerstein and Harwood 1990). A consensus view prepared for the World Health Organization (WHO) (Porter, Arif, and Curran 1986) was that compulsory treatment was legally and ethically justified only if the rights of the individuals were protected by due process and if the treatment provided was effective and humane.

Research into the effectiveness of legally coerced treatment for opioid dependence has been limited to observational studies (W. Hall 1997; Manski, Pepper, and Petrie 2001; Wild, Roberts, and Cooper 2002). Anglin's (1988) quasi-experimental studies of the California Civil Addict Program provide the strongest evidence of efficacy. These studies compared heroin-dependent offenders who entered the program between 1962 and 1964 with a group of similar offenders who went through the criminal justice system during the same period. They found that compulsory hospital treatment followed by close supervision in the community substantially reduced heroin use and crime.

The effectiveness of less coercive forms of treatment has been supported by analyses of the effectiveness of community-based treatment provided while on probation or parole (Hubbard and others 1989; Simpson and others 1986). These studies showed that individuals who entered community-based therapeutic communities and drug-free outpatient counseling under legal pressure did as well as those who did so voluntarily (Hubbard and others 1988; Simpson and Friend 1988). The recent creation of specialized drug courts in the United States to process those arrested for drug-related offenses awaits rigorous evaluation (Belenko 2002; Manski, Pepper, and Petrie 2001).

Legally coerced MMT is also effective. The strongest evidence comes from a study in which drug offenders were randomly assigned to parole with and without community-based MMT (Dole and others 1969). This study showed a greater reduction in heroin use and lower rates of incarceration among those enrolled in MMT in the year following their release from prison. These findings are supported by observational studies that found no major differences in response to MMT between those who enrolled under legal coercion and those who did not (Anglin, Brecht, and Maddahain 1989; Brecht, Anglin, and Wang 1993; Hubbard and others 1988).

Economic Evaluations of Interventions for Illicit Opioid Dependence

The few published economic evaluations of treatment interventions for illicit opioid dependence indicate varying levels of cost-effectiveness.

Detoxification. The National Evaluation of Pharmacotherapies for Opioid Dependence Project in Australia conducted a cost-effectiveness analysis of five interventions:

- naltrexone-induced rapid opioid detoxification under anesthesia
- naltrexone-induced rapid opioid detoxification under sedation
- conventional inpatient detoxification
- conventional outpatient detoxification
- buprenorphine outpatient detoxification.

A successful outcome was defined as achieving abstinence from heroin for one week (Mattick and others 2001).

Rapid detoxification under sedation was the most cost-effective method of detoxification (US\$2,355 for one week of abstinence) and conventional outpatient detoxification the least cost-effective (US\$12,031). Rapid detoxification under anesthesia achieved high rates of abstinence in the first week, but its expense reduced its cost-effectiveness (Mattick and others 2001).

Doran and others (2003) compared the cost-effectiveness of detoxification from heroin using buprenorphine in a specialist Australian clinic and in a shared care setting. They conducted a randomized controlled trial with 115 heroin-dependent patients receiving a five-day treatment regime of buprenorphine. The specialist clinic was a community-based treatment agency in Sydney. Shared care involved treatment by a general practitioner, supplemented by weekend dispensing and some counseling at the specialist clinic. They estimate that buprenorphine detoxification in the shared care setting was US\$17 more expensive per patient than the costs of treatment at the clinic (US\$236 per patient).

Drug-Free Treatment. The limited economic evaluations of drug-free treatment have used data from observational studies of treatment outcomes in samples of patients who have mixed substance abuse problems that include opioids. For example, Shepard, Larson, and Hoffmann (1999) calculate a range of estimated costs for achieving an abstinent year in 408 patients at two different treatment facilities in the United States. The cost-effectiveness depended on the severity of the problem and the intensiveness and cost of the intervention. For outpatients with the least severe drug problems, the cost of an abstinent year was US\$7,000, whereas the same outcome in patients with more severe problems who received long-term residential treatment cost US\$20,000.

Shepard and others (forthcoming) use these data to estimate the cost-effectiveness of involvement in mutual self-help groups, such as Alcoholics Anonymous and Narcotics Anonymous, in sustaining abstinence for up to 24 months after treatment. They find a positive association between self-help

involvement and abstinence 12 and 24 months after treatment. Applying statistical methods to correct for the effects of self-selection into self-help, they find that in a Veterans Administration hospital, the effects of self-help on abstinence persisted after the statistical correction, but at the other site, the results depended on the method of analysis that was used. They estimate the cost of achieving an abstinent year by means of self-help in the year following treatment at US\$13,000, all of that due to the costs that participants incurred in attending a group.

Oral Opioid Maintenance Treatment. Goldschmidt's (1976) economic evaluation of MMT found that it was as effective as a therapeutic community intervention and twice as cost-effective. Cartwright's (2000) review of the literature since 1976 identified a number of studies, all of which reported positive benefit-cost ratios for MMT.

Gerstein, Harwood, and Suter's (1994) California Drug and Alcohol Treatment Assessment study is the most comprehensive cost-benefit analysis carried out to date. The authors examine the effects of treatment—residential programs, outpatient programs, and methadone programs—on alcohol and drug use, criminal activity, health and health care utilization, and source of income. For each treatment modality, they found that the benefits during the first year of treatment significantly exceeded the cost of delivering the care. The benefit-cost ratio was 4.8 for residential treatment and 11.0 and 12.6 for outpatients and discharged methadone participants, respectively.

Doran and others (2003) compared the cost-effectiveness of buprenorphine and methadone treatment for opioid dependence. In a randomized controlled trial, 405 subjects were randomly assigned to each treatment at one of three specialist outpatient drug treatment centers. The study found that treatment with methadone was less expensive and more effective than treatment with buprenorphine, but the difference in cost (US\$143 per additional heroin-free day gained) had a wide range of uncertainty around it (–US\$1,469 to US\$1,284).

The National Evaluation of Pharmacotherapies for Opioid Dependence Project also provided a cost-effectiveness analysis of methadone, buprenorphine, LAAM (levo-alpha-acetyl-methadol), and naltrexone maintenance treatments (Mattick and others 2001). The daily costs of these maintenance treatments were similar for methadone and LAAM, but naltrexone was slightly more expensive. Buprenorphine maintenance treatment (BMT) was more expensive, but its cost-efficiency could have been improved to make its cost similar to that for the other treatments. MMT was the most cost-effective treatment for opioid dependence because it achieved one of the highest rates of retention in treatment among the four pharmacotherapies examined. Naltrexone treatment was the least cost-effective.

The costs of injectable heroin maintenance in the Dutch study was between US\$18,015 and US\$23,243 per patient per year (Bammer and others 2003). Most of the costs arose from the supervision of heroin use and the security required to prevent the diversion of heroin to the black market. Injectable heroin maintenance needs to produce substantially greater benefits for each participant than MMT to make it as cost-effective as MMT.

Economic Modeling of the Cost-Effectiveness of Opioid Maintenance Treatment. Barnett (1999), using data on the efficacy of MMT in reducing mortality derived from Gronbladh, Ohlund, and Gunne's (1990) Swedish study and U.S. cost data, estimated that MMT saved an additional year of life at a cost of US\$5,900. Barnett, Zaric, and Brandeau (2001), using a similar approach, estimated that the use of buprenorphine by patients who would not use methadone would cost less than US\$45,000 per quality-adjusted life year. Overall, however, they found that BMT was much less effective and more costly than MMT. Zaric, Barnett, and Brandeau (2000) assessed the economic benefits of using MMT to reduce HIV transmission in heroin users. They found that for heroin users living in a community with a high prevalence of HIV infection, expanding MMT use produced an additional year of quality-adjusted life at a cost of US\$8,200.

Comparing the Cost-Effectiveness of Different Interventions

Comparative cost-effectiveness analyses of these interventions face major obstacles because the small number of published studies used different methods to cost interventions and different endpoints to assess the outcome of treatment. The following list, therefore, only ranks treatment interventions in the approximate order of their cost-effectiveness. We believe that estimates of their likely contribution to DALYs worldwide would be too speculative.

- *Detoxification.* Buprenorphine and supervised naltrexone-accelerated withdrawal delivered on an outpatient basis are the most efficient and effective ways to achieve withdrawal from opioids.
- *Self-help groups.* These groups provide the simplest form of postwithdrawal support for enduring abstinence and are also a low-cost intervention, because patients bear most of the costs; however, they have a low rate of uptake, and their effectiveness is only modest.
- *Oral opioid agonist maintenance treatment.* This form of treatment is the most widely used intervention for illicit opioid dependence in developed societies. It has a better uptake than other interventions, and it is moderately effective under the usual delivery conditions.
- *Drug-free residential treatment.* This form of treatment has a relatively low rate of treatment uptake and is costly because

of its residential character and the need for intensive staff-patient interaction. It is effective for the minority of people who are retained in treatment long enough to benefit from it (usually three months). Retention in treatment may be improved if patients enter treatment under some form of legal coercion.

- *Naltrexone maintenance treatment.* This form of treatment has not been rigorously evaluated.
- *Injectable opioid maintenance.* This intervention is a more expensive variant of agonist maintenance treatment that has been used for patients with more severe cases of dependency but for whom retention and treatment outcomes have been good.

Calculation of the Averted, Avertable, and Unavertable Burden

Assuming that the disease burden from opioid dependence is potentially avertable, we used the following approach to estimate the avoidable burden of opioid dependence. We initially modeled the avertable burden using MMT and used this model for BMT. The first step was to establish the base case for opioid dependence using 2002 as the baseline year. We established the model of the base case for opioid dependence for regions and subregions according to WHO country classifications. We used population estimates for each region for those age 15 to 59, the age range in which heroin dependence is most prevalent. We incorporated Degenhardt, Hall, and others' (2004, table 13.1) figures for the prevalence of opioid use by region, assuming that the prevalence was 30 percent higher among male users than female users.

We obtained population-attributable fractions related to opioid dependence from the editors of this volume. We used nine relevant WHO categories to estimate the burden of disease attributable to opioid dependence—namely HIV/AIDS, drug-use disorders, road traffic accidents, poisonings, falls, fires, drownings, other unintentional injuries, and self-inflicted injuries.

We calculated the mortality rate for opioid deaths by dividing the number of deaths by the estimated number of users. We took estimates of years of life lost (YLLs) and years lived with disability (YLDs), by gender, for each region from data obtained from the editors of this volume. We then used those estimates to calculate the DALYs for male users, female users, and all users ($YLL + YLD = DALY$). We discounted the YLLs, YLDs, and DALYs using a 3 percent discount rate.

The second step was to estimate the avertable burden by treatment with methadone or buprenorphine. Using the population and prevalence data, we assumed, in the first instance, that 50 percent of those dependent on opioids entered treatment. In the sensitivity analysis, we varied this proportion from 25 to 75 percent coverage. On the basis of Caplehorn and others' (1994) meta-analysis, we assumed that MMT reduced

mortality by 25 percent. In the sensitivity analysis, we varied the reduction from 15 to 35 percent (using the confidence intervals around the estimated reduction). We assumed that the reduction in mortality associated with BMT was 20 percent, which we varied in the sensitivity analysis from 10 to 30 percent. Finally, we assumed that those who were alive and in treatment experienced a 25 percent reduction in disability, consistent with the Dutch disability weights.

The third step was to estimate the burden for those not treated. For those users not in treatment, we calculated DALYs using the original mortality rates.

The fourth step was to estimate the total avertable burden from treatment with methadone or buprenorphine by (a) adding the results of the second and third steps, the revised DALYs for those in treatment, and the residual for those not in treatment and (b) subtracting those figures from the base case estimates.

The fifth step was to cost the interventions using data on MMT and BMT from Doran and others (2003). They estimated the cost of MMT at \$A 1,415 and of BMT at \$A 1,729 for six months of treatment. We converted these estimates into U.S. dollars and multiplied them by two to provide yearly estimates of treatment costs of US\$1,732 for MMT and US\$2,117 for BMT.

We applied relative price weights for each region using the Western Pacific as the reference case (1.00). We calculated the relative price weights for each cost type using data provided by the World Bank. The prices are a reflection of the public health systems in each region, and as far as possible they reflect the opportunity cost of health care resources in these regions.

Results. Our results are presented in table 48.1. We explored various combinations of coverage and reductions in mortality for MMT and BMT. For each intervention, as coverage and reductions in mortality increased, the number of DALYs averted increased. The wide discrepancies in DALYs averted within regions primarily reflect differences in population-attributable fractions for HIV/AIDS. Costs increased as a consequence of increased coverage for both interventions, whereas results for cost-effectiveness differ by both intervention and mortality.

The cost-effectiveness analysis suggests that for MMT (with a coverage of 25, 50, or 75 percent and reductions in mortality of 35 percent) the cost in international dollars per DALY averted ranges from a low of \$128 in Africa, with high child and adult mortality where the prevalence of illicit opioid dependence is low (0.01 percent), to a high of \$3,726 in Eastern Europe, with low child and adult mortality where the prevalence of illicit opioid dependence is high (0.55 percent). Across all the regions, the average cost-effectiveness ratio for MMT (with 25, 50, and 75 percent coverage and 35 percent reduction in mortality) is estimated at \$2,236 per DALY averted.

Assessment. The results shown in table 48.1 provide a first approximation of the potential avertable burden in DALYs if

MMT and BMT were applied to 50 percent of the opioid-dependent population in each region. Because the methods and data used to estimate avertable DALYs are subject to certain limitations, those results should be considered preliminary.

RELEVANCE TO DEVELOPING COUNTRIES

Much of the epidemiological research on illicit opioid dependence, its disease burden, and its societal harm comes from Australasia, Europe, and the United States. The major exception is research on the role of injecting drug use in HIV transmission in developing countries (see, for example, Beyrer and others 2000; Yu and others 1998). In addition, research on the effectiveness and cost-effectiveness of interventions for illicit opioid dependence has been conducted primarily in developed countries (Ward, Hall, and Mattick 1998), with the exception of studies of the effectiveness of methadone treatment in Hong Kong, China (see, for instance, Newman and Whitehill 1979), and in Thailand (Vanichseni and others 1991), both of which showed comparable effectiveness to that found in developed countries (W. Hall, Ward, and Mattick 1998).

Translating findings on interventions for opioid dependence in developed countries into disease control priorities for opioid dependence in developing countries presents three major challenges. First, countries differ in the scale of illicit opioid use and in the resulting disease burden. This variation reflects the effects of differences in the prevalence of injecting and noninjecting opioid users; the dependent opioid users' access to treatment and health services for overdoses, blood-borne viruses, and other complications of drug use; the access to needle and syringe programs; the extent to which illicit opioid use is concentrated in socially disadvantaged minority groups; and the capacity of public health services to monitor and respond to emerging infectious disease and drug-use epidemics. The burden is likely to be greatest in settings where the primary route of administration is injecting and where public and personal health services are poorly developed, as appears to be the case in Asia and in Eastern Europe.

Second, societal wealth and health care infrastructure affect the capacity of developing societies to treat illicit opioid dependence. A country's capacity to provide opioid substitution treatment will be affected by the cost of oral opioid drugs, such as methadone, LAAM, and buprenorphine, and the existence of specialist drug treatment centers; trained medical, nursing, and pharmacy staff; and a drug regulatory system, which are required so as to deliver opioid substitution treatment safely and effectively. Few developing countries possess this infrastructure. However, examples exist of apparently successful drug substitution programs, using such tools as sublingual buprenorphine, that have been conducted with minimal resources in extremely poor settings (Crofts and others 1998).

Third, in societies with a sizable illicit opioid dependence problem, cultural attitudes and beliefs will affect societal responses, especially attitudes toward illicit opioid use and dependence (Gerstein and Harwood 1990). A critical determinant of the social response will be the relative dominance of moral and medical understandings of drug dependence in general and opioid dependence in particular. A moral model of addiction sees addiction as largely a voluntary behavior, in which case it is seen as an excuse for bad behavior that allows drug users to continue to take drugs without assuming responsibility for their conduct (Szasz 1985). In this view, drug users who offend against the criminal code should be imprisoned (Szasz 1985). This model is the dominant one in many developed societies, which imprison drug users at high rates without any effect on the prevalence of drug abuse. Countries that adopt punitive policies toward drug users are reluctant to embrace harm reduction measures, such as needle and syringe programs and opioid maintenance treatment (Ainsworth, Beyrer, and Soucat 2003). A medical model of addiction, by contrast, recognizes that dependent opioid users require specific treatment if the sufferer is to become and remain abstinent (see, for example, Leshner 1997).

These competing views will affect the societal acceptability of opioid maintenance and abstinence-oriented approaches to the treatment of opioid dependence (Cohen 2003). Those who have a moral view of addiction will tend to prefer drug-free and self-help approaches toward treatment. Supporters of medical models of addiction will favor some form of opioid substitution treatment and the provision of clean needles and syringes to reduce the transmission of bloodborne viruses by injecting opioid and other drug users. Stronger advocacy by international organizations and agencies is needed for the adoption of such harm reduction measures as needle and syringe programs and agonist substitution programs.

RESEARCH AND DEVELOPMENT

Two main areas are important for research and development. First, better estimates are needed of the prevalence of illicit opioid dependence and prospective studies of the morbidity and mortality that it causes in both developed and developing countries. These estimates are especially needed in countries where illicit opioid use is high because of their proximity to source countries. Second, we need evaluations of the effectiveness and cost-effectiveness of self-help, drug-free, and oral opioid substitution treatment in developing countries. A priority should be the identification of safe, innovative, and less expensive ways of effectively delivering culturally acceptable forms of opioid maintenance treatments in developing countries. This effort may require experimentation with a range of substitute opioids, such as buprenorphine, and cheaper options, such as codeine and opium tincture.

CONCLUSIONS: PROMISES AND PITFALLS

Illicit opioid use, especially injecting use, contributes to premature mortality and morbidity in many developed and developing societies. Fatal overdoses and HIV/AIDS resulting from the sharing of dirty injecting equipment are major contributors to mortality and morbidity, and the economic costs of illicit opioid dependence are substantial. Illicit opioid dependence generates substantial externalities that are not included in burden-of-disease estimates, principally law enforcement costs incurred in handling drug dealing and property crime.

The most popular interventions for illicit opioid dependence in many developed societies have been law enforcement efforts to interdict the drug supply and enforce legal sanctions against the use of opioid drugs. One consequence of this strategy has been that most illicit opioid users have been exposed to the least effective intervention: imprisonment for drug or property offenses. Prisons rarely take the opportunity to treat dependence using opioid maintenance or to reduce the harm caused by illicit opioid use by providing access to clean injecting equipment.

In treatment settings, the most popular interventions have been detoxification (which is not a treatment but a prelude to treatment) and drug-free treatment (which is the least attractive and the least effective in retaining opioid-dependent people in treatment). Opioid agonist maintenance treatment has been ambivalently supported in many developed societies despite its being the treatment for which there is the best evidence of effectiveness, safety, and cost-effectiveness. The range of opioid agonists available for maintenance treatment is increasing. A number of developed countries have approved the use of BMT, which the limited data suggest may be approximately equivalent to MMT in efficacy and cost-effectiveness. Opioid antagonists have a niche role in the treatment of opioid dependence because of poor compliance and an increased risk of overdose on return to heroin use. Their efficacy may improve with the development of long-acting injectable forms of the drug.

ANNEX 48.A: PREVALENCE OF USE, ADVERSE HEALTH EFFECTS OF AND INTERVENTIONS FOR CANNABIS, COCAINE, AMPHETAMINES, AND MDMA USE AND DEPENDENCE

Cannabis

Cannabis is the most widely used illicit drug globally, with about 150 million users, or 3.7 percent of the world's population age 15 and older (UNODCCP 2003). Patterns of cannabis use have been most extensively studied in Australia, Canada, the United States, and Europe (W. Hall and Pacula 2003). Europe generally has lower rates of use than Australia, Canada,

and the United States, with the highest rates in Denmark, France and the United Kingdom (EMCDDA 2002; W. Hall and Pacula 2003). The limited data from developing countries suggest that, with some exceptions (for example, Jamaica and South Africa), rates of cannabis use are lower in Africa, Asia, the Caribbean, and South America than they are in Europe and in English-speaking countries (W. Hall, Johnston, and Donnelly 1999).

Surveys in the United States have found long waves of cannabis use among young people since 1975. Cannabis use increased during the 1970s to peak in 1979, before declining steadily between 1980 and 1991. Use rose sharply in 1992 and increased throughout the 1990s, before leveling off in the late 1990s (Johnston, O'Malley, and Bachman 1994a, 1994b). There was also a rise in cannabis use during the early 1990s in Australia, Canada, and some European countries (W. Hall and Pacula 2003).

The natural history of cannabis use in the United States typically begins in the mid to late teens and reaches its maximum in the early 20s before declining in the mid to late 20s. Only a minority of young adults continue to use cannabis into their 30s (Bachman and others 1997; Chen and Kandel 1995). Getting married and having children substantially reduces rates of cannabis use (Bachman and others 1997).

Cannabis use can have several adverse health effects, as discussed below.

Acute Effects of Cannabis Use. The most frequent unpleasant effects of cannabis use are anxiety and panic reactions, which most often occur in users who are unfamiliar with the drug's effects. Psychotic symptoms such as delusions and hallucinations may be experienced following very high doses. There are no cases of fatal cannabis poisoning in the medical literature, and the fatal dose in humans is likely to exceed what recreational users are able to ingest (W. Hall and Pacula 2003).

Cannabis intoxication impairs a wide range of cognitive and behavioral functions that are involved in driving an automobile or operating machinery (Beardsley and Kelly 1999; Jaffe 1985). It has been difficult to determine whether these impairments increase the risk of being involved in motor vehicle accidents (Smiley 1999). Studies of the effect of cannabis on driving performance on the road have found only modest impairments, because cannabis-intoxicated drivers drive more slowly and take fewer risks than drivers intoxicated by alcohol (Smiley 1999).

Cannabinoids are found in the blood of substantial proportions of persons killed in motor vehicle accidents (Bates and Blakely 1999; Chesher 1995; Walsh and Mann 1999), but these findings have been difficult to evaluate because they have not distinguished between past and recent cannabis use (Ramaekers and others 2004). More recent research using better indicators of recent cannabis use has found a dose-response

relationship between cannabis and risk of motor vehicle crashes (Ramaekers and others 2004). Cannabis used in combination with alcohol substantially increases risk of accidents (Bates and Blakely 1999; Ramaekers and others 2004).

Health Effects of Chronic Cannabis Use. Cannabis smoke is a potential cause of cancer because it contains many of the same carcinogenic substances as cigarette smoke (Marselos and Karamanakos 1999). Cancers have been reported in the aerodigestive tracts of young adults who were daily cannabis smokers (W. Hall and MacPhee 2002), and a case-control study has found an association between cannabis smoking and head and neck cancer (Zhang and others 1999). A prospective cohort study of 64,000 adults did not find any increase in rates of head and neck or respiratory cancers (Sidney and others 1997). Further studies are needed to clarify the issue.

Three studies of different types of cancer have reported an association with maternal cannabis use during pregnancy (W. Hall and MacPhee 2002). There have not been any increases in the rates of these cancers that parallel increases in rates of cannabis use (W. Hall and MacPhee 2002).

High doses of cannabinoids impair cell-mediated and humoral immunity and reduce resistance to infection by bacteria and viruses in rodents (Klein 1999). Cannabis smoke impairs the functioning of alveolar macrophages, the first line of the body's immune defense system in the lungs. The doses that produce these effects have been very high, and extrapolation to the doses used by humans is complicated by the fact that tolerance to these effects develops (Hollister 1992). There is as yet no epidemiological evidence that rates of infectious disease are higher among chronic heavy cannabis users. Several large prospective studies of HIV-positive homosexual men have not found that cannabis use makes it more likely that HIV-positive men develop AIDS (W. Hall and Pacula 2003).

Chronic administration of tetrahydrocannabinol (THC) disrupts male and female reproductive systems in animals, reducing testosterone secretion and sperm production, motility, and viability in males and disrupting ovulation in females (Brown and Dobs 2002). It is uncertain whether cannabis use has these effects in humans because of the limited research on human males and females (Murphy 1999).

The use of cannabis during pregnancy is associated with smaller birthweight (English and others 1997; Fergusson, Horwood, and Northstone 2002), but it does not appear to increase the risk of birth defects (W. Hall and Pacula 2003). In some studies, infants exposed to cannabis during pregnancy show behavioral and developmental effects during the first few months after birth; these effects are smaller than those seen after tobacco use during pregnancy (Fried and Smith 2001).

The changes that cannabis smoking causes in heart rate and blood pressure are unlikely to harm healthy young adults, but they may harm patients with hypertension, cerebrovascular

disease, and coronary atherosclerosis (Chesher and Hall 1999; Sidney 2002). One controlled study suggests that cannabis use can precipitate heart attacks in middle-aged cannabis users who have atherosclerosis in the heart, brain, and peripheral blood vessels (Mittleman and others 2001).

Regular cannabis smoking impairs the functioning of the large airways and causes chronic bronchitis (Tashkin 1999; Taylor and others 2002). Given that tobacco and cannabis smoke contain similar carcinogenic substances, it is likely that chronic cannabis smoking increases the risks of respiratory cancer (Tashkin 1999).

Psychological Effects of Chronic Cannabis Use. Psychological effects of chronic cannabis use can include a dependence syndrome, cognitive effects, and psychotic disorders.

Dependence Syndrome A cannabis dependence syndrome occurs in heavy chronic users of cannabis (American Psychiatric Association 1994). Regular cannabis users develop tolerance to THC. Some experience withdrawal symptoms on cessation of use (Kouri and Pope 2000), and some report problems controlling their cannabis use (W. Hall and Pacula 2003). The risk of dependence is about 1 in 10 among those who ever use the drug, between 1 in 5 and 1 in 3 among those who use cannabis more than a few times, and about 1 in 2 among daily users (W. Hall and Pacula 2003).

Cognitive Effects Long-term daily cannabis use does not severely impair cognitive function, but it may more subtly impair memory, attention, and the ability to integrate complex information (Solowij 1998; Solowij and others 2002). It remains uncertain whether these effects are due to the cumulative effect of regular cannabis use on cannabinoid receptors in the brain or whether they are residual effects of THC that will disappear after an extended period of abstinence (W. Hall and Pacula 2003).

Psychotic Disorders There is now good evidence that chronic cannabis use may precipitate psychosis in vulnerable individuals (see, for example, Arseneault and others 2002; van Os and others 2002; Zammit and others 2002). It is less likely that cannabis use can cause psychosis de novo, because the incidence of schizophrenia has either remained stable or declined while cannabis use has increased among young adults (Degenhardt, Hall, and Lynskey 2003).

Effects of Cannabis Use on Adolescents. Cannabis use has a number of effects on adolescents.

Gateway Hypothesis Adolescents in developed societies typically use alcohol and tobacco before using cannabis, which in turn, they use before using hallucinogens, amphetamines, heroin, and cocaine (Kandel 2002). Generally, the earlier the age of first use and the greater the involvement with any drug

in the sequence, the more likely a young person is to use the next drug in the sequence (Kandel 2002). The role played by cannabis in this sequence remains controversial (W. Hall and Lynskey forthcoming; W. Hall and Pacula 2003).

The simplest hypothesis is that cannabis use has a pharmacological effect that increases the risk of using drugs later in the sequence. Equally plausible hypotheses are that it is due to a combination of (a) early recruitment into cannabis use of nonconforming and deviant adolescents who are likely to use alcohol, tobacco, and illicit drugs; (b) a shared genetic vulnerability to dependence on alcohol, tobacco, and cannabis; and (c) socialization of cannabis users within an illicit drug-using subculture, which increases the opportunity, and encouragement to use other illicit drugs (W. Hall and Pacula 2003).

Adolescent Psychosocial Outcomes Cannabis use is associated with early withdrawal from high school, early family formation, poor mental health, and involvement in drug-related crime. In the case of each of these outcomes, the strong associations in cross-sectional data are more modest when account is taken of the fact that cannabis users show characteristics before they use cannabis that predict these outcomes. For example, they have lower academic aspirations and poorer school performance than peers who do not use cannabis (Lynskey and Hall 2000; Macleod and others 2004). Nonetheless, the evidence increasingly suggests that regular cannabis use adds to the risk of these outcomes in adolescents already at risk (W. Hall and Pacula 2003).

Interventions for Cannabis Dependence. Although many dependent cannabis users may succeed in quitting without professional help, some are unable to stop on their own and will need assistance to do so. There has not been a great deal of research on pharmacological treatments for cannabis dependence, although a recent study trialed divalproex sodium with promising results (Levin and others 2004). Limited research exists on the effectiveness of different types of psychosocial treatments for dependent cannabis use (Budney and others 2000; Copeland and others 2001; Stephens, Roffman, and Simpson 1994). These approaches have involved short-term cognitive behavioral treatments modeled on similar treatments for alcohol dependence, usually given in three to six sessions on an outpatient basis.

In all of these studies, rates of abstinence at the end of treatment have been modest (20 to 40 percent), and subsequent high rates of relapse mean that rates of abstinence after 12 months have been very modest (Budney and Moore 2002). Nonetheless, treatment does substantially reduce cannabis use and problems. These outcomes are not very different from those observed in the treatment for alcohol and other forms of drug dependence (Budney and Moore 2002). Much more research is needed before sensible advice can be given about the best ways to achieve abstinence from cannabis.

Cocaine

After cannabis, cocaine is one of the most widely used illicit drugs in developed and developing societies. Some 14 million people were estimated to have used cocaine globally in 2003, with demand for treatment second only to heroin (UNODCCP 2003). The highest rates of reported cocaine use—and the best data on trends in cocaine use—come from the United States, the world's largest cocaine market. Rates of cocaine use in the United States increased from the mid 1970s until 1985, when 5.7 million Americans age 12 and older reported using cocaine in the preceding month. Rates of cocaine use in the preceding month have declined steadily since 1985. In 2000, 11.2 percent of Americans over age 12 reported that they had used cocaine at some time in their lives, and 0.4 percent (800,000 people) reported weekly cocaine use (SAMHSA 2001). Among young U.S. adults age 18 to 25, lifetime prevalence was 14.9 percent in 2001, rising slightly to 15.4 percent in 2002 (SAMHSA 2003). In 2002, annual prevalence figures from student surveys were 15 percent lower than 1998 figures and 60 percent lower than 1985 figures (UNODCCP 2003). A more recent study of U.S. adults age 35 years found that 6 percent of men and 3 percent of women had used cocaine within the preceding 12 months (Merline and others 2004).

The reported prevalence of cocaine use in other developed societies is much lower than that in the United States. In Europe, for example, rates of lifetime cocaine use range from 0.5 percent to 5 percent (EMCDDA 2003), compared with 12.3 percent among American adults in 2001 (SAMHSA 2001). Rates of cocaine use in Australia resemble those in Europe, with 4.3 percent of adults reporting lifetime use (Darke and others 2000).

The prevalence of cocaine use is likely to be lower in developing societies, but the poor quality of the available data makes it difficult to be sure (UNDCP 1997). There probably has been an increase in cocaine use in some developing countries in recent years, but it is difficult to estimate the size of the increase (United Nations Commission on Narcotic Drugs 2000). The region with the highest rates of cocaine use among developing societies is likely to be Central and South America. The botanical source is indigenous to the region and has traditionally been used by local populations. Moreover, several nations in Central and South America have a history of production and export to global markets. Recent reports indicate that cocaine abuse is increasing in South America (UNODCCP 2003), and a recent household survey on drug abuse in São Paulo, Brazil, estimated cocaine prevalence at 2.1 percent (Galduroz and others 2003).

Adverse Health Effects of Cocaine. Most cocaine use is infrequent; regular cocaine use (monthly or more frequently) can be a major public health problem. Regular cocaine users who

inject cocaine or smoke crack cocaine are especially likely to develop dependence and to experience problems related to their cocaine use (Platt 1997). In the United States, it has been estimated that one in six of those who ever use cocaine become dependent on the drug (Anthony, Warner, and Kessler 1994). High rates of cocaine dependence are found among people treated for alcohol and drug problems and among arrestees in the United States (Anglin and Perrochet 1998).

In large doses, cocaine may be harmful in both cocaine-naïve and cocaine-tolerant individuals (Platt 1997; Vasica and Tennant 2002). The vasoconstrictor effects of cocaine in large doses place great strains on a number of the body's physiological systems (McCann and Ricaurte 2000). Effects on the cardiovascular system can result in a range of difficulties, from chest pain to fatal cardiac arrests (Lange and Hillis 2001). Neurological problems include cerebral vascular accidents such as strokes or seizures. Other effects of cocaine can include gastrointestinal problems such as vomiting, colitis, and bowel infarction and respiratory problems such as asthma, respiratory collapse, pulmonary edema, and bronchitis. Hyperthermia may occur because of the increased metabolism, peripheral vasoconstriction, and inability of the thalamus to control body temperature (Crandall, Vongpatanasin, and Victor 2002). Obstetric complications can include irregularities in placental blood flow, premature labor, and low neonate birthweight (Majewska 1996; Platt 1997; Vasica and Tennant 2002).

Adverse health effects from cocaine are potentially fatal and can occur among healthy users irrespective of cocaine dose and frequency of use (Lange and Hillis 2001; Vasica and Tennant 2002). Although the likelihood of health problems may increase with dosage and frequency of use, there is wide individual variation in reactions to cocaine and, therefore, no specific combination of conditions under which adverse health effects can be predicted. There is no antidote to cocaine overdose as there is for an overdose of heroin (Platt 1997).

The impact of cocaine on mental health is also complex. Although cocaine can produce feelings of pleasure, it may also result in negative psychological symptoms such as anxiety, depression, paranoia, hallucinations, and agitation (American Psychiatric Association 1994). Regular cocaine users experience high rates of psychiatric disorders. In the United States, regular cocaine users report high rates of anxiety and affective disorders (Gawin and Ellinwood 1988; Platt 1997). The repeated use of large doses of cocaine can also produce a paranoid psychosis (Majewska 1996; Manschreck and others 1988; Platt 1997; Satel and Edell 1991). People who are acutely intoxicated by cocaine can become violent, especially those who develop a paranoid psychosis (Platt 1997).

Animal studies suggest that cocaine use may be neurotoxic in large doses—that is, it can produce permanent changes in the brain and neurotransmitter systems (Majewska 1996; Platt 1997). It is unclear whether use is also neurotoxic in humans.

Previous studies have documented a variety of neuropsychological effects of cocaine use, including deficits in memory and problem solving (Beatty and others 1995; Hoff and others 1996; O'Malley and others 1992). More recently, a twin study indicated that cocaine may lead to impaired attention and motor skills up to one year after the conclusion of heavy use (Toomey and others 2003).

The method by which cocaine is administered can result in adverse health effects (Platt 1997). Snorting cocaine through the nose can lead to rhinitis, damage to the nasal septum, and loss of the sense of smell. Smoking cocaine can lead to respiratory problems, and injecting cocaine leads to the risks of infections and bloodborne viruses associated with all injecting drug use.

Users who inject cocaine, either on its own or in combination with heroin (“speedballs”), inject much more frequently than other injecting drug users and, as a consequence, engage in more needle sharing, take more sexual risks, and have higher rates of HIV infection (Chaisson and others 1989; Schoenbaum and others 1989; van Beek, Dwyer, and Malcolm 2001). Associations between cocaine use and HIV risk-taking have been reported in Europe (Torrens and others 1991), Australia (Darke and others 1992), and the United States (Chaisson and others 1989). Recent Australian research has indicated that injecting cocaine users report more problems related to injecting drug use—such as vascular problems, abscesses, and infections—than other injecting drug users (Darke, Kaye, and Topp 2002).

The link between cocaine use and HIV risk is not restricted to those who inject cocaine. Crack smoking has been linked to higher levels of needle risk, sexual risk taking, and HIV infection (Chaisson and others 1989; Chirgwin and others 1991; Desjalais and others 1992; Grella, Anglin, and Wugalter 1995). Two mechanisms probably underlie the relationship between cocaine use and HIV infection. First, the short half-life of cocaine promotes a much higher frequency of injecting by users than that seen in heroin injectors. Second, cocaine itself disinhibits and stimulates users, encouraging them to take greater risks with sexual activity and needle use (Darke and others 2000).

Cocaine is associated with a risk of intentional injuries and injuries in general. A recent review reported that 28.7 percent of people with intentional injuries and 4.5 percent of injured drivers tested positive for cocaine (Macdonald and others 2003). Users are also at risk of death from an accidental overdose of cocaine. A recent study of accidental deaths from drug overdose in New York between 1990 and 1998 found that 70 percent of deaths were caused by cocaine, often in combination with opiates (Coffin and others 2003). The causes of cocaine-related deaths are usually related to cardiovascular complications (Vasica and Tennant 2002), but death may also be due to brain hemorrhage, stroke, and kidney failure (Brands, Sproule, and

Marshman 1998). Injection of cocaine is most likely to cause an overdose, followed by smoking it, with intranasal use involving the least risk (Pottieger and others 1992).

Much less is known about nonfatal cocaine overdose. A study in Miami, Florida, found that 40 percent of users had overdosed on cocaine at least once (Pottieger and others 1992). More recently, a study in Brazil found that 20 percent of users had experienced an overdose, with 50 percent knowing someone who had died from an overdose (Mesquita and others 2001). A study in Sydney, Australia, found that 17 percent of injecting cocaine users and 6 percent of noninjecting cocaine users had ever overdosed, with 9 percent and 3 percent, respectively, overdosing in the preceding 12 months (Kaye and Darke 2003). Frequency of cocaine use, severity of dependence, and route of administration did not predict an overdose, supporting the view that cocaine overdose is an unpredictable event.

Interventions for Cocaine Dependence. Efforts at intervention have included pharmacological treatments as well as psychotherapy and cognitive behavioral therapy.

Pharmacological Interventions Despite much research effort there are no effective pharmacological treatments for cocaine dependence (Kreek 1997; McCance 1997; Mendelson and Mellon 1996; Nunes 1997; Silva de Lima and others 2002; van den Brink and van Ree 2003). Attempts have been made to develop longer-acting agonist drugs that act on the same molecular targets as cocaine without producing its euphoric effects (for example, methylphenidate) (Kreek 1997) or that block its rewarding and euphoric effects (McCance 1997). There has also been a search for drugs that indirectly change the effects that cocaine has on the brain by acting on other neurotransmitter systems, such as the serotonergic system (for example, fluoxetine) (McCance 1997). None of these approaches has produced an effective pharmacotherapy for cocaine dependence (Lima and others 2003; Platt 1997; Soares and others 2003).

Development of pharmacological therapies for cocaine dependence and their evaluation is complicated by the multiple interactive processes that may have contributed—for example, coexisting substance abuse or mental health issues (Mendelson and Mellon 1996). Many of the approaches to the treatment of cocaine dependence have also been used in treating patients with alcoholism and other substance abuse disorders.

A number of drugs have been used to treat cocaine based on their relevance to the symptoms of cocaine dependence (Silva de Lima and others 2002; van den Brink and van Ree 2003). The frequency of depressive symptoms has led to the exploration of the effectiveness of antidepressant drugs. Desipramine has been used with mixed effectiveness for cocaine detoxification and the maintenance of abstinence (Covi and others 1994; Gawin, Kleber, and Byck 1989), but it appears to be most effective when

there is evidence of previous or consequent symptoms of depression. Other antidepressants have been used with mixed results: imipramine and trazodone have been found to have more adverse effects than desipramine, and fluoxetine has not been found to be effective (Mendelson and Mellon 1996). A recent systematic review found no current evidence to support the use of antidepressants in the treatment of cocaine dependence (Lima and others 2003).

Dopamimetic drugs have also been used to treat cocaine dependence; such treatments are based on the action of cocaine to block reuptake of dopamine. Unfortunately, although some of these drugs are relatively effective, they also result in quite severe adverse effects (Mendelson and Mellon 1996). Current evidence does not support the clinical use of dopamine agonists for cocaine dependence (Soares and others 2003). Opioid antagonists (for example, naltrexone) or opioid mixed agonist-antagonists (such as buprenorphine) have been explored, on the basis that cocaine dependence may be accompanied by dependence on opiates. Although there have been problems with compliance with naltrexone therapy (National Research Council Committee on Clinical Evaluation of Narcotic Antagonists 1978), buprenorphine has shown promising preclinical and clinical trial results (Kosten, Kleber, and Morgan 1989). Other promising directions include cannabinoid receptor antagonists and cortisol synthesis inhibitors (van den Brink and van Ree 2003) and vaccination against the effects of cocaine (Kantak 2003), but there is as yet no evidence on the effectiveness of any of these interventions.

Acupuncture has also been used to treat cocaine dependence. Auricular acupuncture is frequently used, but the small number of trials that have been conducted have not provided sufficient evidence of effectiveness (van den Brink and van Ree 2003).

Psychotherapy and Cognitive Behavioral Therapy The lack of evidence for pharmacological therapy means that treatment for cocaine dependence currently relies on cognitive behavior therapies combined with contingency management strategies. Unfortunately, psychosocial treatments for cocaine dependence are also of limited effectiveness. Treatments such as therapeutic communities, cognitive behavioral treatments, contingency management, and 12 step-based self-help approaches benefit cocaine-dependent people by reducing their rates of cocaine use and improving their health and well-being, but rates of relapse to cocaine use after treatment remain high (Platt 1997).

Mendelson and Mellon (1996) conclude that there are no specific cognitive or behavioral interventions that are uniquely effective in treating cocaine dependence. However, some success has been demonstrated with incentive-based programs in which rewards are provided for urine samples that are free of cocaine, although there is doubt about whether results are sustained (Roozen and others 2004). Such programs are generally more

effective when the patient's family and friends are involved (Higgins and others 1994). Petry and others (2004) suggested that contingency management was effective in reducing cocaine use in a community-based treatment setting. They found that the benefits of treatment depended on the magnitude of reward, with those earning up to US\$240 obtaining better results than those earning up to US\$80. They suggested that this form of intervention may work best for people with more severe dependence on cocaine.

A multicenter investigation examining the efficacy of four psychosocial treatments for cocaine-dependent patients concluded that individual drug counseling in combination with group drug counseling showed the most promise for effective treatment of cocaine dependence over two forms of traditional psychotherapy (Crits-Christoph and others 1999). Community reinforcement involving an intensive, biopsychosocial, multifaceted approach to lifestyle change has shown positive effects over four to six weeks and has the advantage of being tailored to individual goals (Roozen and others 2004).

The few studies of the long-term effects of treatment have not shown particularly encouraging results. A one-year follow-up of the U.S. Drug Abuse Treatment Outcome Studies reported that reductions in the use of cocaine in the year following treatment were associated with longer duration of treatment, particularly six months or more in long-term residential or outpatient treatments (Hubbard, Craddock, and Anderson 2003). A five-year national follow-up study of 45 U.S. treatment programs found that only 33 percent of the sample had highly favorable outcomes (Flynn and others 2003).

Amphetamines

According to WHO, amphetamines and methamphetamines are the most widely abused illicit drugs after cannabis, with an estimated 35 million users worldwide (Rawson, Anglin, and Ling 2002).

In Australia, the lifetime prevalence of amphetamine use is between 6 and 8 percent in the general population, making amphetamines the most commonly used illicit drug after cannabis during that period (Makkai and McAllister 1998). In 1998, the lifetime prevalence of amphetamine use was highest (25 percent) among male users age 20 to 29.

The use of amphetamines is generally less frequent than that of opioids (Darke and Hall 1995; Darke, Kaye, and Ross 1999; W. Hall, Bell, and Carless 1993; Hando, Topp, and Hall 1997; Vincent and others 1998). This pattern is no doubt due to the physical and psychological toll taken by regular amphetamine use. Although such use is less frequent overall, however, there is widespread bingeing on amphetamines, with frequent use over several consecutive days, which may be followed by benzodiazepine use to "come down." Polydrug use is particularly common among amphetamine users, who show a marked preference

for stimulant drugs such as hallucinogens and cocaine (Darke and Hall 1995; Hando and Hall 1994; Vincent and others 1998).

Globally, Europe is the main center of amphetamine production, particularly Belgium, the Netherlands, and Poland, with production increasing in Eastern Europe (UNODCCP 2003). Half of all Western European countries reported an increase in amphetamine abuse in 2000, but in 2001 the figure fell to 33 percent (UNODCCP 2003). Lifetime use of amphetamines is reported to be between 0.5 percent and 6 percent among European Union countries, with the exception of the United Kingdom, where the figure is 11 percent. Denmark and Norway also have relatively higher rates of use (EMCDDA 2003).

Adverse Health Effects of Amphetamine Use. Amphetamine users who inject the drug are at high risk of bloodborne infections through needle sharing. Amphetamine users are as likely as opioid users to share injection equipment (Darke, Ross, Cohen, and others 1995; Darke, Ross, and Hall 1995; W. Hall, Bell, and Carless 1993; Hando and Hall 1994; Kaye and Darke 2000; Loxley and Marsh 1991). In addition, the youth of amphetamine users places them at risk of sexual transmission of diseases such as HIV and hepatitis B virus (although not hepatitis C). Primary amphetamine users have been demonstrated to be a sexually active group, and small proportions engage in paid sex to support their drug use (Darke, Ross, Cohen, and others 1995; Hando and Hall 1994). Among gay and bisexual men, amphetamines may be used to enhance sexual encounters, which may lead to unprotected anal intercourse and increased risk of HIV infection (Urbina and Jones 2004).

High-dose amphetamine use, especially by injection, can result in a schizophreniform paranoid psychosis, associated with loosening of associations, delusions, and hallucinations (Gawin and Ellinwood 1988; Jaffe 1985). The psychosis could be reproduced by the injection of large doses in addicts (Bell 1973) and by the repeated administration of large doses to normal volunteers (Angrist and others 1974).

High proportions of regular amphetamine injectors describe symptoms of anxiety, panic attacks, paranoia, and depression. The emergence of such symptoms is associated with injecting the drugs, greater frequency of use, and dependence on amphetamines (W. Hall and others 1996; McKetin and Mattick 1997, 1998). Recent evidence also suggests that women may experience more emotional effects of amphetamine intoxication than men and higher rates of anorexia nervosa than women without amphetamine disorders (Holdcraft and Iacono 2004).

In sufficiently high doses, amphetamines can be lethal (Derlet and others 1989). However, the risk is low compared with the high risks of overdose associated with central nervous system depressants such as heroin. Typically, amphetamine-related deaths are associated with the effects of amphetamines on the cardiovascular system—for example, cardiac failure and cerebral vascular accidents (Mattick and Darke 1995).

There is evidence that amphetamines are neurotoxic (Robinson and Becker 1986). Evidence from animal studies indicates that heavy amphetamine use results in dopaminergic depletion (Ellison 1992; Fields and others 1991). The few studies of the neuropsychological effects of amphetamine abuse report findings similar to those found with cocaine abuse. Deficits in memory and attention have been attributed to amphetamine use (McKetin and Mattick 1997, 1998). More recently, a twin study indicated that amphetamine abuse might lead to impaired attention and motor skills up to one year after the conclusion of heavy use (Toomey and others 2003).

Interventions for Amphetamine Dependence. Treatment for methamphetamine abuse has been a relatively recent development and has generally been based on previous treatments for cocaine abuse (Huber and others 1997). Cretzmeyer and others (2003) reviewed treatments for methamphetamine abuse, noting that there has been little research on the effectiveness of drug treatment, probably because many amphetamine users use multiple drugs. The combination of methamphetamine use with use of marijuana or other sedating drugs indicates that effective treatments need to address the use of multiple drugs. A Cochrane Review concluded that evidence for success in treatment of amphetamine dependence is very limited, with no pharmacological treatment demonstrated to be effective (Srisurapanont, Jarusuraisin, and Kittirattanapaiboon 2003).

An early study explored the use of aversion therapy in a multimodal treatment program using educational groups, individual counseling, occasional family counseling, and after-care planning. The intervention paired an aversive stimulus (either chemical or electrical) with the act of using methamphetamines. Cocaine use was also treated in this way. After 12 months, 53 percent of patients were abstinent and the researchers noted that their results were promising, despite a number of limitations to the study (Frawley and Smith 1992).

An intervention combining imipramine, a tricyclic antidepressant, with intensive group counseling has been evaluated with cocaine and methamphetamine abusers. Patients received either a low or higher dose (as needed) of imipramine, as well as intensive group counseling and access to medical and psychiatric care. Those who received the higher dose stayed in treatment longer, but the results did not support the use of imipramine for methamphetamine abuse (Galloway and others 1994).

The Matrix Program for methamphetamine and cocaine abusers has also been evaluated. The Matrix Program uses a cognitive behavioral approach with an emphasis on relapse prevention (Huber and others 1997). The study evaluated the effectiveness of three conditions: Matrix treatment alone, Matrix treatment plus desipramine, and Matrix treatment plus placebo (Shoptaw and others 1994). The researchers concluded

that those who received more Matrix treatment had better abstinence rates than those who had less treatment but that desipramine had no effect on treatment outcome.

J. Hall and others (1999) conducted an evaluation of the effectiveness of the Iowa Case Management Project. The project was designed to supplement interventions provided by a drug abuse treatment agency and is a comprehensive social work intervention, including outreach activities and provision of limited emergency funds. The results of the evaluation showed that comprehensive case management was effective in improving employment status among amphetamine users subsequent to treatment. There was an almost significant lower incidence of depression among those who received the program compared with controls. Drug use decreased significantly for clients in both control and program conditions.

More recently, an Australian study evaluated the effectiveness of brief cognitive-behavioral interventions among regular users of amphetamines (Baker, Boggs, and Lewin 2001). The researchers found a clinically significant reduction in daily amphetamine use among the intervention groups compared with controls and concluded that further studies of brief cognitive-behavioral interventions are feasible and warranted. Although some promising interventions have been identified to assist methamphetamine abusers, no single treatment option has yet been established as better than any other in a randomized controlled trial (Cretzmeyer and others 2003).

Methylenedioxymethamphetamine

Methylenedioxymethamphetamine is more widely known as *ecstasy* or *MDMA*. In Australia, the lifetime prevalence of MDMA use increased from 1 percent of the population in 1988 to 4.6 percent (about one in 20 persons) in 1998, with 2.3 percent reporting MDMA use in the preceding 12 months (Topp and others 1998). In 2001, 6.1 percent of Australians age 14 years or older reported lifetime use of MDMA, with 2.9 percent reporting use within the preceding year (Degenhardt, Barker, and Topp 2004). Rates of use are generally higher among males than females (3.1 percent versus 1.5 percent). MDMA use in the preceding 12 months is most common among those age 20 to 29 (5 percent of females and 12 percent of males) (Topp and others 1998).

The availability of MDMA has also increased, as indicated by the proportion of the population who have been offered MDMA (from 4 percent in 1988 to 7 percent in 1991) (Makkai and McAllister 1998), with 14 percent of those age 14 to 29 reporting that they had been offered MDMA in the preceding year.

Research suggests that the pattern of MDMA use changed during the 1990s (Topp and others 1998). Users of MDMA are commencing use at a younger age, and they appear to be using larger doses more frequently. The incidence of bingeing on MDMA appears to have increased, as does the prevalence of the parenteral use of this drug. The increase in the use of MDMA

by injection has been noted among surveys of MDMA users and of injecting drug users generally.

An examination of trends in the United States suggested that, although the use of MDMA has increased over time, its prevalence is significantly less than that of other drugs of abuse (Yacoubian 2003b). A study of 14,520 U.S. college students indicated 6 percent lifetime use of MDMA, 3 percent within the preceding 12 months, and 1 percent within the preceding 30 days. Those who had used MDMA in the preceding 12 months were more likely to be white and a member of a fraternity or sorority and to have used a range of other drugs (Yacoubian 2003a). Rates of use are much higher in surveys of club attendees. A recent U.S. survey found 86 percent reporting lifetime use, 51 percent 30-day use, and 30 percent use within the preceding 2 days (Yacoubian and others 2003).

Abuse of MDMA had showed signs of decreasing in Western Europe but has recently shown signs of increase (UNODCCP 2003). Although MDMA use appears to be still diffusing, in 2003 only four countries (Ireland, the Netherlands, Spain, and the United Kingdom) reported a rate of more than 3 percent use among young adults in the preceding 12 months (EMCDDA 2003). In the United States, use declined in 2002 for the first time, but it increased in other regions, particularly the Caribbean, parts of South America, Oceania, Southeast Asia, the Near East, and southern Africa (UNODCCP 2003). Lifetime experience of MDMA is reported to range from 0.5 percent to 5 percent in European Union countries, with use more common in the Netherlands (EMCDDA 2003).

Population survey findings from New Zealand reported an increase in the preceding-year use of MDMA from 1.5 percent in 1998 to 3.4 percent in 2001. The increase was particularly evident among young men age 20 to 24 (from 4.3 percent to 12.5 percent) (Wilkins and others 2003).

Adverse Health Effects of MDMA. Early studies of MDMA use in Australia and the United States documented relatively few problems associated with the drug's use (Beck 1990; Beck and Rosenbaum 1994; Downing 1986; Solowij, Hall, and Lee 1992). A survey of 100 MDMA users (Solowij, Hall, and Lee 1992) found that the most common adverse effects were the side effects of acute use, such as appetite loss, dry mouth, palpitations, and bruxism (teeth grinding). Among the few heavy users in the study, only two reported feeling dependent on the drug.

With a change in the pattern of MDMA use in Australia, there has been an increase in the MDMA-related harms reported (Topp and others 1998). Some of the acute physical and psychological adverse effects that MDMA users have attributed to the use of this drug include energy loss, irritability, muscular aches, insomnia, and depression. More chronic adverse effects were also reported, including weight loss, depression, energy loss, insomnia, anxiety, and teeth problems.

A recent U.K. study of 430 regular users of MDMA reported that 83 percent of participants reported low mood and 80 percent experienced impaired concentration. Long-term effects of MDMA included the development of tolerance to MDMA (59 percent), impaired ability to concentrate (38 percent), and depression (37 percent) (Verheyden and others 2003).

Physical symptoms that were perceived as being due to MDMA use alone (Topp and others 1998) included an inability to urinate, blurred vision, vomiting, numbness or tingling, loss of sexual urge, and hot and cold flushes. As with amphetamines, the use of MDMA to facilitate sexual encounters may lead to risky sexual behavior and risk of sexually transmitted infections such as HIV. Studies of gay and bisexual men have found an association between MDMA use and high-risk sexual behavior (Urbina and Jones 2004).

MDMA has been implicated in a growing number of deaths, both in Australia and in other countries (Henry, Jeffreys, and Dawling 1992; Solowij 1993; White, Bochner, and Irvine 1997). Although the reasons for extreme reactions have yet to be clearly determined, deaths have most often been attributed to hyperthermia when MDMA was used at dance venues. A combination of sustained exertion, high ambient temperatures, and inadequate fluid replacement appears to compound the effect of MDMA on thermoregulatory mechanisms, causing a rapid and fatal rise in body temperature (Topp and others 1998). Some deaths have been attributed to excessive water consumption, which causes cerebral edema (Cook 1996; Matthai and others 1996).

Learning and Developmental Disabilities

Maureen S. Durkin, Helen Schneider, Vikram S. Pathania, Karin B. Nelson, Geoffrey C. Solarsh, Nicole Bellows, Richard M. Scheffler, and Karen J. Hofman

Learning and developmental disabilities (LDDs) include functional limitations that manifest in infancy or childhood as a result of disorders of or injuries to the developing nervous system (Institute of Medicine Committee on Nervous System Disorders in Developing Countries 2001). These limitations range from mild to severe and can affect cognition, mobility, hearing, vision, speech, and behavior. The known causes of LDD are numerous and include genetic factors, nutritional factors, infections, toxic exposures, trauma, perinatal factors, and multifactorial conditions (table 49.1). Selected causes of LDD that are not addressed in detail in this chapter are described in box 49.1.

Although information on the prevalence and impact of disabilities in low- and middle-income countries (LMICs) is scarce, five considerations support the conclusion that LDDs are a public health priority in LMICs today:

- *Prevalence.* Although each individual cause is relatively rare, taken together, LDD affects a large proportion of children. In high-income countries, 10 to 20 percent of children have an LDD (Benedict and Farel 2003). With improvements in child survival in LMICs, it is not known whether the prevalence of disabilities among children is increasing, as has been seen in wealthier countries (Winter and others 2002), but the few data available from LMICs suggest that the prevalence of specific causes and types of LDD may be even higher than in high-income countries. Examples include cognitive disabilities associated with prenatal iodine deficiency, brain infections, and blindness associated with vitamin A deficiency (Durkin 2002). The prevalence of childhood disabilities in LMICs is not well established, but it is likely higher than in high-income countries.
- *Lifelong duration.* By definition, LDDs have an early onset, with the causes frequently occurring in the prenatal period. These effects are typically lifelong, affecting learning and other neurological functions, educational achievement, quality of life, earning potential, and productivity across the life span.
- *Costs.* The extensive costs include the direct costs of acute care, outpatient health care services, long-term care, rehabilitation, and special education, as well as the indirect costs of morbidity and increased mortality (Waitzman, Romano, and Scheffler 1994). Additionally, the costs and effects extend beyond the individuals affected to include entire families. Health, careers and employment of parents, family disposable income, health and adaptation of siblings, and family interaction are adversely affected when a family member has an LDD (Stein and Jessop 2003). It is difficult to comprehend the extent of these effects, just as it is difficult to measure them and develop economic models that account for them.
- *Education and work.* As societies and economies become increasingly information-oriented and dependent on educated and literate workers, the impact of disabilities affecting cognition and learning becomes greater (Institute of Medicine Committee on Nervous System Disorders in Developing Countries 2001).
- *Proven interventions.* The prospects for preventing LDD and for improving outcomes are considerable and can be achieved, to some extent, by implementing interventions that have been shown to be effective and cost-effective elsewhere but that are not being implemented in LMICs.

This chapter provides an overview of the range of interventions likely to improve child development and educational

Table 49.1 Categories of Causes of LDD

Category	Examples
<i>Genetic</i>	
Chromosomal	Down syndrome, chromosomal rearrangements
Segmental autosomal syndromes	Prader-Willi syndrome, Angelman syndrome
Sex-linked, single gene	Fragile X syndrome, Rett syndrome
Autosomal recessive	Phenylketonuria, Tay–Sachs disease
Autosomal dominant	Neurocutaneous syndromes, such as neurofibromatosis
<i>Multifactorial</i>	
Genetic and nutritional	Neural tube defects
<i>Nutritional</i>	
Prenatal: maternal iodine deficiency	Developmental iodine deficiency disorder
Childhood: vitamin A deficiency	Xerophthalmia, night blindness
<i>Infections</i>	
Prenatal or perinatal	Toxoplasmosis, rubella, cytomegalovirus, herpes, gonorrhea, syphilis, group B streptococcus, chlamydia, trichomonas vaginalis, bacterial vaginosis, herpes simplex virus, HIV
Postnatal or childhood	Encephalitis, meningitis, varicella, cerebral malaria, polio, trachoma, otitis media
<i>Toxic exposures</i>	
Prenatal	Alcohol, lead, mercury, antimicrobials (such as sulfonamides, isoniazid, ribavirin), anticonvulsants (such as phenytoin, carbamazepine), and other drugs (such as accutane, thalidomide)
Postnatal or childhood	Lead, mercury
<i>Other maternal disorders</i>	
Thyroid disease	Cerebral palsy
<i>Other perinatal complications</i>	
Brain injuries associated with premature birth, birth asphyxia	Cerebral palsy, cognitive disabilities, seizure disorders
<i>Injury</i>	
Traumatic brain injuries and other disabling injuries from vehicle crashes, child abuse and neglect, falls, burns, warfare, and so forth	Cognitive, motor, speech, vision, hearing, seizure, and behavioral disabilities
<i>Poverty, economic disadvantage</i>	
Social and cognitive deprivation	Mild mental retardation
<i>Unknown</i>	LDD of unknown cause

outcomes for children in LMICs. Evidence of cost-effectiveness is considered in some detail for three selected interventions. An overview of other key risk factors and conditions that result in LDD is provided. A research agenda is outlined for advancing knowledge of how to prioritize cost-effective interventions and how best to devote resources for the prevention of LDD in LMICs.

LDD AND THE GLOBAL BURDEN OF DISEASE

Estimates for disability-adjusted life years (DALYs) (Mathers 2006) are not available to convey the full range of LDDs or their

risk factors. Attempts have been made to estimate the DALYs associated with specific causes of LDDs. For example, it is estimated that 9.8 million DALYs, or nearly 1 percent of the global burden of disease, are due to one relatively minor form of LDD, namely, mild mental retardation (MR) caused by lead ingestion from environmental sources (Fewtrell and others 2004). Since only a small fraction—probably much less than 10 percent—of LDD worldwide can be attributed to lead-induced mild MR, this estimate suggests that LDD as a whole must account for a large proportion, perhaps more than 10 percent of the global burden of disease. Where DALY estimates are available, we use them as a basis for economic analysis to estimate the costs of

Interventions for the Prevention of Childhood Neurological Disabilities

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is the most common neurological disorder in children in the United States, with an estimated prevalence of 3 to 11 percent. The prevalence is not known in LMICs, but as schooling increasingly becomes the norm, ADHD is likely to become more obvious. The burden of ADHD in settings of large class sizes will likely pose an increasing challenge. In addition to its major impact on school performance, ADHD affects family relationships and social competence, with lasting consequences. Children with ADHD are also at higher risk for injury, depression, and substance abuse. Worldwide, with the growing use in school settings of stimulants to control this chronic disorder, the impact on health care costs is potentially huge. Although there are a paucity of data on this topic, in one study, the cost of medicating children for ADHD was close to an average of US\$500 or more per child per year, and this figure is considered a substantial underestimate (Chan, Zhan, and Homer 2002).

Autism Spectrum Disorders

All autism spectrum disorders (ASDs) are characterized by varying degrees of impairment in communication skills and social interactions and in restricted, repetitive patterns of behavior or interests. Although only 50 percent of children in the United States with ASDs are diagnosed before six years of age, this group of disorders can reliably be diagnosed by three years of age and in some cases by as early as 18 months. ASDs range from a severe form called *autistic disorder* to a milder form known as *Asperger syndrome*. Prevalence studies of ASDs in Asia, Europe, and North America estimate that 2 to 6 out of every 1,000 children have an ASD. Screening instruments using responses from children and parents are available. Evidence indicates that early intervention (ideally in optimal educational settings for at least two years during preschool) results in improved outcomes. Individuals with ASDs generally respond well to highly structured, specialized programs. A variety of medications is used to treat associated depression, anxiety, ADHD, seizures, and other behavioral symptoms. Adults with severe ASDs require intensive and constant supervision. Little information is available regarding the parental and service costs of ASDs. In a 2001 study in the United Kingdom, the lifetime cost

for a person with autistic disorder exceeded UK £12.4 million, with most of the expense related to living support and daily activities.

Infection

Numerous prenatal, perinatal, and postnatal infections can damage the developing nervous system or sensory pathways and cause long-term disabilities in children. The relative contribution of these infections to the burden of LDD is likely to vary by country. It will be influenced by overall infant mortality, postneonatal contribution to infant mortality, and regional difference in the distribution of the infections known to be associated with neurological sequelae during different periods in the early life cycle. A few of the most important infections that may result in LDD include the following:

- *Congenital rubella (chapter 20)*. This disease is a major global cause of preventable hearing impairment, blindness, and intellectual disability. The incidence of congenital rubella syndrome has been variably set at 0.5 to 2.2 out of every 1,000 live births in LMICs during epidemics, which occur every four to seven years (Cutts and others 1997). Though some LMICs have set elimination goals and vaccination has been noted to be cost-effective, only 28 percent of LMICs routinely vaccinate against rubella (Robertson and others 1997).
- *HIV/AIDS infection (chapter 18)*. Neurological problems in HIV-infected children vary in different parts of the world but may be as high as 40 to 50 percent (Bobat and others 1998). The developmental trajectory of infected children is confounded by maternal, social, and biological risk factors during pregnancy and early childhood. Maternal substance and drug abuse, more common in HIV-infected women, have an independent adverse effect on brain growth and neurodevelopmental outcome. Low birthweight and prematurity, poverty, protein calorie malnutrition, and micronutrient deficiencies—more frequently seen in HIV-infected children and particularly in LMICs—may similarly compromise early child development (Brouwers and others 1996).
- *Malaria (chapter 21)*. In Sub-Saharan Africa, malaria is the leading cause of childhood mortality and morbidity. Cerebral malaria is a well-known complication and

Box 49.1

(Continued)

may result in neurological sequelae in survivors, contributing significantly to the burden of LDD.

- *Bacterial meningitis (chapter 20)*. This disease results in long-term sequelae for many children, including approximately 40 percent of children who survive *Haemophilus influenzae* meningitis, 50 percent who survive pneumococcal meningitis, and 10 percent who survive meningococcal meningitis. Cost-effective immunization can prevent meningitis from all these causes.

Alcohol

Prenatal alcohol exposure resulting in fetal alcohol syndrome may be the most common single preventable cause of MR worldwide (Viljoen 1999), but substantial challenges remain in diagnosing and preventing this disorder (see chapter 47). In addition to growth retardation and congenital heart disease, effects include ADHD, memory deficits, and mood disorders. Adults continue to have attention and social difficulties and higher rates of alcohol, nicotine, and drug dependence. Children exposed to even small amounts of alcohol (half a drink per day) in utero have poor outcomes, suggesting that abstinence should be recommended during conception and throughout pregnancy (Sokol, Delaney-Black, and Nordstrom 2003).

Although tools are available to help providers identify women who consume alcohol, detection of maternal alcohol exposure is a challenge. The overall rate of fetal alcohol syndrome for LMICs has been placed at 1 to 4.8 out of every 1,000 population (Sampson and others 1997) and is higher among low socioeconomic populations and subpopulations with particularly high alcohol intakes. If individuals with the full spectrum of fetal alcohol syndrome–related effects are included, this rate may be as high as 1 in every 100 births. A prevalence rate of 40.5 to 46.4 out of every 1,000 children in South Africa, the highest rate worldwide, is attributable to particular historical and social conditions (May and others 2000).

Public health measures to prevent prenatal alcohol exposure have had limited success, and rates have not changed over the past decade in the United States (Floyd and Sidhu 2004). These measures include putting warning labels on alcoholic beverages and broadcasting public messages about alcohol dangers during pregnancy. Improved outcomes might result from targeting the use of

screening tools for high-risk drinkers, who include women in prisons, drug rehabilitation centers, hospital emergency facilities, and sexually transmitted disease clinics (Sokol, Delaney-Black, and Nordstrom 2003). Little is known about the costs around the world. Annual costs for all individuals with fetal alcohol syndrome in the United States during 1998 was estimated at US\$4 billion, with lifetime care per person, for individuals requiring such care, at US\$1.4 million (Lupton, Burd, and Harwood 2004).

Environmental Exposures

Children are more susceptible to environmental factors, including unsafe home environments, road traffic, and chemicals (see chapters 42 and 43). Even in high-income countries in Europe, mild MR resulting from lead exposure accounted for 4.4 percent of DALYs among children zero to four years of age. Legislative efforts are under way to eliminate lead from gasoline and other environmental sources of lead exposure in LMICs (Khan and Khan 1999; Alliance to End Childhood Lead Poisoning 2002). In the 0 to 19 years age group, injuries from all causes accounted for 19 percent of DALYs. The poor and vulnerable road users—pedestrians, cyclists, and motorcyclists—bear the greatest burden of road injuries. Nearly 25 percent of all nonfatally injured victims requiring hospitalization sustain a traumatic brain injury as a result of motor vehicle crashes (Peden and others 2004). Although the effectiveness of bicycle helmets for road safety is high, their use in LMICs is low (Thompson, Rivara, and Thompson 1999).

Interventions aimed at reducing children's exposure to environmental factors and injuries could result in substantial gains. Targeted action by region, even within a single country, is likely to prove most productive (Valent and others 2004).

Nutritional Deficiency

Iodine deficiency from inadequate quantities of iodine in soil, water, and food affects 13 percent of the world's population, and an additional 30 percent are at risk (see chapter 28). Maternal iodine deficiency during pregnancy may result in an average loss of 15 IQ points in offspring, making it a leading preventable cause of MR. Iodine deficiency can be prevented with adequate consumption of iodized salt, which is now consumed by about 70 percent of households worldwide.

prevention of LDD. In this chapter, we estimated only costs of the interventions for Down syndrome (DS), neural tube defects (NTDs), and congenital hypothyroidism.

IMPAIRMENT, DISABILITY, AND PARTICIPATION

Quantifying the impacts of LDD and their preventive interventions is complicated by the fact that these disorders can exist and be measured at multiple levels, including three levels distinguished by the World Health Organization (WHO) in *International Classification of Functioning, Disability, and Health* (WHO 2001):

- *impairment*, which refers to physiological or psychological defects or abnormalities, such as failure of the neural tube to close
- *function* or *disability*, which refers to the ability of an individual to perform a task, such as walking, seeing, hearing, learning language, and reading
- *participation*, which refers to the degree to which an individual participates in school, employment, social role, and recreational activities.

A given impairment may be associated with a range of functional outcomes. Some but not all of these may be recognized as disability. Disability is context specific and may vary from culture to culture. For example, conditions such as dyslexia, attention deficit and hyperactivity disorder (ADHD), and mild MR may be especially disabling in school but not as noticeable in nonacademic settings and environments where schooling is optional. Environmental factors and social stigma may determine the participation of people with disabilities more than do the functional deficits themselves. Some interventions may be designed to enhance participation (for example, ramps, accessible public toilets, inclusive education), whereas others may target impairment and disability (for example, nutritional fortification, surgery, rehabilitation, special education, newborn screening, and early treatment).

THREE LEVELS OF PREVENTION

Prevention of LDD involves primary, secondary, and tertiary prevention activities:

- *Primary prevention* includes efforts to control the underlying cause or condition that results in disability. Examples include (a) maternal antiretroviral therapy to reduce the risk of mother-to-child transmission of HIV and (b) fortification of the food supply to prevent birth defects such as spina bifida and iodine deficiency disorders.
- *Secondary prevention* aims at preventing an existing illness or injury from progressing to long-term disability. Examples include newborn screening for metabolic disorders followed

by dietary restrictions to prevent damage to the nervous system and effective emergency medical care for head injury.

- *Tertiary prevention* refers to rehabilitation and special educational services to mitigate disability and improve functional and participatory or social outcomes once disability has occurred.

UNINTENDED CONSEQUENCES OF SUCCESSFUL OR PARTIALLY SUCCESSFUL INTERVENTIONS

Interventions to reduce mortality and morbidity may be followed by increases in the prevalence of LDD. Examples include the following:

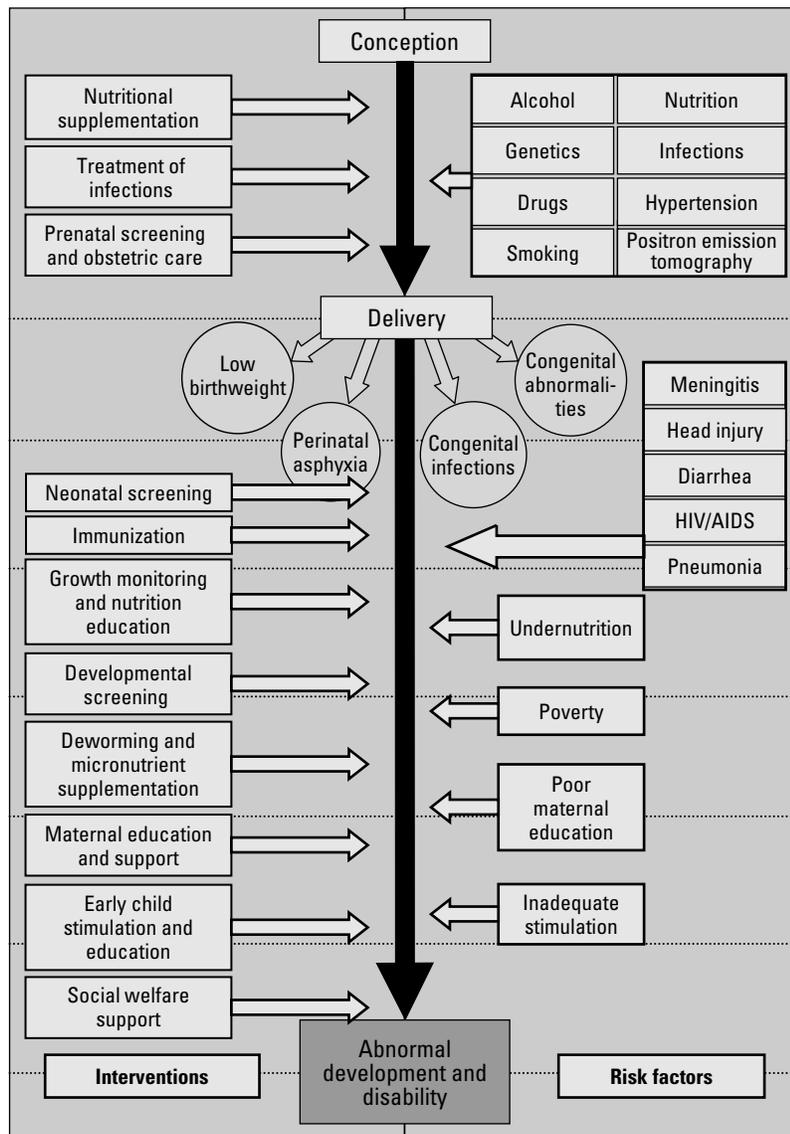

- Improved survival of very low birthweight infants at high risk for LDD may cause the prevalence of disability in the population to increase at the same time that it increases the absolute number of survivors without disabilities.
- Rubella vaccination programs with less than optimal coverage will prevent infections in those vaccinated but leave unvaccinated girls at risk for acquiring rubella infection during their childbearing years (rather than during childhood, as might be expected in the absence of a vaccination program), thereby increasing the risk of congenital rubella infection and disability in the population.
- Newborn screening and treatment for phenylketonuria in infancy and childhood prevent MR, but phenylalanine dietary restriction for women with phenylketonuria during their childbearing years is essential to prevent prenatal neurological damage and MR in their offspring.

OTHER FACTORS LEADING TO INCREASES IN MEASURED PREVALENCE

Progress in the field of LDD may result in increases in the recognized prevalence of disability and in social and economic costs, as in the following examples:

- Increased availability of services may increase the number of children with recognized disabilities. Just as it is ethically problematic to screen for disorders for which no services can be offered, expansion of case finding becomes justified and ethically demanded as services become available, with the potential result of increasing the measured prevalence of disability.
- As educational expectations and awareness of LDD increase, the prevalence of recognized disability may increase.

In consideration of these trends and relationships between public health advances and increases in disability, it may not be realistic to expect short-term control of disability or cost savings following interventions that reduce mortality, even if those

Source: Authors.

Figure 49.1 Causal Pathways for LDD

interventions have a net positive effect on public health. The costs of disability and its prevention may increase initially in the wake of interventions that successfully reduce mortality. Figure 49.1 summarizes the causal pathways and potential interventions for the prevention of LDD.

INTERVENTIONS IN LOW- AND MIDDLE-INCOME COUNTRIES

Numerous interventions are effective in preventing LDD. Table 49.2 provides a summary of these interventions classified on two axes. The horizontal axis distinguishes whether the intervention would accomplish primary, secondary, or tertiary

prevention of disability. The vertical axis distinguishes four levels of evidence for cost-effectiveness:

- evidence available for LMICs
- evidence available for high-income countries only
- evidence for cost-effectiveness not available, but cost-effectiveness can be estimated from existing data
- evidence not available, but potential for benefits exists.

The literature indicates that the economic outcomes of a given intervention may vary widely for two reasons:

- Variations exist across populations, even within the same country, in the prevalence of the disorder, the cost of health care, and the existing infrastructure available to implement the intervention.

Table 49.2 Classification of Interventions to Prevent LDD

	Primary (prevention of condition that can lead to disability)	Secondary (prevention of disability once condition has occurred)	Tertiary (rehabilitation or prevention of further disability once disability has occurred)
Evidence for cost-effectiveness available for LMICs	Food fortification (<i>folic acid</i> and iodine ^a) Rubella vaccine ^a Hemophilus vaccine Removal of lead from paint and fuel Vitamin A supplementation (vision) Measles vaccine		
Evidence for cost-effectiveness available for high-income countries only		<i>Prenatal screening for DS and prevention of DS births</i> <i>Newborn screening for metabolic disorders followed by interventions to prevent disability</i>	
Evidence for cost-effectiveness not available, but cost-effectiveness can be estimated from existing data	Malaria prevention ^b	Early detection and care of neonatal jaundice Management of malaria Treatment for otitis media Prevention and treatment of neonatal complications through emergency obstetric and pediatric services Eyeglasses Hearing aids Detection and treatment of maternal thyroid disorders	Special education Prosthetics Braille Sign language Occupational, physical, and speech therapies Surgery Residential care Assistive devices
Evidence for cost-effectiveness not available, but potential for benefits exists	Fetal alcoholism prevention Trauma prevention (bicycle helmets, burns) Prevention of shaken baby syndrome and child abuse	Dehydration/diarrhea treatment Postnatal combined cognitive stimulation and nutritional intervention Therapeutic stimulants for treatment of ADHD	<i>Community-based rehabilitation</i>

Note: Italicized text represents somewhat detailed consideration of cost-effectiveness included in this chapter.
a. Covered in chapter 56, but chapter emphasis is not on implications for preventing developmental disabilities.
b. Covered in detail in chapter 21.

- Differences between studies exist in analytical methods used, such as the willingness to pay versus the human capital approach to valuation, and in cost categories, such as whether to include parental time costs. Though these differences make cross-population comparisons difficult, the overall evidence of cost-effectiveness is demonstrated by repeated findings that the benefits of a particular intervention outweigh the costs in a number of different settings.

Current evidence suggests that three interventions are cost saving: folic acid fortification to prevent NTDs, prenatal screening and selective pregnancy termination to prevent DS, and neonatal screening and treatment for congenital hypothyroidism (CH).

Too little is known about the fourth type of intervention, community-based rehabilitation, to evaluate it. There is a paucity of knowledge and a history of failed interventions for the prevention of premature birth and the disabilities associated with premature birth.

Neural Tube Defects: Burden and Cost-Effectiveness of Folic Acid Fortification

NTDs, which are the most common malformation of the central nervous system, result from failure of the neural tube to close during the first month of pregnancy. Anencephaly typically results in pregnancy loss, stillbirth, or neonatal death. Spina bifida (open spine defect) is associated with a range of

functional deficits (requiring multiple surgical and rehabilitative interventions), including paralysis of the lower extremities and often primary enuresis and cognitive disabilities. Large geographic variations in the prevalence of NTDs exist both within and between countries. The burden of disease is highest in South Asia and lowest in LMICs of Europe and Central Asia. Similarly, deaths from NTDs are high in South Asia but lowest in high-income countries. Estimates suggest that almost all NTD disease burden is concentrated in the age group zero to four years (Mathers 2006).

Folic Acid. Folate is a vitamin that occurs naturally in green leafy vegetables, legumes, citrus, and other foods. Folic acid (FA) is an easily absorbed synthetic form of folate that can be delivered as a dietary supplement or through FA fortification of flour or other common staple foods. NTDs can be reduced by 70 percent if women consume 400 μg of FA daily around the time of conception and until closure of the neural tube. At a population level, either supplementation or fortification of the food supply is necessary to ensure that 400 μg of FA is consumed at the critical period of fetal development, as this dose is higher than can reasonably be consumed by relying on naturally occurring folate in foods. Fortification is much more likely than supplementation to reach the population at risk because the benefit of enhanced FA intake occurs early, typically before the pregnancy is recognized. Fortification is of particular value to women who may not receive prenatal care until the third trimester.

This section considers only evidence of cost-effectiveness of FA fortification in LMICs with respect to the benefit of preventing NTDs. Additional health benefits can be expected with respect to stroke, heart disease, and cancer.

Cost-Effectiveness of Folic Acid Fortification A cost-benefit analysis of grain fortification in the United States (Romano and others 1995) included costs related to the addition of FA to food, to annual testing and surveillance, to a one-time packaging change, and to potential (though not substantiated) adverse health effects associated with undiagnosed vitamin B₁₂ deficiency. Benefits included avoided costs of NTDs, such as mortality costs (particularly for anencephaly) and costs of caring for those with spina bifida. The benefits of fortification outweighed costs with cost-benefit ratios of 1 to 4.3 for low-level fortification and 1 to 6.1 for high-level fortification.

Cost-effectiveness relative to status quo of FA fortification depends on several factors:

- Costs of food fortification depend on the types and quantity of food that are fortified and the level of fortification.
- The proportion of the target population reached by the fortified food is important since, in most LMICs, many people consume food produced on their own farms or within their villages.

- Grains from large mills are relatively cheap to fortify; more resources are required to fortify grains milled in smaller neighborhood mills.
- The amount of folate consumed by different populations in the absence of fortification varies.
- Prevalence of NTDs varies across populations, and the cost-effectiveness increases with prevalence.

Costs of food fortification may be lower in high-income countries, where most people consume cereals processed in a few large mills, equipment for fortification is likely to be in place, and quality assurance is facilitated. In contrast, mills in LMICs lack fortification equipment and capital, and running costs are higher in the short run.

Costs of Food Fortification For optimal daily consumption, the actual level of food fortification (defined as μg of FA per 100 grams of the food item) should be adjusted for storage and other losses so that a daily dose of 400 μg is achieved. Food items that should be fortified depend on specific dietary habits. Staples such as rice and flour are obvious choices; salt, sugar, bread, milk, and edible oils are promising candidates. There are economies of scale in FA fortification. It can be and usually is carried out in conjunction with other forms of fortification, such as iron, iodine, and vitamin A fortification. Many food items are already fortified in high-income countries. Other factors to be considered in the choice of food for fortification are items that are centrally processed and allow for quality control. Soy sauce in China is an example: it is consumed on a daily basis by 70 percent of the population and is prepared in a few large factories.

The recommended fortification level is thus 240 μg per 100 grams of the staple food. This fortification rate is assumed for all regional strata where the per capita staple consumption per day is less than 300 grams. Wheat, rice, maize, or a combination of these foods is the staple in most countries. The recommended level of FA fortification varies from 150 μg to 240 μg per 100 grams of cereal. So that women receive a daily dose of 400 μg , the target cereals for fortification should be those for which daily per capita consumption is at least 200 grams. In Sub-Saharan Africa, daily per capita cereal consumption exceeds 200 grams only if wheat, rice, and maize are considered together.

Quality assurance is done through analytic testing of fortified products to confirm FA levels. Quality assurance costs in the United States are estimated at US\$0.64 cents per ton of fortified grain in quality assurance costs.

The costs of FA fortification include the cost of FA, setup, and analytic testing. The analysis is done using two different cost estimates: US\$0.15 and US\$0.50 per ton of grain fortified. The cost of FA determines the cost of premix added to the flour. FA is almost never added alone; usually FA, iron, zinc, and niacin are added in combination. The material cost of FA alone is about US\$0.10 to US\$0.20 per metric ton of milled

wheat. However, a more realistic cost for the premix (including other supplements) is about US\$0.50 per metric ton of milled wheat. This higher estimate is conservative and does not account for the health benefits from the other supplements. Either way, the per capita costs are only a few cents in each region. The low per capita cost in high-income countries of US\$0.009 assumes that 80 percent of the cereal supply is fortified. In South Asia, where NTDs have the highest burden, the per capita cost is estimated at US\$0.067 (Bagriansky n.d.).

Benefits of Folic Acid Fortification The cost-effectiveness of FA fortification in terms of its cost per DALY and per death averted assumes that the fortification strategy will reduce the incidence of NTDs by 50 percent. The costs are relatively high because of the high cost of FA. Even a few cents per capita becomes expensive if the per capita prevalence of NTD is very low.

Other Costs and Benefits The benefits of FA fortification outweigh the costs. The benefits estimated here are conservative for three reasons:

- Strokes and coronary deaths are also prevented by FA fortification and occur more frequently than NTDs.
- The percentage of NTDs that can be prevented by FA fortification may be greater than 50 percent, because up to 70 percent of NTDs can be prevented by 400 µg of periconceptional FA daily.
- These estimates do not take account of the costs of clinical care and management for complications when NTDs are not prevented.

Interventions to Prevent Disability Caused by Down Syndrome

Screening programs are critical public health interventions that use universal or targeted screening tests to identify potential causes or cases of LDD, including DS.

Prenatal and Neonatal Screening. Prenatal screening for genetic abnormalities allows parents to determine whether to continue with an affected pregnancy, whereas neonatal screening's fundamental purpose is to improve the infant's prognosis through early diagnosis and treatment.

A number of LDDs have been screened for in high-income countries since the 1960s, and researchers have conducted economic evaluations of these screening programs, including those for Tay-Sachs disease carriers, DS (Cusick and others 2003), sickle cell disease (Panepinto and others 2000), phenylketonuria (Lord and others 1999), and several other inborn errors of metabolism (Insinga, Laessig, and Hoffman 2002).

Estimates for Prenatal Screening, Diagnosis, and Selective Pregnancy Termination for Down Syndrome. DS is the most

common genetic cause of mental retardation. Identifying a fetus with DS before birth and giving parents the option to terminate the pregnancy early can help decrease the burden of the disease on families and society. During counseling, parents may receive information about the consequences of DS, which will allow them to make an informed decision about the best care for the newborn or about termination of the pregnancy. Prenatal screening services provide an opportunity to profoundly reduce the impact of MR. The cost-effectiveness of prenatal screening for DS is based on two parameters: efficacy (by assessing the false positive rate of screening procedures and the number of fetal losses caused by screening) and financial costs (costs of screening per DS pregnancy averted). On the basis of the evidence, the best screening method is proposed, and sensitivity of the parameters of interest to the LMIC is tested. No formal comparisons are made between the costs of screening and care for a person with DS. The purpose of this analysis is to suggest the most cost-effective way of screening that provides families with information about the health of the child; it is not a cost-benefit analysis of whether a couple should terminate a pregnancy.

Burden. DS is caused by trisomy of chromosome 21—an extra chromosome rather than the usual diploid form—and is a major cause of severe MR (IQ less than 50 with substantial deficits in adaptive behavior). The incidence of DS is higher than the birth prevalence because many fetuses are spontaneously miscarried and, in some cases, selectively terminated. In the absence of prenatal screening and intervention, most DS conceptions (71 percent) result in spontaneous abortion; another 3 percent result in stillbirth, and 26 percent result in live birth with subsequent LDD (Kline, Stein, and Susser 1989). Because the incidence of DS cannot be determined without doing surveillance of all conceptions, the frequency of DS is typically measured in terms of prevalence per 1,000 live births rather than in terms of incidence. Thus, the population prevalence of DS varies depending on the maternal age structure (steep increase after age 35 years) as well as the availability and use of prenatal diagnosis followed by selective termination. Estimates from 10 LMICs range widely, from 0.1 out of every 1,000 live births in Indonesia to 4.4 out of every 1,000 live births in Pakistan (Institute of Medicine 2003). Most studies, in both high-income countries and LMICs, show DS birth prevalence in the range of 1.0 to 1.6 out of every 1,000 births. The birth prevalence of DS is likely higher in LMICs because of a higher proportion of births among women over age 35 (11 to 15 percent) relative to that in high-income countries (5 to 9 percent) (Kline, Stein, and Susser 1989) and possibly because of differential access to prenatal screening for chromosomal abnormalities.

Life Expectancy and Quality of Life. Life expectancy for children with DS is substantially lower than that of the general

Table 49.3 Distribution of DALYs Lost to and Deaths Caused by Down Syndrome, by World Bank Region, 2002

Region	DALYs	Deaths
East Asia and the Pacific	4,101,694	1,328
Europe and Central Asia	507,723	652
High income countries	199,215	2,113
Latin America and the Caribbean	214,346	1,979
Middle East and North Africa	347,898	1,311
South Asia	2,005,766	11,336
Sub-Saharan Africa	478,851	4,967

Source: Mathers and others 2006.

population. Congenital heart disease occurs in 40 to 60 percent of children with DS and accounts for 30 to 35 percent of deaths. Survival and life expectancy of children with DS have increased dramatically: In a 1940–60 birth cohort in England, only 50 percent of infants with DS survived beyond age two. By comparison, in 1981–85, 90 percent survived beyond age five (McGrother and Marshall 1990). Table 49.3 describes the estimated total deaths caused by DS by region, as well as the estimated total DALYs lost.

DS is always associated with cognitive impairment. Disability can range from mild to profound, and most children are affected moderately (IQ 40–55). Early intervention and therapy can improve functional outcomes. Of children with DS, 60 to 80 percent have hearing loss, and approximately 70 percent have ophthalmologic problems. As life expectancy of DS individuals has increased, many grow to adulthood and face an increased risk of early onset Alzheimer's disease, cataracts, hearing loss, hypothyroidism, and degenerative vascular disease.

Costs of Care. Based on 1988 data, the estimated incremental lifetime economic costs of DS are US\$410,000 per case or US\$647,709 in 2004 dollars (Waitzman, Romano, and Scheffler 1994). In another study, the estimate of per capita incremental costs of DS, converted to 2004 dollars, include net medical costs of US\$168,567, developmental services costs of US\$80,530, special education costs of US\$171,593, and total costs of US\$420,690 (Waitzman, Romano, and Scheffler 1994).

An estimate of lifetime costs per live born baby with DS—including education, health, and lost productivity costs—ranged from US\$137,000 in 1990 to US\$515,000 in 1993 (Gilbert and others 2001). Net savings using the annual program of screening, diagnosis, and selective termination was estimated to be US\$885, with costs of US\$446,000 per 10,000 pregnancies for a program that detects and prevents 9.7 DS births per year and a lower bound estimate of US\$137,000 of potential lifetime costs per 9.7 births prevented.

The increased life span of individuals with DS and accompanying age-associated morbidity impose heavy demands on

medical care and community services, as well as on sustained support from family members. It is also important to note that dollar costs of care for a DS child in LMICs would be much lower than such costs in high-income countries because of lower prices as well as lower treatment intensity. For example, in some countries, congenital heart disease, which affects 40 to 60 percent of DS children, cannot be treated effectively. This lack of treatment will lower costs of care as well as life expectancy, and cost estimates will vary for each individual area or region.

Cost-Effectiveness of Prenatal Screening, Diagnosis, and Selective Pregnancy Termination. Prenatal screening can be implemented to allow selective termination of DS pregnancies and prevention of disability related to DS in the population. This intervention raises ethical, social, and cultural concerns for some individuals and populations that may preclude its applicability.

A screening program incorporating maternal serum triple screening in all pregnant women, regardless of maternal age, yields an excellent DS detection rate and is associated with a low false-positive rate (Wald and others 2003). DS pregnancies yield lower levels of alpha-fetoprotein and unconjugated estriol but have elevated levels of human chorionic gonadotropin compared with other pregnancies. Ultrasound evaluation of the fetus neck thickness improves screening sensitivity. It is also useful when used in conjunction with serum screening (Wald and others 2003). A positive screening result is followed by diagnosis using amniocentesis or chorionic villus sampling (CVS).

Although both diagnostic procedures are guided by ultrasound to reduce risk, they are invasive, are more expensive than the screening procedure, and carry a small risk of miscarriage of an unaffected pregnancy. Thus, only a select group screening positive for possible trisomy 21 are offered the invasive diagnostic procedures. Amniocentesis, which involves the aspiration of amniotic fluid, is performed between the 14th and 16th weeks of pregnancy. CVS involves aspiration of villi and can be performed between the 10th and 12th weeks of pregnancy. Although CVS can be performed earlier in the pregnancy, amniocentesis is easier to perform and is more widely used in the second trimester. Following diagnostic confirmation of DS, parents are provided with genetic counseling and the option of terminating the pregnancy.

Although DS risk increases with maternal age, most births occur in younger women and, therefore, two-thirds of all DS births occur in younger mothers (Ross and Elias 1997). If prenatal diagnosis is available only for mothers 35 years or older, only 33 percent of DS births will be detected. Studies demonstrate that heavy reliance on maternal age to screen for DS may not be desirable in LMICs. Maternal age factor is not so useful in settings where early marriage and motherhood are the norm and most DS pregnancies involve mothers younger than 35 (Gupta and others 2001). Therefore, maternal serum screening

of all pregnant women is important in preventing DS births and achieving cost-effectiveness (Wald and others 2003).

Procedure Costs Genetic screening and counseling services are expensive. Even after initial high fixed costs to establish prenatal screening services, provision of high-quality services requires staff training, equipment, and laboratory maintenance. A recent report suggests establishing genetic screening services when other public health interventions have reduced the infant mortality rate to the range of 20 to 40 out of every 1,000 live births (Institute of Medicine 2003). Above this level, other public health interventions may have greater benefits.

The breakdown of tasks is as follows:

- *screening costs*, which consist of laboratory expenses (consumables and staff); informing women of results (by mail if negative, by phone if positive); service costs (processing results and monitoring the service); training in ultrasound measurement of neck skin translucency; and overhead expenses
- *diagnostic costs*, which comprise counseling before CVS or amniocentesis, equipment and staff for these procedures, laboratory expenses (consumables and staff), and overhead expenses
- *costs of termination of selected pregnancies*, which include surgical dilation, evacuation (11 to 13 weeks), or medical termination with mifepristone (after 13 weeks).

We assume infrastructure exists for prenatal screening, diagnosis, and intervention. We use the following costs: triple serum test, US\$70; amniocentesis, US\$1,200; genetic counseling, US\$100; and termination of pregnancy, US\$2,000. These cost estimates have been widely used in the literature (Cusick and others 2003). However, the medical costs can be significantly lower in LMICs and will also vary across and within countries.

Cost-Effectiveness and Efficacy We assume that 100 percent of women attend a prenatal clinic between 10 and 14 weeks of gestation and are offered tests in the first trimester, or between 15 and 19 weeks for the tests in the second trimester. We discuss the effect of low uptake of prenatal care and its effect on cost-effectiveness of prenatal screening programs in our sensitivity analysis.

In terms of economic considerations, it is desirable to balance the probability of the birth of a DS child with the risk of procedure-related miscarriage. Sensitivity of prenatal screening and the false-positive rates vary widely, depending on the method used. The risk of procedure-related miscarriage can vary from 0.04 to 0.8 percent (Nyberg and others 1998). We use the conservative fetal loss rate of 0.9 percent (Gilbert and others 2001) for both procedures.

Efficacy of prenatal screening is defined as the number of unaffected fetuses lost due to prenatal testing per each DS birth

averted (Institute of Medicine 2003). The goal is to minimize this ratio. The efficacy of prenatal screening varies with prevalence, and the primary determinant of variations in prevalence of DS is the age structure of women giving birth. The prevalence of DS and the efficacy of prenatal screening increase with the percentage of births to mothers over the age of 35. In this analysis, a 90 percent rate of selective termination is used (Waitzman, Romano, and Scheffler 1994). On this basis, the number of fetal losses per DS birth avoided varies from 7.13 (for 1 in 10,000 prevalence) to 0.16 (for 44 in 10,000 prevalence). Therefore, in countries with low prevalence of DS, such as Indonesia, more unaffected fetuses are lost than DS births averted because of screening. In areas where the ratio of unaffected fetal losses to DS births avoided is above 1, the efficacy of screening for DS is questionable.

Because of higher loss rates for CVS, we use a 1.5 percent fetal loss rate in our sensitivity analysis (Lippman and others 1992). Other costs not considered in this study are the psychological effects of a positive test on the parents, anxiety that may persist from a false-positive test, and potential complications resulting from pregnancy termination. Complications from termination may vary (Stray-Pedersen and others 1991) and may not be the same in LMICs, which should be taken into account. The sensitivity rate for the triple serum test followed by the amniocentesis is 62.3 percent in the clinical trials (Vintzileos and others 2000), and the uptake of amniocentesis is 90 percent for affected mothers and 80 percent for unaffected mothers (Waitzman, Romano, and Scheffler 1994). We assume the false-positive rate of 5 percent. The false-positive rate affects the probability of losing an unaffected fetus as a result of invasive testing that follows serum screening.

Financial cost-effectiveness is defined as the screening costs per DS birth averted. It is presented in table 49.4. Cost-effectiveness is the highest in countries with high birth prevalence of DS, given that women have access and receive prenatal care. Costs of prenatal screening and termination per DS birth averted vary from US\$1,497,390 in Indonesia (for 1 in 10,000 prevalence) to US\$37,185 in Pakistan (44 in 10,000 prevalence). A similar relationship is seen between prevalence and cost per DALY. In our analysis, we use costs data that are based on estimates from developed countries. Because costs of care will vary widely across and within countries, cost estimates should be done for individual regions. Lower costs of care will reduce cost-effectiveness of prenatal screening for DS. However, even after the cost adjustment, it is unlikely that the benefits will completely go away, because of the large difference between a relatively cheap screening program and high burden of disease of DS.

Sensitivity Analysis The results of the analysis above depend on assumptions that may not hold in some LMICs. For example, if many women accept screening but few decide to have an amniocentesis, cost-effectiveness will be adversely affected. The

public health benefits of screening for DS in socioeconomically deprived areas are small because of low uptake of amniocentesis (Ford and others 1998). With lower uptake rates of amniocentesis, both efficacy and financial cost-effectiveness are adversely affected as a result of low detection rates, and the number of unaffected fetal losses decreases. It is also important to note that, in some countries, many women may not have access to prenatal care or may not seek prenatal care and prenatal testing. In such areas, programs that try to reduce DS prevalence will have limited success, especially if a population at greater risk of DS is not tested.

Cost-effectiveness is often measured per DS birth averted since reduction in DS prevalence is the ultimate goal of prenatal testing. In many cultures, an abortion is not an acceptable option. Acceptance of elective termination of pregnancy may also vary across ethnicities and other subgroups within a given country. A study in California found the uptake of termination following the DS diagnosis varied from 47.5 percent for Hispanics to 65.8 percent for whites and 70.8 percent for Asians (Cunningham and Tompkinson 1999). If few families decide to terminate pregnancy to avoid having a child with severe disability, cost-effectiveness per DS birth averted will be adversely affected, and the screening program may fail to reduce the birth prevalence of DS. If a large percentage of families are opposed to induced abortion of fetal DS, the uptake of amniocentesis also will be low.

Because fetal losses following CVS are often higher than those for amniocentesis, efficacy analysis should be conducted assuming a 1.5 percent fetal loss risk attributable to invasive testing in the first trimester. With higher fetal losses, the efficacy of the prenatal screening is adversely affected, although the cost-effectiveness will not change.

In addition, assuming a higher false-positive rate of 8.3 percent increases the number of invasive tests on unaffected mothers and the number of unaffected fetal losses, thus adversely affecting the efficacy of the prenatal testing (Vintzileos and others 2000).

The analysis presented above is limited to an evaluation of the cost-effectiveness of prenatal screening for DS only. Some serum markers (for example, alpha-fetoprotein) will identify other abnormalities, the benefits of which are not included in this analysis.

Equity and Access The desirable policy is that women of similar risk for DS have equal access to diagnostic tests. With limited access to prenatal care, the introduction of the screening programs can have small public health effects. Although the approach used in cost-effectiveness analysis is optimization of societal net benefit, the policies to be recommended for the prevention of disability must also consider individuals' freedom in decision making at each step of the prenatal diagnosis. Successful policies need to be based on cost-effectiveness

estimates that take into account the needs, sensitivities, and values of individuals and cultures (Institute of Medicine 2003).

Interventions to Prevent Disability Caused by Congenital Hypothyroidism

For CH, like DS, screening programs are critical public health interventions.

Neonatal Screening in Low- and Middle-Income Countries.

When considering the costs and benefits associated with a CH screening program, one must first have an estimate of how prevalent CH is in the population so that the avoided costs associated with disability can be calculated. It is important to note that in high-income countries and in several middle-income countries screening is usually done for a series of conditions rather than for a single disorder. This fact is likely to affect the cost. In several of these conditions, the treatment includes dietary modification as well as costly prepared foods and formulas. Policies in countries where this type of screening occurs include labeling of food to alert potentially vulnerable consumers.

Several studies have examined the prevalence of CH in specific populations, with substantially varying results. A review of 13 studies reporting findings on CH prevalence identified through individual screening programs found the lowest rate to be 1 case of CH per over 6,000 screened in Thailand (Wasant, Liammongkolkul, and Srisawat 1999). Contrasting this is the highest rate reported: 1 case in 1,000 screened in Pakistan (Lakhani and others 1989). Prevalence can vary not only from one country to the next, but also within countries, depending on different analyses or subpopulations within one country. These variations demonstrate the need for identifying the appropriate population in order to conduct economic evaluations of screening interventions.

According to three cost-benefit analyses of CH screening (Layde, Von Allmen, and Oakley 1979; Barden and Kessel 1984), the benefits included savings from institutionalization, special education, medical care, lost parent and child productivity, and slightly decreased life expectancy. The costs included those of the screening program as well as the cost of treating detected cases. Overall, CH screening programs are substantially cost saving, with a cost-benefit ratio as high as 1 to 8.9 in high-income countries (Dhondt and others 1991). Such savings have not yet been evaluated in LMICs. Because the treatment is inexpensive and highly effective, it is anticipated that CH screening would also be substantially cost saving in LMICs.

Burden. Congenital hypothyroidism is a common cause of MR that can be prevented by newborn screening and treatment. By the end of the 1970s, neonatal screening programs had been established in many regions of Canada, Europe, Japan, and the United States. Thyroid hormone is required for

normal brain development, and little or no thyroid hormone in the neonatal period results in damage to the nervous system. Various causes of anatomical maldevelopment of the thyroid gland are responsible for CH, and several genes have been implicated. With biochemical newborn screening (best conducted in centralized regional laboratories) using dried blood spots and diagnosis in the first few weeks of life, MR is avoidable. Without appropriate treatment, two-thirds of patients with CH have low IQ, and 30 percent experience severe or profound cognitive disability (Beaulieu 1994). Even with appropriate treatment, some subtle intellectual impairment and behavior deficits may still occur—the mean IQ may be approximately 10 points lower than that of the general population (Tillotson and others 1994). In the United States, infants are screened as newborns and again at two to six weeks of age to detect missed cases. For optimal outcomes, lifelong treatment with thyroid hormone is required, with subsequent monitoring and adjustments recommended every 3 to 12 months until growth and puberty are complete. Many females born with CH are now reaching childbearing age and require increased dosages of thyroid hormone during pregnancy for optimal neuropsychological outcome in their offspring.

Costs of Care. Estimated lifetime costs of care for the child with CH include the following (Barden and Kessel 1984):

- *Institutional care.* At the time of the study, 15 percent of congenital hypothyroid individuals were institutionalized from age 5 to 70.
- *Foster care.* About 25 percent of congenital hypothyroid cases received foster care from age 5 to 20.
- *Residential care.* Such care was provided for 40 percent of affected cases.
- *Special education expenditures.* Such expenses varied with the level of MR (15 percent severe, 25 percent moderate, and 40 percent mild).

In 2004, estimated lifetime costs of CH care is US\$191,000, with a 6 percent discount rate. This estimate of the financial costs of care for an affected person is fairly conservative; it does not take into account lost productivity of the person with CH, a potential loss of income attributable to the time inputs of the family members who are taking care of the affected person, or effects on quality of life.

Cost-Effectiveness of Neonatal Screening. Table 49.5 presents cost-effectiveness analysis of neonatal screening for representative countries in the World Bank regions. Screening costs include blood sample collection, laboratory costs, discounted lifetime treatment cost, and costs of care for those missed by the screening. Specimen collection and laboratory costs (Barden and Kessel 1984; OTA 1988) constitute (in 2004 dollars) US\$989,000 and US\$969,000, respectively, per

Table 49.5 Cost-Effectiveness of Neonatal Screening for Congenital Hypothyroidism by World Bank Region

Representative country	CH births per 100,000 (birth prevalence)	CH births detected	Program costs for screening and treatment (US\$)	Cost per disability averted (US\$)	Cost without testing (US\$)	Cost savings (US\$)

Pakistan	100.00	95.00	3,417,801	35,977	18,145,000	14,727,199
<i>Sub-Saharan Africa</i>						
South Africa	24.13	22.93	2,239,768	97,686	4,379,292	2,139,524

100,000 children tested. Lifetime discounted (at 6 percent) treatment costs are US\$6,292.64 in 2004 dollars (Barden and Kessel 1984). Analysis of costs and benefits in table 49.5 shows that, although screening for the population as a whole requires considerable investment and infrastructure, the burden from the disorder is high and treatment is cheap. Screening all newborns is beneficial compared with the high costs of lifelong care for the affected individuals. Cost savings are positive for all representative countries despite high variance in the prevalence of CH. Even for a low birth prevalence estimate of 4 out of every 100,000 in Thailand (Wasant, Liammongkolkul, and Srisawat 1999), the cost savings would be US\$106,326.

Effectiveness of the newborn screening in identifying the affected infants depends on the ability of the screening program to collect blood samples from all infants in the first week and to perform tests in time to initiate treatment. This effort may be difficult in some settings, where infants are born at home or released on the first day after birth and do not have contact with the health care system in the first month of their lives (Sack, Feldman, and Kaiserman 1998). The wider the coverage of the screening program, the higher will be the cost savings of screening. Also, follow-up screening for those infants who test as false negative will increase sensitivity to 100 percent and improve cost-effectiveness of the program.

In our cost-effectiveness analysis, we assumed the lifetime care and treatment costs to be similar to those estimated for the United States. However, medical costs may vary significantly among and within countries. Such variation is unlikely to alter

the cost-effectiveness analysis, because the difference between program and treatment expenditures and lifetime costs will remain even after we scale the medical costs.

The analysis presented above is limited to an evaluation of the cost-effectiveness of neonatal screening for CH. For minimal extra cost, collected blood samples for CH can also be used to identify other inherited disorders, including phenylketonuria, maple syrup urine disease, and other inborn errors of metabolism. Without the benefits of early detection and treatment for these conditions, the result is severe MR.

Community-Based Rehabilitation

Community-based rehabilitation is a set of low-cost approaches to providing rehabilitation services such as physical therapy, occupational therapy, prosthetics, and assistive devices for people with disabilities in developing countries. Such rehabilitation also aims to minimize stigmatization of people with disabilities and to support inclusive education and integration of people with disabilities into society. WHO and other organizations have actively promoted community-based models for providing rehabilitation services—including services for children with developmental disabilities—in resource-poor settings (Institute of Medicine Committee on Nervous System Disorders in Developing Countries 2001).

Although 80 percent or more of the world's people with disabilities live in developing countries, only 2 percent have access to rehabilitation services (WHO Community-Based

Rehabilitation 1982). If families of people with disabilities are taken into account, the number of people experiencing the effects of disability is estimated to be up to 25 percent of the world population. Community-based rehabilitation is designed to expand access to rehabilitation services in poor and rural areas by providing training in rehabilitation techniques to individuals with disabilities, their family members, and others in their communities. It also attempts to change negative attitudes toward disability and to remove barriers in the physical environment that prevent people with disabilities from fully participating in society.

Costs. In the community-based rehabilitation model, community interventions are shifted from institutions and centers to the homes and communities of people with disabilities and are carried out largely by family members and volunteers. By using volunteer workers and the existing infrastructure in the communities, this form of rehabilitation minimizes costs of delivering services and is assumed to be cost-effective relative to the alternative institution-based rehabilitation (Institute of Medicine Committee on Nervous System Disorders in Developing Countries 2001; WHO Community-Based Rehabilitation 1982; Lagerkvist 1992). Institutional care has higher costs because it relies on paid staff, medical equipment, building maintenance, and medical costs. Some advocate for provision of institutional, center-based, medical, and community-based approaches in a complementary fashion. In a Zimbabwean community-based rehabilitation project two-thirds of the patients were referred to hospitals or clinics (Rottier and others 1993). Annual costs for training workshops and salaries of rehabilitation workers amounted to US\$60,000 to treat 1,614 individuals with disabilities.

Little information is available about the full costs of community-based rehabilitation and how they vary across disabilities, age groups, and societies. The cost-effectiveness of such rehabilitation or whether its costs are lower than alternative rehabilitation models is unknown. It is usually implemented in settings where no other rehabilitation models exist. The costs to consumers in terms of their efforts, time, and money may be substantial (Thomas and Thomas 1998). No formal estimates are available of time costs and opportunity costs to family members involved in community-based rehabilitation. Meeting the needs of a family member with a disability may prohibit or disrupt labor force participation of the caregiver and reduce family income. This need for caregiving may especially affect women (Giacaman 2001). The effectiveness of community-based rehabilitation in improving functional outcomes for children with cerebral palsy in Bangladesh showed no improvement, but researchers unexpectedly found a significant increase in reported stress and symptoms of depression in the mothers of children in the community-based rehabilitation intervention group (McConachie and others 2000).

Efficacy. Other attempts to evaluate community-based rehabilitation in different settings and for a range of outcomes include one for preschool children with disabilities in rural Guyana. The children showed significant improvement after six months in the program, and noticeable improvements in the attitudes of parents and others toward children with disabilities were seen (O'Toole 1988). Community-based rehabilitation programs in the Philippines and Zimbabwe found gains in activities of daily living and communication as well as higher rates of starting school and employment after six months in the program (Lagerkvist 1992). Similarly, people with disabilities participating in a community-based rehabilitation program in Botswana showed high levels of independence in activities of daily living; 20 percent of adults were working, and most school-age children were attending class (Lundgren-Lindquist and Nordholm 1996).

Some have questioned the efficacy of community-based rehabilitation and its ability to expand access for people with disabilities. Many people with disabilities do not patronize such programs, and many who do try leave dissatisfied (Kassah 1998). After initial diagnosis, only half of the identified individuals with disabilities continued (Rottier and others 1993). Community-based rehabilitation programs also face the difficulty of working in diverse communities with unique cultural, religious, economic, and social conditions, making it difficult for a single model to meet the needs for rehabilitation services in developing countries (Crishna 1999).

Prevention of Premature Birth

Premature birth—after 20 weeks but before 37 weeks—is a powerful predictor of death and disability. Infants born before 28 weeks of gestation have a 50-fold increased risk of cerebral palsy (Drummond and Colver 2002) and heightened risk of sensory, cognitive, and educational impairment (Taylor and others 2004). The rate of preterm births in the United State has increased steadily since 1990 (MacDorman and others 2002). Survival of infants born before 34 weeks requires intensive and expensive medical care (Gilbert, Nesbitt, and Danielsen 2003), and the global survival rate differs depending on neonatal care availability (Lorenz and others 2001). Infection or inflammation of the placenta is common in preterm pregnancies (Goldenberg and Culhane 2003), and many deaths attributed to asphyxia may be caused by maternal, placental, or neonatal infection. The cerebral palsy rate is significantly higher in premature infants whose births are monitored electronically (Shy and others 1990). With the exception of magnesium sulfate administered to women in preterm labor (Crowther and others 2003), no specific interventions result in decreased cerebral palsy among premature infants (Crowther and Henderson-Smart 2004).

Dietary supplements might decrease the frequency of low-birthweight births and perhaps the frequency of marked prematurity. In Bangladesh, where the rate of preterm labor

was high, women who went into labor before term were older, shorter, thinner, less educated, and more disadvantaged economically, with closer spacing of births (Begum, Buckshe, and Pande 2003). Deaths attributable to prematurity in LMICs are seldom due to poor management and are largely related to poor health facilities (Pattinson 2004).

Electronic Fetal Monitoring in Labor

For decades most cerebral palsy and a major share of MR, epilepsy, and learning and behavioral disorders of childhood were considered to be due to deprivation of oxygen supply to the fetus during birth. Recent research confirms that only a minority of cerebral palsy cases, as well as associated MR and seizures, are related to markers of birth asphyxia (Nelson and Ellenberg 1986; Torfs and others 1990). Low Apgar scores, the need for respiratory support, and neonatal seizures are more commonly due to etiologies other than asphyxia, most notably intrauterine exposure to infection (Wu and others 2003). So that medical workers could recognize the onset of asphyxia and “rescue” the fetus, continuous electronic fetal monitoring (EFM) of the fetal heart rate during labor was introduced in the 1970s. This intervention was disseminated before being tested in randomized trials to compare continuous electronic monitoring with intermittent observation by stethoscope (auscultation). Since the introduction of EFM, fetal death in labor has decreased, the cesarean section rate has quadrupled (Natale and Dodman 2003), and the rate of cerebral palsy has remained steady. Accordingly, EFM cannot be recommended for use in LMICs. Intermittent auscultation with a stethoscope appears to be the appropriate way to monitor fetal status during labor.

RESEARCH AGENDA FOR PREVENTION OF DISABILITIES IN LOW- AND MIDDLE-INCOME COUNTRIES

Research needed as a basis for developing policies and interventions to prevent LDD in low- and middle-income countries includes basic research, epidemiology, and evaluations of early interventions, clinical treatments, prevention strategies, and health services that are culturally appropriate and feasible. Suggested research priorities include the following:

- etiology and prevention of adverse pregnancy outcomes associated with LDD, such as low birthweight, preterm birth, intrauterine growth retardation, and related factors
- community-based rehabilitation, including effectiveness, cost-effectiveness, and social effects of different models for providing rehabilitation services and special education to children with LDD in LMICs

- methodological and prevalence studies to ensure that the impacts of LDD are effectively measured by DALYs or other international indicators
- cost-effectiveness of interventions to prevent specific nutritional, infectious, genetic, and other causes of LDD
- impact on child development of multiple insults and risk factors especially common in LMICs, such as neurotoxic exposures, trauma, infectious disease or malnutrition, poverty, maternal illiteracy, and other social factors
- health services research related to access to prenatal care and prenatal and newborn screening and evaluation of components of the public health system that might impair or enhance integration of services for patients with LDD
- prevalence of ADHD and a cost-benefit analysis of the use of psychotropic medications
- prevalence and costs of autism spectrum disorders
- strategies to improve interventions for the prevention of fetal alcohol syndrome and to develop effective intervention programs for children affected by prenatal alcohol exposure
- evaluation of criteria for newborn screening and effects of new technology on measured incidence, costs, and system effectiveness
- evaluation of financing of successful newborn screening and treatment programs
- model systems of care for individuals diagnosed through newborn screening from infancy to adulthood.

SUMMARY

Many potential interventions exist for the prevention of LDDs, and relatively few are being implemented for the benefit of children in LMICs. The following three interventions are effective and cost-effective in preventing LDD:

- Folic acid fortification of the food supply can reduce the occurrence of NTDs by 50 percent or more. This intervention was found to be highly cost-effective in the United States; however, in low-income countries, high capital and running costs may compromise cost-effectiveness, at least in the short run.
- Prenatal screening and selective pregnancy termination to prevent DS are highly cost-effective under some conditions but raise ethical, social, and cultural concerns that may preclude their applicability in some LMICs. Screening is not only expensive; it also has negative health outcomes: the false-positive rates and the subsequent anxiety, a risk of miscarriage of an unaffected pregnancy, and the resulting potential complications from pregnancy termination. Another concern is that, where access to prenatal care is limited, the potential for public health benefits of prenatal screening will be small.

- Neonatal screening and treatment for CH is highly cost-effective in developed countries, where it provides a low-cost strategy for preventing MR. For minimal extra cost, collected blood samples from newborns can also be used to identify and prevent the disabling effects of other inborn errors of metabolism, such as phenylketonuria and maple syrup urine disease. However, when only a part of the newborn population is reached by screening, high costs will be incurred to care for those missed by the screening, thereby reducing the cost-benefit ratio.

For another type of intervention considered, community-based rehabilitation, costs and benefits have not been quantified sufficiently to allow evaluation. Such rehabilitation is designed to expand access to services in poor and rural areas, to change negative attitudes toward disability, to lower the costs of delivering services, and to enhance the participation of persons with disabilities in society. The benefits of community-based rehabilitation may come at a high cost in terms of time and financial resources of family members.

Another intervention, electronic fetal monitoring in labor, has been shown to be unsuccessful in preventing childhood neurological disability associated with premature birth: the risk of cerebral palsy was significantly higher in infants delivered using EFM. Consequently, this intervention is not recommended for use during labor.

DALY estimates are not available to convey the full range of LDDs or their risk factors. However, available data are consistent with the possibility that these disabilities account for a large proportion of the global burden of disease. Quantifying the impacts of LDDs and their preventive interventions is complicated by the fact that these disorders can exist at multiple levels and that disability is context-specific, with impacts that may vary across cultures. Several research priorities for improving knowledge and developing policies and interventions to prevent LDD in LMICs are suggested.

Loss of Vision and Hearing

Joseph Cook, Kevin D. Frick, Rob Baltussen, Serge Resnikoff, Andrew Smith, Jeffrey Mecaskey, and Peter Kilima

Although the loss of vision and hearing has multiple causes, and the burden of these diseases is complex, three major points emerge from the outset:

- Impairments of the essential senses of vision and hearing contribute to early demise and are important causes of morbidity for individuals who are blind or deaf.
- Cost-effective interventions are available to address several causes of these burdens now.
- The number of cost-effectiveness analyses of interventions to preserve hearing or vision in developing countries is quite limited.

Table 50.1 summarizes the conditions causing the sensory deficits, the proposed interventions and sites of delivery, and the cost and effectiveness of these interventions to the extent of current knowledge. Earlier work by Evans and others (1996) in Myanmar does not appear because the cost data are quite old and because the cost-effectiveness data were in dollars per case of blindness averted rather than dollars per disability-adjusted life year (DALY) averted, which the latest information provides.

NATURE, CAUSES, AND EPIDEMIOLOGY OF VISION LOSS

Table 50.2 provides definitions of visual impairment, blindness, and low vision according to the *International Classification of Diseases, Injuries, and Causes of Death* (WHO 1993). At this time, the World Health Organization (WHO) is considering changing the classification in order to take into

account uncorrected refractive errors, but this change has not yet been approved.

The major causes of adult-onset blindness are cataract (47.8 percent), glaucoma (12.3 percent), macular degeneration (8.7 percent), diabetic retinopathy (4.8 percent), trachoma (3.6 percent), and onchocerciasis (0.8 percent). Uncorrected refractive errors are also a major cause of morbidity related to vision, but this type of disability is not included in the global burden of disease by definition. It has been estimated to be on the order of 15 percent of the total blind population and could add 50 percent to the low-vision population. However, there are no published data to do more than speculate.

The major causes of childhood vision loss have marked regional variations. They include vitamin A deficiency (xerophthalmia) and ophthalmia neonatorum in low-income countries, retinopathy of prematurity and hereditary conditions in middle-income countries, and congenital cataract and glaucoma everywhere. Table 50.3 shows the estimated number of blind persons worldwide in 2002.

Vision loss is chronic and, almost invariably, without remission. The extent of morbidity is related to the level of alteration of vision function. However, 80 percent of cases are avoidable, either through treatment (cataract and refractive errors) or through primary prevention (onchocerciasis, trachoma, glaucoma, and diabetic retinopathy). Strictly speaking, blindness attributable to glaucoma and diabetic retinopathy can be prevented. However, prevention depends on the availability of a simple, cheap, and efficacious diagnostic test and rigorous treatment. These are not readily amenable to public health programs even in the most technologically advanced countries, especially in the case of glaucoma.

Table 50.1 Cost and Effectiveness Data for Vision and Hearing Care Interventions

Condition	Intervention	Cost data (2004 US\$)	Effectiveness data	Incremental cost-effectiveness data (2004 US\$/DALY averted)
Trachoma	Trichiasis surgery	7.14 per village-based surgery ^a	77 percent cure rate over two years ^b	4–82 ^c
	Tetracycline	—	51 percent cure rate in children at six months following treatment ^d	>9,600 ^d
	Azithromycin	—	88 percent cure rate in children at six months following treatment ^e	>4,100 ^d
Cataract	Extracapsular surgery	—	—	<200 (low- and middle-income countries); <2,400 (high-income countries) ^p
Onchocerciasis	Ivermectin	—	—	40 ^f

Burden of Loss for Vision and Risk Factors

The risk factors for loss of vision are age, gender, poverty, and poor access to health care. The overall prevalence of vision loss, which mainly affects the population above age 40, is a function of age. It is estimated that more than 82.2 percent of all blind individuals are 50 or older. Increasing life expectancy results in a growing number of cases of age-related blindness (for example, cataract, glaucoma, macular degeneration). Among the 50 and older age group, cigarette smoking is a clear risk factor for both cataract and macular degeneration. Childhood vision loss represents approximately 4 percent of the total number of visually impaired. However, it is the second largest cause of “blind-person years,” following cataract. Retinopathy of prematurity

Table 50.3 Number of Blind Worldwide in 2002 from Various Conditions

Condition	Number blind (millions)
Cataract	17.6
Glaucoma	4.5
Age-related macular degeneration	3.2
Corneal opacity	1.9
Diabetic retinopathy	1.8
Childhood blindness	1.4
Trachoma	1.3
Onchocerciasis	0.3
Other causes	4.8
Total	36.8

Sources: Pascolini and others 2004; Resnikoff and others 2004.

(ROP) is an important cause in middle-income countries (Gilbert and Foster 2001). Unfortunately, screening for ROP in preterm infants, as well as the organization and provision of low-vision services, is a tertiary-level function (requiring a well-equipped clinic or hospital with the most modern facilities), and no data on cost-effectiveness of interventions are available. More disease-specific factors are poor hygiene, overcrowding, ultraviolet radiation, diabetes mellitus, drugs, micronutrient deficiency, heredity and ethnic background, and consanguinity.

Estimates of the global burden of visual impairment in 2002 were updated using the most recent available data on blindness and low vision (Pascolini and others 2004). The global number of people who are visually impaired is in excess of 161 million,

of whom 36.8 million are blind (Resnikoff and others 2004). Because the international definition refers to the best-corrected visual acuity (table 50.2), these figures actually underestimate the magnitude of the global burden of the visual impairment, especially in developing countries, where most of the refractive errors are not corrected (Dandona and Dandona 2003; Fotouhi and others 2004; Naidoo and others 2004). A WHO working group has recommended the use of the more accurate “presenting vision,” recognizing that many people do not have their best-corrected vision. This recommendation is under review and, if approved, would substantially increase the estimates of the burden of disease attributable to impaired vision.

The number of women with visual impairment, as estimated from the available studies, is higher than that of men, even after adjustment for age. Female-to-male prevalence ratios indicate that women are more likely to have a visual impairment than men in every region of the world: the ratios from past studies range between 1.5 to 1 and 2.2 to 1. (Resnikoff and others 2004). The major reported reason is women’s reduced access to eye care services. Higher exposure to risk factors also contributes in the case of trachoma. (Abou-Gareeb and others 2001; Nirmalan, Padmavathi, and Thulasiraj 2003).

Several population-based surveys reported higher risk of mortality among people with visual impairment. Relative risk of mortality among blind and low-vision people varied from 1.5 to 4.1 and from 1.1 to 1.6, respectively. In industrial countries, the relative risk of mortality varied from 1.6 to 2.0. The effect may vary by gender (Lee and others 2002; Taylor and others 1991). The link between visual impairment and mortality remains poorly understood and cannot be attributed to known associations with underlying disease.

The burden from visual impairment accounts for approximately 3 percent of the total global burden of disease and 9 percent of total years lived with disability in 2001. Table 50.4 shows the global burden by vision-related cause in DALYs. Globally, half of the burden from visual impairment is due to cataract.

The burden of visual impairment is not distributed uniformly throughout the world; the least developed regions carry the largest share, as shown by World Bank region in table 50.5. Local and in-country variations, as well as regional variations, are related to the following factors:

- Epidemiology of cause (for example, onchocerciasis, trachoma).

Table 50.4 Global Burden of Visual Impairment, by Major Cause, 2002

Condition	Blindness (thousands of DALYs)	Low vision (thousands of DALYs)	Visual impairment		
			Thousands of DALYs	Percentage of total YLDs	Percentage of total DALYs
Cataract	8,798	15,053	25,251	4.5	1.7
Glaucoma	1,202	2,442	3,866	0.7	0.3
Trachoma	1,403	772	2,329	0.4	0.2
Onchocerciasis	203	146	484	0.1	0.0

- Socioeconomic patterns (poverty and socioeconomic deprivation), an essential element in most causes.
- Access to adequate eye care. Uneven access to good-quality eye care (for example, for cataract, glaucoma, diabetic retinopathy) results from such factors as distance, affordability, and culture. Lack of resources is only part of the problem; existing facilities are sometimes underused.

Interventions

Not all causes of visual impairment can be addressed using public health types of interventions. Cataract, trachoma, childhood blindness, and onchocerciasis are discussed below.

Cataract. Surgery to remove the opacified lens is the only effective treatment for cataracts. Neither diet nor medications have been shown to stop cataract formation. There are several possible approaches for the surgical extraction of cataracts. Intracapsular cataract extraction using aphakic glasses is a technique by which the whole lens is removed from the eye. After surgery, special eyeglasses are provided to patients to restore sight. A disadvantage of this intervention is the non-compliance of people who need to wear glasses, which has been found to be between 18 and 73 percent. Although this behavior may be characterized as noncompliance, it must be said that some programs do not provide glasses or provide aphakic glasses of inferior quality. Also, replacing needed aphakic glasses is impossible for some patients. It is also true that aphakic glasses cause tremendous distortions in vision, thus impairing compliance.

In extracapsular cataract extraction with implantation of a posterior chamber intraocular lens, the lens and the front portion of the capsule are removed and then replaced with an artificial lens. Baltussen, Sylla, and Mariotti (2004) have evaluated work on the cost-effectiveness of cataract surgery. That work (done by WHO regions rather than by World Bank regions) showed that both intracapsular and extracapsular surgeries are cost-effective ways to reduce the impact of cataract blindness. However, extracapsular surgery is both less costly and more effective than intracapsular surgery and can therefore be considered the best choice for cataract control. Its cost-effectiveness ratios are below US\$200 per DALY averted in low- and middle-income countries and below US\$2,400 in high-income countries.

Trachoma. WHO recommends an integrative approach to trachoma control through its SAFE strategy (surgery, antibiotics to control the infection, facial cleanliness, and environmental improvements). The facial cleanliness and environmental improvements are preventive public health measures aimed at reducing the incidence of infection. Antibiotic treatment, especially when given on a mass or community basis, is both primary prevention (reducing transmission in the community) and secondary prevention (treating active infection to avoid

morbidity). Surgery is in fact tertiary prevention—that is, repairing (and halting further) damage. The SAFE strategy has not been subjected to a comprehensive economic evaluation, but some cost-effectiveness information is available regarding the antibiotic and surgery components.

The initial trachoma infection can be effectively treated with antibiotics, either through mass treatment of all children below 10 years of age or through targeted treatment of infected children and household members. A work by Baltussen and others (2005) for trachoma-endemic areas in the world—similar to studies of cataract control surgery—reveals that interventions using antibiotics cost between US\$4,000 and US\$220,000 per DALY averted for all regions studied. Targeted treatment with antibiotics (be it on the basis of azithromycin or tetracycline) is not cost-effective, and mass treatment of all children (not entire communities) is cost-effective only when azithromycin is donated. In Myanmar, tetracycline has been shown to be moderately cost-effective (Evans and others 1996). Cost-effectiveness studies are not available on mass treatment of entire communities, the approach now most commonly in use with donated azithromycin. Recent studies by Solomon and others (2004) report a 70 percent fall in prevalence in an area in Tanzania; moreover, the total community burden of ocular *Chlamydia trachomatis* infection (measured by polymerase chain reaction) fell to 8.7 percent of pretreatment levels at six months after treatment. Additionally, Chidambaram and others (2004) have demonstrated that, after mass azithromycin treatment of a population in Ethiopia, an indirect protective effect occurred among untreated children who resided in villages in which most individuals had been treated. As noted in table 50.1, greater efficacy of azithromycin than that used to calculate cost-effectiveness of mass treatment of children alone may lead to better cost-effectiveness than shown in the table. To date, if governments purchased the drug, mass distribution would be excessively expensive from a societal perspective. However, from the perspective of the governments of countries in which azithromycin (donated by Pfizer Inc. through the International Trachoma Initiative) is being distributed, mass distribution appears to be relatively cost-effective.

Trichiasis scarring is amenable to surgical repair. To date, the cost-effectiveness analyses that have been done suggest that surgery is not particularly expensive per case of blindness prevented, assuming that the eyelid correction prevents blindness and that the individuals with operated trichiasis are not more likely to be affected by other conditions (for example, dry eye) that might lead to corneal opacification. Baltussen and others (2005) suggest that trichiasis surgery—with cost-effectiveness ranging between approximately US\$4 and US\$82 per DALY averted across trachoma-endemic areas—would be even more cost-effective than cataract surgery.

From these cost-effectiveness evaluations, one could conclude that it is best simply to correct lid damage attributable to

trachoma. Surgery (tertiary prevention) would then remain a low but continuing cost. These evaluations do not, of course, take into account the possibility of eliminating this blinding disease. The implementation of the full SAFE strategy includes primary, secondary, and tertiary prevention, and although more costly at the outset, it could eliminate infection, pain, and blindness (and the need and cost of lid surgery) into the future. The WHO Alliance for the Global Elimination of Trachoma (GET 2020) was established in 1997 to support the work of a broad spectrum of collaborating international organizations, nongovernmental development organizations, and foundations in implementing the SAFE strategy. Kumaresan and Mecaskey (2003) report that 10 countries have initiated trachoma elimination programs using donated azithromycin, and many more programs are expected. They make the point that the promise of elimination provides the justification for investing in trachoma control.

Childhood Blindness. In 1993, WHO estimated that as many as 13.8 million children have some degree of eye damage because of vitamin A deficiency; however, the number of children with actual blindness is much lower—less than 500,000 in 1992. Recent WHO studies (Resnikoff and others 2004) include vitamin A deficiency among causes of childhood blindness. Cost-effectiveness studies of vitamin A supplementation, discussed in chapter 56, focus only on deaths averted unrelated to blindness, but this public health intervention appears to be cost-effective.

Onchocerciasis. Onchocerciasis, or “river blindness,” is endemic in 28 countries in tropical Africa, where 99 percent of infected people live. Isolated foci of infection also occur in Latin America (six countries) and Yemen. Although it accounts for only 0.8 percent of world blindness (Resnikoff and others 2004), the distribution of ivermectin, given at no cost by Merck, has so far proved successful in drastically reducing this cause of blindness. Additionally, patients suffer severe skin lesions and pruritus, also remedied by the annual dosing with ivermectin. Studies have shown that the cost per DALY averted is as little as US\$40 when adjusted for inflation (Waters, Rehwinkel, and Burnham 2004).

During the past 25 years considerable progress has been made by the Onchocerciasis Control Program in West Africa, both through control of the black-fly vector (insecticide spraying) and through the distribution of ivermectin. This success, expressed in health, economic, and development terms, was the motivating rationale for the launching in December 1995 of a new program, the African Program for Onchocerciasis Control. The objective is to create, by 2007, sustainable community-directed distribution systems using ivermectin. In Latin America, the Onchocerciasis Elimination Program in the Americas is successfully using ivermectin dis-

tribution. A coordination group of nongovernmental organizations is working closely with all three onchocerciasis control programs and with national counterparts in virtually all endemic countries. If present efforts in endemic countries are successfully completed, the disease will be brought under control by 2010.

NATURE, CAUSES, AND EPIDEMIOLOGY OF HEARING LOSS

In this chapter, the term *hearing loss*, used by itself, denotes any or all levels of severity of hearing difficulty. These levels of hearing impairment comprise mild (26–40 decibel hearing level, dBHL), moderate (41–60 dBHL), severe (61–80 dBHL), and profound (81 dBHL or greater). The term *deafness* denotes profound hearing impairment (WHO 1991, 1997). Disabling hearing impairment in adults is defined as “a permanent unaided hearing threshold level for the better ear of 41 dB or greater; for this purpose, the hearing threshold level is to be taken as the better ear average hearing threshold level for the four frequencies 0.5, 1, 2, and 4 kHz.” Disabling hearing impairment in children under the age of 15 years is defined as a permanent, unaided hearing threshold level for the better ear of 31 dB or greater; for this purpose, the hearing threshold level is to be taken as the better ear average hearing threshold level for the four frequencies 0.5, 1, 2, and 4 kHz.

Mathers and others (2003) estimate that in 2002, 255 million people worldwide had disabling hearing loss (moderate or worse hearing loss in the better ear). Those 192 million people with adult-onset loss (age 20 years and above) and 63 million people with childhood-onset loss make up almost 4.1 percent of the world’s population and just over 40 percent of all people globally with hearing loss of any severity. The prevalence rates of adult-onset hearing loss were estimated by subtracting the prevalence rate for childhood onset (estimated in terms of prevalence in ages around 15 to 19). Numbers with childhood-onset hearing loss by cause have so far not been estimated separately but are included among sequelae of other diseases (for example, infectious diseases such as meningitis, otitis media, congenital conditions). It has been estimated that at least 50 percent of the burden of hearing loss could be prevented by primary, secondary, and tertiary preventive measures (Brobbly 1989; WHO 1991).

Causes and Characteristics

Hearing loss is grouped according to *International Classification of Diseases and Related Health Problems*, 10th revision, version for 2003 (ICD-10) into conductive and sensorineural loss and other hearing loss, ICD-10 codes 90–91 (WHO 2003). The main causes are shown in table 50.6 according to the proportion that these contribute to the total burden (WHO 1986).

Table 50.6 Main Causes of Hearing Loss, by Proportion of Total Burden

High proportion	Moderate proportion	Low proportion
Genetic causes	Excessive noise	Nutritionally related
Otitis media	Ototoxic drugs and chemicals	Trauma related
Presbycusis	Prenatal and perinatal problems	Menière's disease
	Infectious causes	Tumors
	Wax and foreign bodies	Cerebrovascular disease

Source: WHO 1986.

Chronic otitis media (COM, as in ICD-10 codes H65–H67) includes chronic suppurative otitis media and otitis media with effusion. These forms of otitis media, together with some other middle ear diseases, such as perforation of the tympanic membrane, cholesteatoma, and otosclerosis, are the major causes of conductive hearing loss. In most WHO estimates of the burden of otitis media, the data are not disaggregated into acute and chronic otitis media.

Hearing loss is a chronic and often lifelong disability that, depending on the severity and frequencies affected, can cause profound damage to the development of speech, language, and cognitive skills in children, especially if commencing prelingually. That damage, in turn, affects the child's progress in school and, later, his or her ability to obtain, keep, and perform an occupation. For all ages and for both sexes, it causes difficulties with interpersonal communication and leads to significant individual social problems, especially isolation and stigmatization. All these difficulties are much magnified in developing countries, where there are generally limited services, few trained staff members, and little awareness about how to deal with these difficulties.

In addition to its individual effects, hearing loss substantially affects social and economic development in communities and countries. Ruben (2000), taking into account rehabilitation, special education, and loss of employment, estimated the cost to the U.S. economy in 1999 of communication disorders (hearing, voice, speech, and language disorders) at between US\$176 billion and US\$212 billion (2004 dollars; 2.5–3 percent of the gross national product of the United States in that year). Hearing loss accounted for about one-third of the prevalence of these communication disorders.

Risk Factors

Occupations exposed to high levels of noise or ototoxic chemicals are also at risk, and noise exposure potentiates chemical ototoxicity in some cases (Fechter 1995; Morata 1998). Certain lifestyles (for example, use of personal stereos, noisy toys, firecrackers) and hobbies (for example, hunting) are also linked to levels of noise exposure that can cause hearing loss (Berglund and others 2000; Goelzer, Hansen, and Sehrndt 2001). Smoking may be a risk factor for high-frequency hearing loss, adding to

the effect of noise (Mizoue, Miyamoto, and Shimizu 2003). Other risk factors include poverty, poor access to health care, poor hygiene, and overcrowding, all of which can lead to upper respiratory tract infections, otitis media, and other infections that may cause hearing loss, such as measles and meningitis. Detailed risk factors and indicators have been developed for neonates and infants (Joint Committee on Infant Hearing 2000); these include conditions that should require admission to a neonatal intensive care unit, stigmata of syndromes causing hearing loss, positive family history, craniofacial anomalies, certain in utero and post-natal infections (cytomegalovirus, herpes, rubella, syphilis, toxoplasmosis, meningitis), hyperbilirubinemia, conditions requiring prolonged mechanical ventilation or oxygenation, persistent otitis media with effusion, and others.

Ototoxic medications, low birth-weight, and low Apgar scores have also been cited as risk factors for neonates (Vohr and others 2000). Offspring of consanguineous marriages have a significantly higher incidence of autosomal recessive diseases, including hearing impairment. Such diseases are an important cause in communities where consanguinity is common (Shahin and others 2002; Zakzouk 2000). Certain ethnic groups (First Nations peoples such as Inuit and North American Indians, as well as Australian Aboriginal people) appear to be at higher risk of developing COM (WHO 1998).

Age, Geographic, and Gender Burdens

The prevalence of disabling hearing impairment that increases markedly with age is mainly related to the effect of presbycusis. The current shortage of data, particularly in developing countries, prevents accurate assessment of the global distribution of the burden and causes.

Male-to-female ratios of age-standardized adult-onset prevalence rates were found to be greater than 1 in most studies in all WHO regions (Mathers, Smith, and Concha 2005). This finding may be related to occupational noise-induced hearing loss, which differentially affects men.

Mortality

Barnett and Franks (1999) have found evidence that adults with postlingual onset of deafness have higher mortality than nondeaf adults. A 10-year longitudinal analysis of participants (age 55 to 74 years) in the U.S. National Health and Nutrition Examination Survey I found that, at baseline, hearing loss predicts mortality; relative risk = 1.17 (Mui and others 1998). Other studies have reported that the association disappears after controlling for age, and in any case, any relationship that may exist is too small to appear in published WHO estimates of deaths by cause (WHO 2004a, annex table 2) and by years of life lost, or YLLs (Mathers, Smith, and Concha 2005), in any region. A small number of deaths (4,000 globally in 2002) are recorded for otitis media (WHO 2004a), but these deaths are

mainly due to infective complications and, hence, are not directly caused by hearing loss.

Years Lived with Disability and DALYs

Data on years of life lived with disability (YLDs) and DALYs are available only for adult-onset hearing loss. The disease model used, the assumptions and methods used for calculation, and the disability weights are described elsewhere (Mathers, Smith, and Concha 2005). Total global YLDs for adult-onset hearing loss in 2001 are estimated to be 25.87 million, or 4.7 percent of total YLDs attributable to all causes, which makes hearing loss a leading cause of YLDs. Because YLLs are taken to be zero for all regions, the DALY figures are identical to the YLD figures. The most comprehensive data available are for all adult-onset hearing loss (WHO 2004b; Mathers, Smith, and Concha 2003). Fewer data on the burden are available at present for childhood hearing loss and specific causes.

Interventions

Effective interventions include screening programs, education, surgery, medications, and assistive devices.

Population-Based Interventions. Neonatal or early infant hearing screening is important because early identification of hearing loss (before 6 months of age, with early intervention) is associated with significantly better language development and may lead to better school and occupational performance than that of children identified after 6 months with early intervention (Keren and others 2002; Yoshinaga-Itano and others 1998). Implementation of neonatal hearing screening raises from 20 to 80 percent the numbers of children with normal development of language, compared with children whose hearing loss is detected later (Yoshinaga-Itano and Gravel 2001). Early identification of hearing impairment can reduce the median age of identification of hearing impairment from between 12 and 18 months to 6 months or less. Universal neonatal hearing screening is highly sensitive, but depending on the test method used, it may result in many false positives (which may increase parental anxiety and lead to unnecessary follow-up tests and interventions). It has a low positive predictive value. Some screening protocols may decrease false-positive rates (Kennedy and others 2000). Universal neonatal hearing screening has been endorsed in developed countries (Joint Committee on Infant Hearing 2000), although some experts urge caution (Paradise 1999); however, it is expensive to implement and, for most developing countries, is not yet an option. Hearing screening targeted at high-risk neonates is generally used in developing countries that do any type of neonatal screening, but screening may fail to detect 50 percent or more of cases of impairment (Lutman and Grandori 1999). Neonatal screening programs will not detect the 10 to 20 percent of cases of permanent childhood hearing impairment that

starts later in life and for which later surveillance is needed (Grote 2000). No publications were found that have addressed the DALY burden that might be avoided by implementing neonatal hearing screening.

A recent WHO meeting of experts on noise-induced hearing loss (WHO 1998) concluded that exposure to excessive noise is the major avoidable cause of permanent hearing impairment worldwide. They agreed that, in developing countries, occupational noise and urban environmental noise are increasing risk factors for hearing impairment. Experts attending the meeting recommended that all countries implement national programs for prevention of noise-induced hearing loss, including effective hearing conservation. However, there are no published reports yet on the effectiveness of such programs in developing countries. The United States has produced a guide to hearing conservation programs in the workplace (Franks, Stephenson, and Merry 1996). It advises how to appraise programs by assessing the completeness of their components and by evaluating both the individual audiometric data for threshold shift and the group data for variability compared with a nonexposed population. Even in developed countries, there have been few, if any, clinical trials and little convincing evidence of the efficacy of occupational hearing conservation programs (Dobie 1995).

Personal Services. Chronic suppurative otitis media is one of the most common causes of hearing impairment in developing countries. Opportunities for prevention arise at all levels of national health systems, particularly in the community and at the primary level through primary ear and hearing care (PEHC) (WHO 1998). Appropriate health promotion measures include breastfeeding, immunization, adequate nutrition, personal hygiene, improved housing, reduced overcrowding, and adequate access to clean water. Primary health care workers can be given appropriate training and basic equipment for early detection and management of chronic suppurative otitis media, but the effectiveness and cost-effectiveness of this intervention in developing countries has not yet been assessed.

Although WHO does not currently recommend treating what is commonly called *chronic middle ear infection* with antibiotics at the primary level (WHO 2000), evidence suggests that antibiotics, especially topical quinolones, are more effective and cost-effective than ear toilet alone (Acuin, Smith, and Mackenzie 2000). WHO is reviewing these recommendations (WHO 2004b). New methods of delivery of effective but expensive topical antibiotics may lower the cost in poor communities, but treatment failure may be due to a high reinfection rate attributable to poor hygienic conditions. To be effective as public health measures, interventions need to be implemented on a large scale, with good coverage of the targeted population (van Hasselt and van Kregten 2002). Ear surgery plays an essential part in the prevention of further hearing impairment and, sometimes, in the improvement of hearing.

Services at the secondary level of intervention include provision of hearing aids in developing countries, which should assign priority to children with moderate or severe hearing loss, followed by adults (Arslan and Genovese 1996; WHO 2004c). However, even though globally about 6 million hearing aids are dispensed annually (WHO 1999), there have been no published randomized, controlled trials of the effectiveness of hearing aids in reducing hearing disability in developing countries and few trials in developed countries.

A randomized trial of amplification in 194 U.S. veterans showed significant improvements in communication, cognition, and social and emotional function, plus significant alleviation of depression, with hearing aids compared with controls (Mulrow and others 1990). No significant differences were observed in clinical effectiveness and cost-effectiveness between newer hearing aids that use digital signal processing and those that do not—in particular, analog-based aids (Parving 2003; Taylor, Paisley, and Davis 2001). Digital signal processing aids are not affordable for most people in developing countries. Over-the-counter hearing aids that can be purchased and used without prior training are commonly available in some developing countries. Those aids were found not to meet the prescription gain requirements of the majority of elderly clients who usually purchased them (Cheng and McPherson 2000).

Learning to use a hearing aid and developing “hearing tactics” are also important. Random assignment to a course for new hearing aid users significantly reduced the handicap compared with controls not assigned (Beynon, Thornton, and Poole 1997). Lack of compliance in use is a substantial problem everywhere among elderly and child users, including in developing countries (Furuta and Yoshino 1998; Sorri, Luotonen, and Laitakari 1984). Thus, measuring coverage without taking into account actual usage is not enough to assess alleviation of the burden.

Cochlear implants are provided to children and adults with severe and profound bilateral deafness on the basis that known short-term outcomes in auditory receptive skills (Richter and others 2002) will translate through various medium-term outcomes into greater social independence and quality of life (the social and quality outcomes have not yet been tested in a trial or observational study) (Summerfield and Marshall 1999). Cochlear implantation is beneficial in prelingually and postlingually deaf children (Makhdoum, Snik, and van den Broek 1997) and, when accompanied by aural (re)habilitation, leads to higher rates of mainstream placement in schools and lower dependence on special education support services (Francis and others 1999). Multichannel implants are superior to single-channel implants (Cohen, Waltzman, and Fisher 1993) and are more beneficial when implanted in young children (Richter and others 2002). There has been no economic analysis of cochlear implants in developing countries, and such interventions are currently not a priority in most parts of the developing world (Berruecos 2000; WHO 2004c; Zeng 1995).

Intervention Cost and Cost-Effectiveness. All the data on the costs and cost-effectiveness of interventions related to hearing loss (including school-age screening, treatment of COM, surgical interventions, hearing aids, and cochlear implants) come from developed countries. Although they can be summarized quite readily, it is not clear whether and how they relate to the costs that would be experienced in developing countries.

RESEARCH AND DEVELOPMENT AGENDA

The public health research and development agenda for controlling and reducing the burden of disease related to the loss of sight and hearing should include the following:

- further population-based studies on the magnitude, causes, and distribution of the burden
- economic analysis, especially on cost-effectiveness (for example, cost-effectiveness of each of the components of the SAFE strategy in trachoma control)
- research to develop eye and hearing care systems
- operational research on eye and hearing care delivery (particularly for cataract, diabetic retinopathy, and affordable hearing aids in underserved areas)
- clinical and field trials on interventions: pneumococcal and meningitis vaccines, treatment for chronic suppurative otitis media, primary care of ears and hearing, and prevention of noise damage.

Basic scientific research, particularly for age-related macular degeneration, must move forward, as it is doing in the industrial countries, where this disease constitutes a major burden and where highly developed research establishments exist.

CONCLUSIONS: PROMISES AND PITFALLS

With what we now know about some of the cost-effective interventions cited above, we could make significant reductions in the burden of disease related to loss of vision. Although waiting for someone to have a condition and then remedying the situation is not a particularly common “public health” recommendation, given the costs of and knowledge of prevention at this point, we can strongly recommend surgery both for cataract (the primary option) and for trachoma (apparently a better use of resources than mass treatment with antibiotics—even if not acceptable on a humanitarian basis). For example, clearing the backlog of cataract surgery globally could reduce the DALYs associated with vision loss by more than half.

Hearing loss interventions have only begun to demonstrate their potential effectiveness in developing countries, and no cost work has been done in these settings. Furthermore, although the means to reduce the burden of adult-onset hearing loss are not as straightforward nor as easily applied,

eliminating adult hearing loss would avoid slightly more YLDs than eliminating the cataract surgery backlog. The data suggest that these interventions (particularly cataract surgery) are relatively cost-effective, but a lack of political will, a failure to recognize that steps can be taken now, insufficient capacity within ministries of health to carry out the known beneficial interventions, and, finally, a lack of equipment or funding for the programs still remain barriers to alleviating disabilities related to vision and hearing loss.

Cost-Effectiveness of Interventions for Musculoskeletal Conditions

Luke B. Connelly, Anthony Woolf, and Peter Brooks

BURDEN OF MUSCULOSKELETAL DISEASE

Musculoskeletal conditions are the most common cause of chronic disability around the world. The importance of musculoskeletal conditions as a cause of mortality and morbidity has been recognized by the designation of 2000–10 as the Bone and Joint Decade (Hazes and Woolf 2000) by the United Nations, World Health Organization (WHO), and more than 60 countries around the world. WHO (2003, 2004) has highlighted the burden of musculoskeletal conditions. Estimates of the global burden of these conditions have increased 25 percent over the past decade (WHO 2000). Conditions considered under this rubric include osteoarthritis (OA); inflammatory arthritis (rheumatoid arthritis and the seronegative spondyloarthropathies); back pain; musculoskeletal injuries, including sports injuries; crystal arthritis (gout and calcium pyrophosphate disease), and metabolic bone disease, principally osteoporosis (OP).

Back pain is extremely common in both industrial and developing countries, with up to 50 percent of workers suffering an episode each year. Back pain causes 0.8 million disability-adjusted life years (DALYs) each year and is a major cause of absence from work and of correspondingly high economic losses. Nearly 40 percent of back pain is due to occupational risk factors, and many of these factors can be prevented with the cooperation of labor, management, industrial engineers, ergonomists, and health workers.

OA is increasing among the world's aging populations and is the sixth leading cause of years lost because of disability globally. It accounts for nearly 3 percent of the total global years lost to disability, and 10 percent of men and 18 percent of women

over the age of 60 have OA. Table 51.1 provides an estimate of the contribution of musculoskeletal conditions to the global burden of disease, including a disaggregation by gender and between the developed and developing world. The proportions presented in the second and third panels are the most noteworthy data in table 51.1. First, the second panel shows that musculoskeletal conditions account for approximately 1.7 and 2.4 percent of the burden of disease experienced by males and females, respectively, or, across both genders, approximately 2 percent of the global burden of disease. The disaggregation by developing and developed regions, however, shows that while musculoskeletal conditions account for around 3.4 percent of the total burden of disease in the developed world, they account for 1.7 percent in the developing world. The data also show that, of the set of musculoskeletal conditions, OA accounts for the largest burden, approximately 52 percent of the total in developing regions and 61 percent in developed regions.

Table 51.2 provides a further disaggregation of the estimated burden of musculoskeletal conditions by developing region and mortality stratum. Note that the burden of disease caused by musculoskeletal conditions varies considerably by region: in Africa, mortality stratum D, musculoskeletal conditions account for less than 1 percent of the burden from all causes, while in the Western Pacific, mortality stratum B, they account for more than 3 percent of the total burden of disease. Similarly, the relative importance of rheumatoid arthritis (RA) and OA varies considerably by region. In the African regions, where the prevalence of RA is low, only 12 percent of the burden created by musculoskeletal diseases is due to RA; in the Americas, however, that proportion is approximately 24 to 27 percent.

Table 51.1 Estimated Burden of Musculoskeletal Diseases, by Gender and by Developed or Developing Regions, 2001

	Total	Males	Females	Developing regions (both genders)	Developed regions (both genders)
Numbers of DALYs (thousands)					
Rheumatoid arthritis	4,757	1,353	3,404	3,238	1,520
Osteoarthritis	16,372	6,621	9,750	11,049	5,323
Other musculoskeletal diseases	8,699	5,033	3,638	6,789	1,880
All musculoskeletal diseases	29,798	13,007	16,792	21,076	8,723
Percentage of total DALYs					
Rheumatoid arthritis	0.32	0.18	0.49	0.27	0.59
Osteoarthritis	1.12	0.86	1.39	0.91	2.05
Other musculoskeletal diseases	0.59	0.65	0.52	0.56	0.73
All musculoskeletal diseases	2.03	1.69	2.40	1.74	3.37
Percentage of musculoskeletal DALYs					
Rheumatoid arthritis	15.96	10.40	20.27	15.36	17.42
Osteoarthritis	54.94	50.91	58.07	52.43	61.02
Other musculoskeletal diseases	29.10	38.69	21.66	32.21	21.56

Note: Totals may not sum due to rounding.

Table 51.2 Estimated Burden of Musculoskeletal Conditions by Region and Mortality Stratum, Selected WHO Regions, 2001

Condition	Africa		Americas		Southeast Asia		Eastern Mediterranean		Western Pacific
	D	E	B	D	B	D	B	D	B
Numbers DALYs (thousands)									
Rheumatoid arthritis	127	141	532	83	117	855	99	218	1,065
Osteoarthritis	625	687	969	117	931	2,474	227	577	4,442
Other musculoskeletal diseases	285	316	677	107	516	1,756	159	408	2,590
All musculoskeletal diseases	1,037	1,144	2,178	307	1,564	5,085	485	1,203	8,097
Percentage of total DALYs									
Rheumatoid arthritis	0.09	0.07	0.66	0.47	0.19	0.24	0.43	0.19	0.44
Osteoarthritis	0.42	0.33	1.19	0.67	1.52	0.69	0.99	0.51	1.84
Other musculoskeletal diseases	0.19	0.15	0.83	0.60	0.84	0.49	0.69	0.36	1.06
All musculoskeletal diseases	0.70	0.55	2.68	1.74	2.55	1.42	2.11	1.06	3.34
Percentage of musculoskeletal DALYs									
Rheumatoid arthritis	12.28	12.29	24.45	27.23	7.50	16.82	20.38	18.11	13.19
Osteoarthritis	60.27	60.10	44.49	38.50	59.51	48.66	46.90	47.97	54.99
Other musculoskeletal diseases	27.44	27.61	31.06	34.27	32.99	34.53	32.71	33.92	31.82

Source: Calculated from WHO (2004).

Notes: The letters in the column heads refer to mortality strata. B = low child and low adult mortality, D = high child and high adult mortality, E = high child and very high adult mortality.

RA has a prevalence of 0.7 to 0.1 percent worldwide and results in significant work disability and long-term treatment costs. In addition, OP is increasing with the aging of populations: one in three people over the age of 50 suffers a fracture

because of OP. Back pain, OA, trauma, and RA account for 32,948,765 DALYs, or 2.15 percent of the global total for 2000.

A recent review of the prevalence of rheumatic disorders in Sub-Saharan Africa suggests that the frequency of RA is

increasing in East, Central, and South Africa but is rare in West Africa (McGill and Oyoo 2002). Gout is also prevalent throughout the continent, and the HIV epidemic has spawned a variety of associated spondyloarthropathies among the aging population. Countries such as Thailand are also recognizing an increasing burden of disease caused by arthritis and trauma (Jitapunkul and others 2003).

NATURE, CAUSES, AND EPIDEMIOLOGY OF MUSCULOSKELETAL CONDITIONS

Osteoarthritis is the most common condition affecting human joints and causes significant disability. The principal clinical features are pain, which varies in severity and character, and stiffness. Disability occurs as a result of pain, weakness, joint instability, and reduced range of motion.

The following are the major forms of inflammatory arthritis:

- rheumatoid arthritis
- seronegative spondyloarthropathies
 - ankylosing spondylitis
 - reactive arthritis
 - enteropathic arthritis
 - psoriatic arthritis
- juvenile chronic arthritis
 - systemic
 - pauciarticular
 - polyarticular
- arthritis associated with systemic connective tissue diseases
 - systemic lupus erythematosus
 - progressive systemic sclerosis
 - vasculitis
 - polydermatomyositis
- crystal arthritis
 - gout
 - calcium pyrophosphate deposition disease

RA has a prevalence of between 1 and 3 percent in most countries for which figures are available, but it may be slightly less common in tropical countries. The exact etiology of RA is unknown, but the evidence suggests an immune reaction, and it presents as an inflammation affecting joints and other tissues. Its clinical features can be divided into three groups: constitutional, articular, and extra-articular. Constitutional features involve tiredness, fatigue, weight loss, and fever, and articular features involve principally the synovial joints, producing pain and eventual deformity and disability.

The seronegative spondyloarthropathies are primarily inflammatory arthropathies and share several common features, including familial aggregation, asymmetric joint involvement,

and mucocutaneous lesions. These conditions may follow gastrointestinal or sexually acquired infections and can be associated with HIV. Gout and other forms of crystal arthritis tend to present as an inflammatory response to the presence of uric acid (gout) or various calcium crystals (chondrocalcinosis).

Much of the pain that produces complaints and reduced function does not emanate from a frank arthropathy, but from the soft tissues in or around a joint. When these pains are confined to a particular area of the body's surface, they can be referred to as regional pain syndromes and may or may not be related to injury or overuse. If these pains are more widespread and are associated with specific tender points, the condition is known as fibromyalgia. Fibromyalgia is well recognized in the industrial world and has also been noted in China and Malaysia and among Tamil Indians.

The major causes of infectious arthritis can be viral, bacterial, fungal, or helminthic. Each can present as either a polyarticular presentation or a monoarthritis. Many of the helminthic infections present with more generalized aches and pains and involvement of muscle tissues as well as joints. All the conditions have specific diagnostic features and treatments.

OP is characterized by low bone mass and deterioration in the microarchitecture of the bone, which leads to fracture after low or moderate trauma. The condition is defined by diagnostic criteria based on bone mineral density as follows: a bone mineral density of more than -2.5 standard deviations below the average bone mineral density of young adult women.

The clinical features of OP are primarily due to its major outcome: fracture. The most important fractures occur in the distal radius, vertebrae, or hip, often following minor trauma. Vertebral fractures lead to loss of height, kyphosis, and back pain. The incidence of fracture varies with country and with type of fracture. Hip fractures are low in African countries but high and increasingly reported in Australasia, Europe, and North America. Fracture risk increases with age and is beginning to have a significant impact on quality of life, mortality, and health care costs in many countries.

Rickets is caused by a mineralization defect of newly formed bone in the growing skeleton. This defect leads to an increase in the amount of nonmineralized bone tissue (osteoid) and a thinning of the growth plates. This condition produces bone pain, bone deformation, swelling of the joints, and growth retardation. Rickets is primarily caused by a lack of exposure to sunshine because of climate, pollution, or overuse of clothing or sunscreens. Rickets is relatively rare in industrial countries, but it does occur as a consequence of dietary deficiency or excess clothing.

Osteomalacia is the adult equivalent of rickets. It is similarly characterized by an increase in osteoid tissue and causes bone pain and fractures. It occurs primarily in the elderly in Europe and North America because of a lack of exposure to sunshine that is not compensated for by adequate vitamin D intake.

Osteomalacia may also occur in countries with abundant sunshine where clothing prevents sun exposure. Osteomalacia is commonly reported among migrants to Western Europe from India and the Middle East.

Back pain accounts for the majority of musculoskeletal disease presentations to health professionals, and its lifetime prevalence exceeds 80 percent in most industrial countries. *Spinal disorder* refers to a wide range of specific and nonspecific musculoskeletal disorders affecting the spinal column. These conditions include congenital lesions such as scoliosis, infective problems such as osteomyelitis and neoplastic disorder (myeloma or secondary cancers), and trauma and referred back pain.

The majority of individuals with acute back pain will improve significantly over a six-week period, although in many cases the pain may recur. Early diagnosis and treatment, particularly of pain, by means of a modified exercise program will reduce long-term morbidity and disability.

Musculoskeletal injuries are extremely common, whether in the workplace or associated with sporting activities or with daily living. Motor vehicle trauma, household accidents, and occupational accidents occur frequently and are a major cause of damage to the musculoskeletal system.

Table 51.3 shows the major genetic and environmental risk factors for musculoskeletal diseases. Lack of exercise and obesity are major contributors to soft tissue disorders, OA, and back pain. Infectious forms of musculoskeletal disease depend on the environment and on the types of organisms that are prevalent.

Table 51.3 Risk Factors for Musculoskeletal Disease

Condition	Genetic	Environmental
Rheumatoid arthritis	HLA DR	
Seronegative spondyloarthropathy	HLA B ₂₇	
Osteoarthritis	Severe osteochondropathies	Obesity Lack of exercise
Soft tissue		Occupation Environment
Crystal arthritis	Congenital (Lesch Nyhan)	Obesity Nutrition
Infectious		Environment
Osteoporosis		Lack of exercise Nutrition
Metabolic bone disease		Environment Nutrition
Back pain		Obesity Occupation Lack of exercise
Trauma		Environment

PREVENTIVE STRATEGIES

Obesity brought about by increases in sedentary lifestyles and changes in eating patterns is becoming a major problem worldwide. Weight reduction has been demonstrated to reduce pain and disability from OA of the knee and other forms of lower limb arthropathy. In OA of the knee, weight reduction will not only reduce pain and improve mobility, but it can put off the time when surgical replacement of the weight-bearing joint is necessary. Obesity can also be associated with back pain, and weight reduction is an important factor in reducing the recurrence of episodes of back pain and in reducing long-term disability and chronic pain.

Smoking and excessive alcohol use are also associated with OP. Adequate calcium intake (1,000 to 1,500 milligrams per day) has been shown to maintain bone density and reduce the risk of axial (vertebral) fractures. Smoking also increases the risk of developing RA.

Weight reduction and diet are also important considerations in the management of gout. Appropriate nutrition and exercise underpin many of the preventive and treatment strategies for musculoskeletal disease.

TREATMENTS

A range of treatment approaches is available to address the multiple aspects of musculoskeletal disorders.

Symptomatic Treatments

Symptomatic treatments for musculoskeletal disease principally involve pain reduction. Nonpharmacological treatments such as massage, heat, and ice, and physiotherapeutic techniques such as ultrasound may be useful in the short term. Pure analgesic agents such as acetaminophen should be tried initially; if no response occurs, compound analgesics or opioid derivatives, including codeine, may be useful. The side effects of the latter compounds are significant, particularly in the elderly, with constipation and disorientation being the most common. Table 51.4 shows the principal modalities of pain relief for arthritis and soft tissue rheumatism. In many countries, complementary medicines (traditional medicines) are also used extensively, particularly for the management of pain. These compounds remain unproven, and clinical studies to explore their worth should be encouraged.

Recent years have seen the introduction of a number of specific antiosteoarthritic agents, including glucosamine, chondroitin sulfate, soybean extract, and injectable hyaluronic acid derivatives. Clinical trials have demonstrated that glucosamine and chondroitin sulfate are beneficial in terms of pain reduction in patients with OA, but the effects are relatively small.

Table 51.4 Treatment for Arthritis

Category	Analgesics	Specific antiosteoarthritis agents	Nonsteroidal anti-inflammatory drugs	Disease-modifying antirheumatic drugs

Nonpharmacological treatments	Massage Heat Ice Ultrasound	n.a.	n.a.	n.a.

Source: Authors.
n.a. = not applicable

Many cases of OA and soft-tissue rheumatism and most cases of the inflammatory forms of arthritis will require an anti-inflammatory drug as well as or instead of a pure analgesic. The nonsteroidal anti-inflammatory drugs (NSAIDs) have been the mainstay for treating arthritic conditions for nearly a century. More recently, concern about the adverse gastrointestinal side effects of NSAIDs led to the development of COX-1 (cyclooxygenase-1) sparing agents. These agents have similar effects on pain relief but a reduced incidence of gastrointestinal side effects, although they may produce adverse events in the renal and cardiovascular systems, such as hypertension, decreased renal function, and increased stroke and heart attacks.

Rheumatoid Arthritis

The medical community now appreciates the importance of early diagnosis and treatment of RA. All patients with RA should be started on a specific antirheumatic drug on diagnosis. These drugs have been shown to be efficacious in randomized controlled trials (Gabriel, Coyle, and Moreland 2001), but each has a quite different spectrum of adverse side effects. Even with the new biologic agents, few patients with RA actually go into complete remission, and disease activity continues despite a reduction in endpoints, such as the number of painful and swollen joints, function impairment, and pain. Most patients with RA now receive combinations of antirheumatic drugs, the

most common being methotrexate, hydroxychloroquine, and sulfasalazine. Corticosteroids are also used intermittently in many cases. Patients with RA also need to receive information about exercise programs and education on activities of daily living so that they can make informed choices in relation to their therapies.

Osteoporosis

A number of therapies are available for OP, including calcitonin, calcium, bisphosphonates, hormone replacement therapy (HRT), and selective estrogen receptor modifiers. Clinical trial data support the use of HRT, bisphosphonates, selective estrogen receptor modifiers, calcitonin, vitamin D and calcium supplementation, and calcitriol in reducing fracture rates in high-risk patients. Calcium and vitamin D supplementation are recommended to reduce hip fractures among the elderly living in assisted living accommodations and nursing homes. The recommended daily requirement for calcium varies significantly between countries—for example, from 1,000 milligrams per day in the United States to less than 500 milligrams per day in India. Recommended levels of vitamin D supplementation range from 500 to 1,000 international units per day, particularly for at-risk aging females. In addition to these pharmacological interventions, attention to risk factors for falling is also important.

Surgical treatments vary, from the use of external splints for fractures, to interventions such as arthroscopy, internal fixation for complicated fractures, and insertion of prosthetic devices, most commonly total hip and knee replacements. Biomaterials are increasingly being used to repair bone or cartilage defects in younger patients, particularly those with sporting or other traumatic injuries.

Rehabilitation treatments include a range of activities, from single discipline interventions such as physiotherapy to multi-disciplinary programs, particularly for complex problems such as back pain.

ECONOMIC ISSUES

An economic discussion of health policies designed to prevent, treat, and manage musculoskeletal conditions in developing countries is inherently difficult for a variety of reasons, but primarily because of the lack of both epidemiological and cost-effectiveness data for most developing countries. Some progress has been made by Symmons, Mathers, and Pfleger (2004a, 2004b), who provide incidence estimates for OA and RA from epidemiological data on prevalence and relative mortality risks, although data from many areas are scant.

Perhaps a more important constraint on economic evaluations in this field is the surprising number of interventions for which trial data on efficacy are inadequate. Another issue, currently the target of a concerted effort to improve practice in the field, is the lack of cross-study comparability of the results of economic evaluations of interventions for OA, RA, and OP. One of the most important variables is the choice of comparator used to assess the cost-effectiveness of interventions.

The Outcome Measures in Rheumatology Clinical Trials Economics Working Group, which was established in 1996, has made some progress toward redressing this problem. In principle, the relevant comparator is generally the next-best alternative or alternatives to the intervention of interest. The choice of comparator is especially important for cost-effectiveness analysis, because cost-effectiveness is a relative, not an absolute, concept; whether a particular intervention is considered efficient depends on the efficiency of other interventions and on budget constraints. This issue is a fundamental one, because a great many health sector innovations involve new ways of producing desirable effects with existing technology. The relevant consideration in such cases is the additional benefits that the innovation is expected to confer and the relative cost of achieving those benefits. In such circumstances, the computation of incremental cost-effectiveness ratios (ICERs) on the basis of a no-treatment alternative is of limited use, unless that scenario is genuinely under consideration. Unfortunately, the no-treatment (or, more accurately, the placebo treatment) option is precisely the comparator that much of the literature has used.

Another characteristic of economic evaluations in this field is that they have been performed almost entirely for developed countries. In the sections that follow, we discuss the steps we have taken in an attempt to minimize the adverse consequences of reliance on the literature for developed countries. Nevertheless, the pragmatic approach that we have adopted is subject to some important limitations and caveats.

Cost-effectiveness is a relative concept, in the sense that cost-effectiveness ratios (CERs) are useful only for comparing alternative ways of achieving a desired outcome—for instance, improving the quality and length of life. Assertions that an intervention is, in its own right, cost-effective are usually based on the notion that a particular CER represents a cutoff between those interventions that are efficient and those that are not. Thresholds of this kind involve an assumption about the value of life—for example, that a quality-adjusted life year (QALY) is worth US\$30,000. Nevertheless, the literature routinely uses cost-effectiveness rules that are based on thresholds without the theoretically necessary explicit consideration of implicit budget constraints.

We have tried to avoid using a threshold type of approach in relation to the discussion of cost-effectiveness. Instead, we critically reviewed the cost-effectiveness literature in rheumatology to provide an indication of the relative costs and consequences of available interventions. In some cases, an intervention appears to be inefficient because it costs more and produces fewer benefits than a competing alternative or because two interventions produce identical effects but one costs less than the other. Nevertheless, we have provided a summary of our views—for ease of reference—as table 51.5. This table summarizes our thoughts on the weight of the current effectiveness and cost-effectiveness evidence and the likelihood that developing countries might realistically consider each intervention. For the reasons given above, though, we have articulated the evidence in more detail in the text.

Cross-country differences in the epidemiology of conditions of interest, the age structure of populations, and the access to health care, along with differences in relative prices, are liable to affect the cost-effectiveness of any given intervention. Some of the substantive gaps between the developed and developing worlds may compound the problem. For example, if the price of labor relative to that of capital is consistently lower in the developing countries, capital-intensive interventions may be relatively less attractive than they are in the developed countries, especially if labor-intensive alternatives exist.

To improve comparability across the literature, we adjusted reported CERs by converting them to 2001 U.S. dollar prices (therefore, those we report generally differ from those the original authors cite). Generally, we adjusted outcomes to U.S. dollars for studies outside the United States that reported CERs in local currencies using the official exchange rate in effect at that time, but wherever such studies reported only U.S. dollar

Table 51.5 Summary of the Economic Evaluation of Interventions for Musculoskeletal Conditions

Conditions and treatment options	Considered cost-effective in developed countries? ^a	Generally recommended for developing countries? ^b	References	Additional comments

n.a. = not available.

a. Based on a cost-effectiveness threshold value of approximately US\$30,000 or other favorable quantitative data on costs and benefits.

b. Based on authors' judgment of generally favorable/unfavorable cost-effectiveness evidence. See text for precise cost-effectiveness (for example, cost per QALY) data.

equivalents, we took these as given. Finally, we used the U.S. Bureau of Labor Statistics consumer price index data for 2004 to inflate (deflate) the U.S. dollar CERs to 2001 prices. Thus, unless otherwise stated, all price data are expressed in 2001 U.S. dollars.

For clarity, we have classified cost-effectiveness results by condition and also according to whether the intervention constitutes a primary, secondary, or tertiary intervention. The exception is RA, for which the management protocols are less amenable to this type of abstraction. For RA, we found that categorizing the evidence according to a taxonomy that is problem or intervention based was more useful.

Primary Interventions

This section reviews the evidence on the cost-effectiveness of interventions designed to prevent the onset of OP. The works surveyed analyzed interventions in healthy people, primarily

perimenopausal and postmenopausal women, with no established history of OP.

Physical Activity. The prophylactic effects of physical activity are generally well appreciated, and a large proportion of preventable disease is sometimes attributed to sedentary lifestyles. Katzmarzyk, Gledhill, and Shephard (2000) estimate the relative risks for those who are inactive compared with those who are physically active for a range of conditions, including OP. Their results for Canada suggest mean OP relative risk factors of 1.56 to 1.90 for sedentary versus active women, depending on race, and indicate that the population-attributable fraction of OP caused by inactivity was approximately 27 percent and accounted for more than 16 percent of the direct economic costs of physical inactivity.

The effectiveness and cost-effectiveness of programs intended to encourage lifestyle changes are generally not well established. Geelhoed, Harris, and Prince (1994) consider the

effect of an intervention in Australia involving exercise and calcium supplements for healthy postmenopausal women to prevent osteoporotic fractures. They find that the cost of the intervention was US\$96,119 per QALY; however, note that the authors assumed no toxic effect of the lifestyle regimen on diseases other than OP.

Calcium Plus Vitamin D. Willis (2002) analyzes the cost-effectiveness of administering calcium plus vitamin D₃ to healthy postmenopausal women in Sweden and demonstrates that this intervention is a cost-saving one for 50-, 60-, and 70-year-old women with a maternal family history of hip fracture and for 60- and 70-year-old women with either a history of fragility fractures or a smoking habit. In developing regions, calcium plus vitamin D therapy may be a cost-effective or cost-saving intervention if targeted at older, asymptomatic women with maternal histories of hip and other fragility fractures—especially those who smoke. A targeted strategy of this kind is likely to be the most cost-effective in regions where environmental uptake of these elements is limited for dietary or other reasons.

Hormone Replacement Therapy. Geelhoed, Harris, and Prince's (1994) cost-effectiveness analysis of interventions in a hypothetical cohort of 100,000 healthy postmenopausal women includes several HRT strategies: (a) estrogen from age 50 for life, (b) estrogen from age 50 for 15 years, and (c) estrogen from age 65 for life. Compared with a no-therapy alternative, the cost per QALY was US\$8,609 for strategy c, US\$13,268 for strategy a, and US\$30,183 for strategy b.

Armstrong and others (2001) compare HRT with a no-therapy scenario in healthy postmenopausal women and examine how the risks of breast cancer and coronary heart disease (CHD) might influence the cost-effectiveness of the interventions over 5- and 10-year periods, as well as a lifetime intervention of approximately 31 years. They report a relatively low cost per QALY of US\$2,238 to US\$2,850 for women at a 10 to 15 percent risk of breast cancer. The cost-effectiveness of HRT fell as the risk of breast cancer increased.

Both the base cases in these studies assume that HRT reduces hip fracture rates, and Armstrong and others (2001) also assume reductions in CHD. These constitute important assumptions because, as Kanis and others (2002) point out, data from randomized clinical trials (RCTs) support the hypothesis of no effect of HRT on either appendicular fractures or CHD. Thus, the ICERs reported by both the studies may either understate or overstate the true cost per QALY produced by using HRT as a primary prevention.

Raloxifene. Armstrong and others' (2001) study also includes a cost-effectiveness analysis of raloxifene use (compared with HRT and no intervention) in healthy postmenopausal women. Their results indicate that, by comparison with raloxifene, HRT

is a dominant long-term therapy for U.S. women at average risk (in this case, a 10 percent lifetime risk) of breast cancer: the 5- and 10-year period ICERs were US\$37,620 and US\$33,472 per QALY, respectively. For women at a 30 percent or higher risk of breast cancer, the ICER for raloxifene versus HRT was less than US\$4,160, and decreased with risk.

Kanis and others (2002) argue that existing evidence on raloxifene suggests that it has no significant effect on either appendicular fractures or CHD. On the basis of the existing cost-effectiveness evidence, the use of raloxifene as a prophylactic intervention for OP in the developing regions has little to recommend it.

Secondary Interventions

The following studies were concerned with interventions in people with some indication of OP, either from a bone mineral density assessment or a fracture. Some of the general studies include Jönsson and others' (1999) study based on Swedish epidemiological data. The authors consider two different levels of intervention costs, those associated with HRT and those associated with HRT plus bisphosphonates, and find that the higher-cost intervention (HRT plus bisphosphonates therapy) was dominant for the 80-year-old group modeled. In the context of developing countries, note both the relatively higher incidence of osteoporotic fractures among 80-year-olds and the relatively larger size of this demographic group in Sweden.

Screening. Norlund (1996) conducted a cost-benefit analysis of fracture prevention in osteoporotic women age 50 to 54 in Sweden, assuming 70 percent participation in the screening program and an offer of HRT with 30 percent acceptance. The study provides evidence of a negative net benefit, indicating that the costs of a population screening program of this kind exceed its benefits. Thus, population-based bone mineral density screening programs aimed at perimenopausal or postmenopausal women are likely to be a poor use of health resources in the developing world.

Calcium and Calcium Plus Vitamin D. Citing trial evidence, Kanis and others (2002) assume that calcium supplements alone reduce only vertebral fracture risks in women with established OP. Assuming a compliance rate of 70 percent, the authors find that the intervention's cost per QALY for 50-, 60-, 70-, and 80-year-old cohorts were approximately US\$64,995, US\$31,548, US\$10,271, and US\$10,527, respectively. They also examine the cost-effectiveness of calcium plus vitamin D on the basis of trial evidence that this combination also reduces appendicular fractures. Assuming a 70 percent compliance rate, they find that calcium plus vitamin D was cost saving in 80-year-olds and either cost saving or a low-cost intervention (mean cost per QALY of US\$584) in 70-year-olds. For 50- and

60-year-olds, the mean costs per QALY were US\$29,357 and US\$13,730, respectively. Thus, in developing regions, calcium plus vitamin D therapy may be an attractive investment for elderly women with established OP.

Hormone Replacement Therapy. Fleurence, Torgerson, and Reid (2002) demonstrate an ICER of US\$12,800 to US\$19,700 for HRT for their Scottish sample. Kanis and others (2002) show that while HRT was generally a dominant therapy for 80-year-olds, with a cost per QALY of US\$4,527, it was an expensive therapy for 50-year-olds at a cost per QALY of US\$42,940. These results suggest that HRT is likely to be an attractive intervention for established OP for some age groups in the developing regions. Differences in life expectancy and the underlying incidence of OP will, however, have a considerable bearing on the age at which HRT interventions may be considered desirable in each region.

Raloxifene. Kanis and others (2002) find that the cost per QALY associated with raloxifene was approximately US\$835,622 in 50-year-olds, and although this cost generally fell with age, it remains an expensive intervention. Raloxifene therapy is not an attractive investment for the developing regions.

Calcitonin and Bisphosphonates. The cost-effectiveness evidence on nasal calcitonin is unambiguous. It is a particularly expensive intervention and represents an unattractive investment of health care resources even in wealthy developed countries. The most favorable cost-effectiveness results for nasal calcitonin come from a study by Coyle and others (2001), who find that both calcitonin and alendronate reduced wrist, hip, and vertebral fractures in postmenopausal women but that etidronate had no such effect on hip and wrist fractures. The ICERs for nasal calcitonin for 65-year-old women for five years of therapy were US\$34,166 per QALY compared with no therapy and US\$23,952 per QALY compared with etidronate. The results of this study were sensitive to the underlying fracture rate.

Kanis and others (2002, iv) also conclude that calcitonin is “not cost-effective at any age largely because of its costs.” Indeed, their estimates of costs per QALY for 70- and 80-year-old women, the groups for which the intervention is most cost-effective, equate to approximately US\$245,373 and US\$181,109, respectively. By contrast, both alendronate and etidronate were dominating interventions for 80-year-olds. At current prices, calcitonin therapy is not an attractive investment for the developing regions.

Fluoride. Kanis and others (2002) find that fluoride was generally a dominant intervention in women with established OP, because it appears to decrease the risk of vertebral fracture but to increase the risk of hip fracture, although the latter result is

statistically insignificant. When they assume that fluoride has a neutral effect on hip fractures, the authors find that the cost per QALY was in the acceptable range for interventions in the United Kingdom—that is, less than US\$46,684. Fluoride is unlikely to be a desirable intervention for preventing OP in developing countries.

Alfacalcidol. Kanis and others (2002) report wide confidence intervals on the cost per QALY of an alfacalcidol intervention. This result is largely due to substantial variation in the apparent vertebral, hip, and humeral fracture risk available from RCTs. Thus, alfacalcidol does not appear to be a good investment for developing economies; however, additional RCTs are required to reduce the uncertainty regarding the cost-effectiveness of this intervention.

COST-EFFECTIVENESS OF INTERVENTIONS FOR OA

Primary Interventions

Despite clear evidence of an association of OA with obesity and of a reduction in symptoms and progression of the disease with weight reduction, no formal studies of the cost-effectiveness of this intervention are available.

Secondary Interventions

Patient education programs, exercise programs, medications, and synovial fluid replacement have demonstrated varying levels of cost-effectiveness.

Education Programs. Lord and others (1999) evaluated the cost-effectiveness of a nurse-led education program for patients with OA of the knee in the United Kingdom, using usual care as the comparator. They found that the costs for the intervention group were greater than for the control group, but that the outcomes for the two groups were not statistically different.

The cost-effectiveness of education programs for OA patients in the developing countries is unknown. Education programs will be subject to diminishing returns, and their marginal effectiveness may depend directly on the basic level of education of those targeted. Though the scant evidence presented here suggests that education programs may not be cost-effective, further research on their effectiveness and cost-effectiveness in developing countries is required.

Exercise Programs. Patrick and others (2001) analyzed the cost-effectiveness of an aquatic exercise program for the management of OA and compare it with usual care. The study involved a 20-week randomized trial of aquatic classes for 249

adults age 55 to 75 with a confirmed diagnosis of OA. The results were generally unfavorable. In many cases (24 percent of the bootstrapped estimates), the exercise program was dominated by usual care, and the 95 percent confidence interval ranged from dominated to US\$498,700 per QALY gained.

Evidence of the cost-effectiveness of exercise programs for established OA is currently meager. Nevertheless, as part of a diversified portfolio, low-cost exercise programs may still play a useful role in the aging populations of developing regions and confer some benefit on those with established OA, particularly if they are associated with weight reduction.

Nonselective NSAIDs. In a U.K. study, McCabe and others (1998) consider the cost-effectiveness of the use of five different NSAIDs (nabumetone, diclofenac, ibuprofen, piroxicam, and naproxen) in RA and OA. Taking the least and most expensive of the five NSAIDs—namely, ibuprofen and nabumetone, which were also at the high- and low-risk ends of the spectrum in terms of adverse gastrointestinal events—the authors conclude that nabumetone is not a cost-saving prescription.

Gastroprotective Agents. The most common side effects of NSAIDs are gastrointestinal; therefore, evaluating therapies to reduce these events is important. Van Dieten and others (2000) review the literature on the cost-effectiveness of misoprostol in reducing adverse gastrointestinal events in OA and RA patients who take NSAIDs. Unfortunately, the reviewed studies evidently reported CERs based on such nongeneralizable measures as cost per patient ratios. Nevertheless, van Dieten and others (2000) argue that strong evidence exists that gastroprotection is cost-effective for OA and RA patients taking NSAID therapy. This finding appears to be true in relation to several of the reviewed studies, which produced estimates of cost savings derived from prophylaxis. However, van Dieten and others' (2000) study is at variance with that of Gabriel, Campion, and O'Fallon (1994), who conclude that misoprostol was generally dominant in that it provided no greater quality-of-life improvement and cost more.

Synovial Fluid Replacement. In a Canadian study, Torrance and others (2002) analyzed the cost-effectiveness of synovial fluid replacement in a randomized, one-year, multicenter trial of 255 patients with OA of the knee. Patients were randomized to appropriate care with hylan G-F 20 or to appropriate care without hylan G-F 20. The mean QALY gain in the intervention group was 0.071, and the resulting ICER was US\$5,233 per QALY (with similar results from sensitivity analyses). However, the relevant incremental comparators in developing regions are likely to be quite different from those used by the foregoing study. Also, the relative price of this product is likely to be higher. Thus, we cannot find strong grounds for recommending that developing regions adopt this intervention.

Tertiary Interventions

Total joint replacement for arthritis is one of the most commonly performed and cost-effective operations in developed countries. In developing countries, however, the availability of this intervention is constrained by the availability of surgeons able to perform the operation. If the surgical expertise is available, the cost-effectiveness of total joint replacement is likely to be as good as in Australia, Europe, and North America.

Total Hip Arthroplasty. Chang, Pellissier, and Hazen (1996) assess the cost-effectiveness of total hip arthroplasty in various age groups compared with nonsurgical management. Their analyses suggest that, in 60-year-old white women, total hip arthroplasty is dominant compared with nonsurgical management. For 85-year-old men, the cost per QALY is US\$6,893. Generally, their results suggest that, when total hip arthroplasty is used as a treatment for OA of the hip with significant functional limitation, it is cost-effective.

Knee Replacement. Segal and others (2004) review a number of interventions for OA and suggest a cost per QALY of US\$5,407 for knee replacement in Australia.

COST-EFFECTIVENESS OF INTERVENTIONS FOR RA

The result of a decade of vigorous debate about the appropriate treatment strategies for RA appears to be a consensus that patients with moderate or severe RA should be treated early and aggressively, if possible, by combining several disease-modifying antirheumatic drugs (DMARDs) (Maetzel and others 2002).

The complex medical management of RA can involve the use of a large number of agents, including NSAIDs, low-dose corticosteroids, and a long list of DMARDs. The economic literature for interventions in RA has, for good reason, tended to focus on the cost-effectiveness of the alternatives that arise when a particular management strategy fails. In that sense, the intervention-based taxonomy used in earlier sections of this chapter is a less helpful way to characterize some of the contributions to this field. Thus, the subsections used in this part of the chapter reflect at times a problem-based taxonomy and at other times an intervention-based classification.

Treatment Modalities

One of the challenges common to the developing world is that specialized medical expertise is often scarce. Thus, the consideration of a variety of treatment modalities is worthwhile,

especially those that involve labor substitution between specialist and nonspecialist categories. Unfortunately, relatively few studies of this kind, let alone large randomized studies, are available for RA.

In a nonrandomized study of 26 patients in Finland, Nordstrom and others (1996) compare the costs of treating RA patients either as inpatients or as outpatients. Even though the authors find that the cost of treating patients as outpatients was approximately one-sixth the cost of inpatient treatment, the small sample size and possible bias associated with the non-randomized design mean that the study's results cannot be generalized.

An interesting and possibly cost-effective strategy for managing RA involves the use of a telephone help line staffed by specialist nurses. Hughes and others (2002) examine the costs and benefits of such an intervention in the United Kingdom and conclude that it was cost saving. Their work was based on a sample of 87 RA patients who used the telephone help line in a given month. A large proportion of respondents indicated that they used the help line in place of a visit to a general practitioner, and on this basis, the authors computed that the service produced a net saving.

The existing evidence on the effectiveness and cost-effectiveness of a telephone help line for RA patients is based on a relatively small sample. Nevertheless, this type of intervention may be useful in developing regions with good communications but low levels of access to medical care. This type of intervention may be particularly worthy of consideration when direct access to a medical practitioner is associated with large travel costs.

Disease-Modifying Antirheumatic Drugs

DMARDs include cyclosporine, azathioprine, D-penicillamine, sulfasalazine, etanercept, hydroxychloroquine, methotrexate, leflunomide, and gold compounds. Gabriel, Coyle, and Moreland (2001) provide a comprehensive review of the effectiveness and cost-effectiveness of DMARDs, including a comprehensive literature search in which they retrieved 30 articles from 500 identified for possible relevance. Only six of those papers included economic evaluations, and of those six, only three included measures of both benefits and costs. Only one of the articles used a nonclinical outcome measure (QALYs). Thus, the cost-effectiveness evidence for the use of DMARDs to treat patients with RA is generally scant.

The three full economic evaluations of DMARDs that Gabriel, Coyle, and Moreland identified were studies of auranofin (oral gold) (Thompson and others 1988), cyclosporine (Anis and others 1996), and combined therapy (Verhoeven and others 1998).

Auranofin. Thompson and others (1988) compare the cost-effectiveness of auranofin with that of a placebo using data

from a six-month RCT of 311 patients with RA. The authors report that the cost of auranofin was approximately US\$692 greater than for the placebo treatment, but the lack of efficacy of auranofin means that it is now rarely used in RA treatment.

Cyclosporine, Azathioprine, and D-penicillamine. In a Canadian study, Anis and others (1996) conduct a cost-effectiveness analysis of cyclosporine use in patients with RA based on the results of a meta-analysis of five RCTs. Their comparators included a placebo control, azathioprine, and D-penicillamine and analyses based on societal costs or third-party payer costs, but the ICERs were expressed as the cost per patient per year improved, so the results are difficult to interpret in the context of a general priority-setting exercise for health expenditures. For the purposes of this chapter, perhaps the study's most useful result was that it found no statistically significant differences between cyclosporine, azathioprine, and D-penicillamine.

Given that the existing evidence on cyclosporine, azathioprine, and D-penicillamine indicates similar levels of efficacy, cyclosporine should be used only after less expensive and more effective therapies for the management of RA, including azathioprine and D-penicillamine.

Combination Therapy. Verhoeven and others (1998) analyze the use of combination therapy using data from the Combinatietherapie Bij Reumatoide Artritis, or COBRA study, conducted in Europe between 1993 and 1995. The study was a 56-week trial that involved treating an intervention group with sulfasalazine, methotrexate, and prednisolone versus sulfasalazine alone as a control. Even though the authors conclude that combined therapy is cost-effective, they qualify the results by stating that the study was probably underpowered. Despite the lack of good cost-effective data, the standard approach to RA treatment is to use combination therapy with DMARDs and to maintain corticosteroids at 7.5 milligrams per day or less if possible.

Biologics. A number of trials have shown that the biologic agents (tumor necrosis factor inhibitors and others) are the most effective agents available for reducing inflammation in RA. Their cost (US\$10,000 to US\$15,000 per patient per year); mode of administration (intramuscular, subcutaneous, or by intravenous infusion); and potential side effects (particularly the reactivation of tuberculosis) preclude their use in developing countries. Until trials are carried out in developing environments and are combined with robust cost-effectiveness data, we cannot recommend their use.

Corticosteroids. Bae and others (2003) analyze the cost-effectiveness of low-dose corticosteroids for the long-term treatment of RA. They compare the results of corticosteroid

treatment with treatment using any DMARDs plus a corticosteroid and with treatment using DMARDs and NSAIDs. Their modeling includes a consideration of the rates of relevant side effects of the treatments. They also look at NSAID-use scenarios that included Proton Pump Inhibitor prophylaxis and the use of COX-2-specific inhibitors rather than nonspecific NSAIDs.

The results generally showed that corticosteroids dominate nonselective NSAIDs in terms of their cost-effectiveness. The exceptions were when the adverse events rate for corticosteroids was assumed to be 1.5 times that of the base case and when the comparators' adverse events rates were assumed to be 0.5 to 1.0 times the base case rate. In the latter case, the cost per QALY was US\$114,168, and in the former, NSAIDs were dominant. The comparison of COX-2-specific inhibitors with corticosteroids produced a higher-cost and higher-utility outcome: the resulting incremental cost per QALY was US\$132,880.

The authors also produced useful age-specific estimates of the cost-effectiveness of the two alternative treatment approaches. Their ICERs show that corticosteroids dominate for the management of 50- and 60-year-olds with RA. For 40-, 30-, and 20-year-olds, the ICERs were US\$11,258, US\$30,938, and US\$46,981, respectively.

The evidence suggests that a management strategy of DMARDs plus low-dose corticosteroids is a less costly and more effective strategy than DMARDs plus NSAIDs in older age groups, largely because of the higher risks of adverse gastrointestinal events in those groups. For developing countries, a relevant question to consider is the extent to which life expectancy and risk factors for adverse gastrointestinal events will differ from the age groups Bae and others (2003) studied. Corticosteroid-induced OP is also a long-term risk, but for women with RA starting corticosteroid therapy, watchful waiting is recommended as preferable to screening, as long as the steroid dose remains below 7 milligrams per day.

COST-EFFECTIVENESS OF INTERVENTIONS FOR OTHER MUSCULOSKELETAL CONDITIONS

Low Back Pain

Low back pain is as common in developing countries as it is in the developed world. Health professionals now generally agree that conservative care for acute lower back pain is the initial treatment of choice, unless there is structural evidence of pathology that is amenable to surgical intervention (Gatchel and others 2003). Evidence also indicates that programs that incorporate some physical activity may reduce the costs of both acute and chronic low back pain compared with those that do not involve activity.

For economic evaluations, one of the important complicating factors associated with low back pain is that the

nonmeasurement of indirect costs may introduce substantial bias into estimates of the cost-effectiveness of interventions. This problem is potentially serious because, in some cases, investigators have estimated the indirect costs of low back pain at more than twice those of the direct medical costs (Bolten, Kempel-Waibel, and Pfforinger 1998).

Back Schools. Van Tulder and others (2003) review 15 RCTs of back schools for patients with recurrent and chronic low back pain, but they consider only three of these to be of high quality. They conclude that the evidence is only moderate that back schools have better short-term effects than other treatments for chronic back pain. They also find some evidence that back schools are more effective than placebos or waiting list controls in occupational settings. However, the authors note that little is currently known about the cost-effectiveness of back schools. Thus, evidence is insufficient to provide a recommendation on the probable cost-effectiveness of back schools for low back pain in developing countries; however, early intervention, education, and exercise programs should be encouraged.

Massage. Furlan and others (2002) examine the effectiveness and cost-effectiveness of a variety of massage techniques for nonspecific low back pain by comparing them with (a) sham or placebo massage, (b) other medical treatments, or (c) no treatment. The authors conclude that massage might be beneficial for patients with subacute and chronic nonspecific low back pain, especially when combined with exercises and education. The evidence suggests that acupuncture massage is more effective than classic massage, but this finding needs to be confirmed.

Little is known about the cost-effectiveness of massage for low back pain. On the basis of the existing evidence, in countries or regions in which massage—especially acupunctural massage—is routinely available at low cost, the intervention may be cost-effective. Where acupunctural interventions are considered, the costs of bloodborne disease transmission must also be weighed against the expected benefits of the intervention. This consideration may be important in countries where the prevalence of bloodborne viruses is high, particularly if strict infection control measures are not routinely followed.

Early Interventions. The few studies of early intervention programs to reduce the progression of acute low back pain to chronic pain have tended to report considerable cost savings. Gatchel and others (2003) published a prospective trial of early interventions in individuals with acute low back pain and a high risk of the pain progressing to chronicity. The authors screened approximately 700 patients and designated them as being at either low or high risk. The patients were then assigned to early or nonintervention groups and followed for 12 months. The early intervention was generally conducted over a

three-week period and involved an intensive, multidisciplinary approach that included exercise classes, biofeedback and pain management classes, group education sessions, case manager and occupational therapist sessions, and interdisciplinary team conferences.

The early intervention resulted in statistically significant differences in return-to-work outcomes, number of health care visits, and number of disability days caused by back pain. It also resulted in a variety of pain surrogates. Furthermore, the mean cost savings were approximately US\$9,000 per patient. The direct costs for the intervention group were approximately US\$2,500 higher than those for the intervention group, but this finding was largely the result of the up-front costs of the intervention program itself. The direct costs of health care visits and pharmaceuticals were considerably lower for the intervention group.

The evidence suggests that an intensive, multidisciplinary, early intervention program is cost saving for individuals with acute low back pain who are at high risk of having the pain progress to chronicity; however, the cost savings associated with this intervention are attributable to improved labor market outcomes and earnings for injured individuals. The intervention itself may increase costs in the short term, but it appears to be associated with medium and long-term net benefits. Labor market conditions, including wages, along with the age of low back pain sufferers, may have an important bearing on the viability of this type of intervention in developing countries.

Ankylosing Spondylitis

Although the direct costs associated with ankylosing spondylitis are relatively low, its impact on indirect costs, including pain and suffering, are substantial. To date, little work has been done on the economics of interventions for ankylosing spondylitis. Pharmaceutical interventions are currently typically limited to NSAIDs and DMARDs such as methotrexate and sulfasalazine. Van Tubergen and others (2002), however, analyze the cost-effectiveness of a spa exercise intervention. The intervention period was three weeks, and although the authors argue that the cost-effectiveness of the intervention was favorable, they also note that the ICERs were sensitive to variations in assumptions about indirect costs.

Although a spa exercise program is apparently beneficial and may even be considered cost-effective for ankylosing spondylitis sufferers in developed countries, the current cost-effectiveness evidence does not provide a compelling case for widespread adoption of the intervention in developing regions. Patients, however, should be encouraged to exercise—especially to swim. The cost-effectiveness of tumor necrosis factor-inhibiting drugs is not yet evident for ankylosing spondylitis, but the drugs are currently unattractive investments for developing countries because of their high price.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

Given the increasing burden of musculoskeletal conditions worldwide, addressing ways of preventing musculoskeletal conditions is an important step. Few examples are available of the implementation of strategies aimed specifically at preventing musculoskeletal conditions, but many recommendations are aimed at modifying determinants that affect other aspects of health in addition to musculoskeletal health. These recommendations include ensuring adequate physical activity to maintain physical fitness; maintaining an ideal body weight; ensuring a balanced diet that meets the recommended daily allowances for calcium and vitamin D; avoiding smoking; balancing the use of alcohol and avoiding alcohol abuse; and putting in place accident prevention programs to reduce musculoskeletal injuries related to road traffic accidents, leisure activities, and workplaces. Various programs involve changes in the behavior of individuals and control of environmental hazards (these programs are considered elsewhere in this volume). Personal behavior changes can be achieved by education but may require resources such as sports facilities. A safe environment will involve all sectors, and successful implementation may require legislation. The benefits of these interventions on musculoskeletal health are not quantified, but in any case they are probably small. Physical activity and an ideal weight will benefit the broadest range of musculoskeletal conditions.

Osteoarthritis

The strategy for managing OA is pain management with simple analgesics or NSAIDs, along with education to facilitate self-management and rehabilitative programs to improve function, activities, and participation. These strategies include general and specific exercise programs, devices such as walking sticks, and environmental modifications. Joint replacement surgery should be considered for end-stage joint damage. Simple analgesics can be accessible over the counter or through health clinics. Education and rehabilitative programs can also be delivered through health clinics. Joint replacement surgery requires resources in terms of physical facilities, financial resources, and expertise. The cost-effectiveness of arthroplasty is greatly affected by complications such as infection or failure of the prosthesis, both of which are related to inadequate resources.

Pain management should be available to those who have disabling symptoms and is dependent on access to drugs and education with respect to the benefits and risks. Access to arthroplasty will be the greatest challenge, given the increasing needs in the developing world brought about by aging populations and increases in other risk factors such as reduced physical activity and increasing obesity.

Rheumatoid Arthritis

The greatest successes in recent years include advances in managing RA and the ability to control disease activity; to prevent tissue damage; and to improve function, activities, and participation. Methotrexate is a readily accessible, effective antirheumatic drug. Monitoring full blood count and liver function is recommended, but the rarity of serious adverse events may necessitate a review of this recommendation if the costs and difficulties of monitoring would deny access to the drug. Symptomatic therapy with NSAIDs and multidisciplinary rehabilitation are also key components of the management of RA. Central to this approach is ensuring early and accurate diagnosis with long-term expert review, which requires public awareness about arthritis and adequate competency and facilities in the community and in health clinics for diagnosis and management. Education and rehabilitation can also be delivered in these settings. Paramedical workers can be trained to undertake much of this work. The problem is to ensure adequate training and experience of health care workers for a condition that affects 0.3 to 0.5 percent of adults in developing countries. Without treatment, the effects of RA can be great, so effective management can yield significant gains. The costs are relatively low, because paramedical workers can deliver much of the care and because the drugs are not new and are widely available.

Several established market economies have set up early arthritis clinics, but running such clinics effectively may be more difficult without a system to encourage and enable early access to specialist care. The management of established RA is usually undertaken by specialists in partnership with primary care. Programs for managing RA are usually self-sustaining and expandable because of the chronic incurable nature of the condition and the general public's gradual recognition of what can be achieved.

Osteoporosis

The prevention of fractures related to OP is based on a "bone-healthy" lifestyle of individuals who have adequate dietary calcium, vitamin D, and weight-bearing exercise and who avoid smoking and excessive alcohol consumption. Implementing such measures requires raising public awareness and educating primary care personnel. In addition, those at high risk of fracture who would benefit from a specific intervention need to be identified by the presence of risk factors, including low bone density. The limitation to this approach is a lack of access to bone densitometry, in which case the decision to treat may have to be made on clinical grounds alone. The occurrence of low-trauma fracture is a good indicator of OP and, in the presence of other clinical risk factors, may be reason enough to treat. In particular, multiple vertebral fractures are virtually diagnostic of OP.

Various local programs aim at identifying and treating those with OP. Their costs relate not only to diagnostic tests but also to treatment. The cost of bisphosphonates is high compared with the income levels in those countries likely to experience the greatest increase in the burden of OP. The speed of benefits of bisphosphonates is good, with clinical trials demonstrating fracture risk reduction within 12 to 18 months. The role of HRT is not clear at present, but because of the likely increased risk of cardiovascular disease and strokes outweighing the benefit of fracture prevention, it is not currently recommended for preventing OP in unselected women. However, the benefit-risk ratio will be favorable in those at increased risk of fracture and low risk of cardiovascular disease, and the costs of HRT are more feasible. Adherence to treatments for OP to prevent fracture is poor because of the silent nature of their effect, and patient education to modify expectations is important. The effectiveness of any fracture prevention program depends on adherence for as long as possible, given the long-term character of the condition.

RESEARCH AND DEVELOPMENT

Another important issue with musculoskeletal disease is the development of a research agenda.

Size and Nature of the Burden of Disease

Uncertainty about the epidemiology of some musculoskeletal conditions is still considerable, especially in developing countries (WHO 2003). Incidence estimates for OA and RA have recently been generated from available epidemiological data on prevalence, relative mortality risks, and so on, though for some regions even these basic epidemiological data are scant (Africa, Asia, and South America for RA and Africa, Eastern Europe, and South America for OA). Additional primary measurement is required to produce a more accurate picture of interregional and intraregional epidemiological variations. This deficiency limits estimates of the overall burdens of the various musculoskeletal conditions and the extent to which they might be reduced.

The studies of the Community-Oriented Program for Control of Rheumatic Disease (COPCORD) (Darmawan and others 1995) are, in part, meeting this need. The Bone and Joint Monitor Project is also undertaking initiatives to standardize data collection and reporting in epidemiological studies to improve the collation and comparison of needed epidemiological data. Global burden-of-disease data concentrate on specific diagnoses, but a far greater burden that has yet to be estimated relates to regional and generalized musculoskeletal problems characterized by pain with disability. More research is necessary in this area.

Evaluation of Existing Interventions

Few reliable economic evaluations of available interventions have been done. One reason is that a surprising number of interventions have inadequate trial data or efficacy measures, and many reasonably well-established interventions need to be tested in trials against appropriate comparators. The heterogeneity of comparators used in different economic evaluations and other methodological differences pose material risks to comparisons of the costs and consequences of different interventions for musculoskeletal conditions, and some standardization is needed.

Many studies have used only clinical outcomes and not life years saved or QALYs as outcome measures. Positive steps are being taken to correct the situation. The Outcome Measures in Rheumatology Clinical Trials Economics Working Group (Gabriel, Tugwell, and Drummond 2002) has made some progress toward redressing this problem in the rheumatology economics literature. Although work is not yet complete, this concerted approach to standardization holds promise for the literature.

Avertable Proportion of the Burden

New data are needed to estimate the burden that could be averted by implementing the proposed strategies. Available data are currently limited and relate predominantly to individual interventions in short-term clinical trials with outcomes that do not enable reliable estimates of the avertable burden. Interventions need to be evaluated, often in combination with outcome measures that enable the burden on individuals and society to be measured meaningfully and in more naturalistic circumstances. Concordance cannot be assumed, in particular for these largely chronic conditions, and it is influenced by many personal and environmental factors. The impact of musculoskeletal conditions is pervasive, underrecognized, and underestimated. Therefore, data are needed not only on what is theoretically avertable, but also on what is being averted and the reasons for any disparities.

Resource Requirements

The implementation of strategies for preventing and controlling musculoskeletal conditions is multisectoral, and the resource consequences of this need to be established. Different models for the delivery of a strategy may have different resource implications. These variations need to be explored to ensure appropriate investment and provision of resources.

Likely Effectiveness of Interventions on Both Health and Nonhealth Benefits

Musculoskeletal conditions are common and have a major impact on individuals and society; however, they are inadequately treated, and the success of simple interventions is not

being achieved because of a lack of prioritization and resources. Strategies for preventing musculoskeletal conditions have a wide range of other health benefits; they need to be jointly promoted, and the additional benefits need to be better recognized. The various determinants of ill health—such as lack of physical activity or obesity—that pose a risk to musculoskeletal health need to be quantified along with their other detrimental effects. The benefits and cost-effectiveness of modifying these determinants of health, with regard to preventing or modifying the outcome of musculoskeletal conditions, need to be quantified and compared with strategies that focus on personal interventions.

Implementation

Improving musculoskeletal health requires implementing strategies for preventing and controlling certain diseases and environmental risk factors. Selected strategies must be in line with local needs, priorities, and resources. Informed decision making at the policy level requires data on the burden and the avertable burden of musculoskeletal conditions, plus the costs for particular populations by strategy. Changes in local demographics that are likely to increase the effect of musculoskeletal conditions also need to be considered before developing plans for implementation.

CONCLUSIONS: PROMISES AND PITFALLS

Musculoskeletal diseases are the most common cause of chronic disability worldwide and will become increasingly important as aging populations require relief from chronic pain and disability. One of the characteristics of musculoskeletal diseases is that they are not fatal and do not have the high profile of other conditions, such as cancer and heart disease. However, they are preventable in many cases, and simple interventions, such as maintaining ideal body weight and participating in an exercise program, may have a significant effect on long-term morbidity. However, the field of musculoskeletal disease is thwarted by a significant lack of epidemiological and outcome data across a broad spectrum of geography, condition, and treatments.

The designation of 2000–10 as the Bone and Joint Decade by the United Nations, WHO, and 60 countries will certainly help raise the profile of these diseases in local communities. All nations have a significant opportunity to embrace the decade, to ensure that their populations understand the importance of these diseases, and to encourage the training of a range of health professionals to deal with this burgeoning epidemic.

Improving knowledge among health workers at all levels about musculoskeletal conditions is important for early diagnosis and intervention, as is the provision of access to specialist services, such as orthopedic surgery. Simple programs that

emphasize the importance of obesity and lack of exercise as predictors of poor musculoskeletal outcomes are low cost, but their implementation and their influence on health outcomes need to be assessed in properly conducted studies. Medications—particularly analgesic and anti-inflammatory drugs for arthritis and pain and vitamin D and calcium supplementation to prevent OP—need to be widely available.

Exciting advances in the treatment of inflammatory forms of arthritis with biologics need to be evaluated from an economic perspective, particularly in developing nations, where the risk of exacerbating underlying infections such as tuberculosis is much higher than in developed countries. Currently, biologic agents are not cost-effective in developing countries, but they may be in the future. Access to hip and knee replacements, probably the most cost-effective surgical intervention available, is important but depends on the availability of a qualified staff.

Musculoskeletal diseases will continue to present a challenge to the health systems of both developing and developed countries, but as we solve some of the issues related to communicable diseases, the hope is that more resources will become available for tackling the burgeoning epidemic of noncommunicable disease, including musculoskeletal conditions.

Pain Control for People with Cancer and AIDS

Kathleen M. Foley, Judith L. Wagner, David E. Joranson, and Hellen Gelband

The undertreatment of chronic pain is a global problem, especially for people in the final stages of cancer and, increasingly, AIDS. The pain of dying is often severe, but it can be controlled for most people by a simple and inexpensive intervention: oral analgesic drugs, including morphine and other opioids. Although it was long known that opioid drugs were essential for the relief of moderate to severe pain, even in the 1980s the amounts being used globally were so low that only a minority of those dying could have had adequate pain relief. Since then progress has been made, mainly in resource-rich countries, widening the gap between rich and poor. The absence of opioids in developing countries is not merely a problem of supply or costs, however. This chapter lays out the institutional and political barriers that restrict their availability in most low- and middle-income countries.

BURDEN OF PAIN FROM CANCER AND AIDS

Pain is “an unpleasant sensory and emotional experience associated with either actual or potential tissue damage or described in terms of such damage” (Task Force on Taxonomy 2004). Pain, in its various manifestations, is the most common symptom leading patients to seek medical assistance (box 52.1).

Measurement of Pain

Pain is a subjective experience, but it can be described by patients and assessed using validated questionnaires and scales (Cleeland 1990). In *categorical scales*, the patient describes the pain using specific words, for example, mild, moderate, severe,

or excruciating. With *numerical scales*, patients rate their pain by choosing a number—for example, from 0 (no pain) to 10 (worst pain). *Visual analog scales* often take the form of a ruled line, anchored on the left by the words *no pain* and on the right by *worst possible pain*.

Pain measurement instruments have been validated in clinical trials of analgesic therapies and subsequently used in national and international surveys, repeatedly demonstrating sensitivity and reliability for both cancer and AIDS patients. These instruments include the Brief Pain Inventory (Bernabei and others 1998; Cleeland and others 1996; Daut, Cleeland, and Flanery 1983), the Memorial Pain Assessment Card (Fishman and others 1987), the Memorial Symptom Assessment Scale (Portenoy and others 1994), and the Edmonton Symptom Assessment Scale (Chang, Hwang, and Feuerman 2000).

Effects of Pain

Pain dramatically affects quality of life. Patients with persistent serious pain cease participating in social activities and may be unable to work or care for their families (Daut, Cleeland, and Flanery 1983). Psychological effects, including depression and anxiety, increase with pain intensity (Rosenfeld and others 1996).

The suffering of an individual radiates throughout households, neighborhoods, and villages. Caregivers suffer distress, anxiety, and depression. They may have to give up their own employment to care for a dying relative. The loss of income of the patient and the caregiver may dramatically lower the family’s social status (Murray and others 2003).

Box 52.1

Classification of Pain

Pain is classified according to two main characteristics: temporal and physiologic. *Temporal* categories are

- acute pain
 - characterized by a well-defined onset and self-limited end
 - allows clear description of location, character, and timing
 - shows signs of autonomic nervous system hyperactivity—for example, tachycardia, hypertension, profuse sweating (diaphoresis), dilated pupils (mydriasis), or pallor
- chronic or persistent pain
 - long lasting, usually defined as at least three months
 - characterized by a localization, character, and timing that is often more vague than with acute pain
 - characterized by adaptation of the autonomic nervous system, so signs of hyperactivity disappear

Source: Authors.

- results in significant changes in psychological, functional, and social status.

Physiologic pain categories are

- somatic pain
 - originates in ligaments, tendons, bones, blood vessels, and nerves
 - sharp or dull, but typically well localized and intermittent
- visceral pain
 - originates in body organs and results from activation of nociceptive receptors and efferent nerves
 - characterized by deep aching and cramping, often referred to cutaneous sites
- neuropathic pain
 - results from direct injury to peripheral receptors, nerves, or the central nervous system
 - typically burning and dysesthetic (abnormal and unpleasant), often in area of sensory loss.

Pain in Patients with Cancer and AIDS

Several well-defined acute and chronic pain syndromes are associated with cancer, with HIV/AIDS, and with their treatment (Breitbart 2003; Foley 1979). In low-income countries, where patients usually present late in the course of illness, pain from the disease itself is more common than treatment-related pain.

Researchers consistently report that 60 to 90 percent of patients with advanced cancer experience moderate to severe pain, regardless of age and gender and whether ambulatory or hospitalized (Cleeland and others 1988; Cleeland and others 1996; Daut and Cleeland 1982; Foley 1979, 1999; Stjernsward and Clark 2003). The intensity, degree of pain relief, and effect of pain vary according to the type of cancer, treatment, and personal characteristics, but prevalence and severity of pain usually increase with disease progression. No population-based studies of AIDS-related pain have been published, but several researchers report that up to 80 percent of patients in the last phase of illness experience significant pain requiring analgesics (Larue, Fontaine, and Colleau 1997; Schofferman and Brody 1990; Singer and others 1993).

Pain Days

No standard metric has been developed to describe the pain burden for people at the end of life. We have adopted a transparent and direct measure—the *pain day*—defined as a

day of moderate or severe pain requiring an opioid drug for relief. The elements that determine the number of cancer and AIDS pain days in a population are the numbers dying from each condition and the average prevalence and duration of severe pain associated with dying.

Patterns of pain from specific cancers and from AIDS at given stages appear to be similar everywhere. However, because different cancers produce different symptoms, the mix of cancers in a country will influence the overall pattern and burden of pain reflected in the total number of pain days.

About 2.1 million deaths from cancer and about 3 million from AIDS occur annually in low- and middle-income countries (LMICs) worldwide, and these numbers are increasing. Using expert opinion, we estimate that about 80 percent of people dying from cancer and 50 percent of those dying from AIDS experience moderate or severe pain, lasting for an average of 90 days.

INTERVENTIONS FOR PAIN RELIEF

The goal of pain control is not to cure disease, but to allow patients to function as effectively as possible and to minimize pain. Interventions for pain relief include drugs, radiotherapy, and anesthetic, neurosurgical, psychological, and behavioral approaches (see table 52.1). However, analgesic drugs are the mainstay of treatment and the focus of this chapter. According

Table 52.1 Procedures Used to Control Specific Types of Cancer Pain

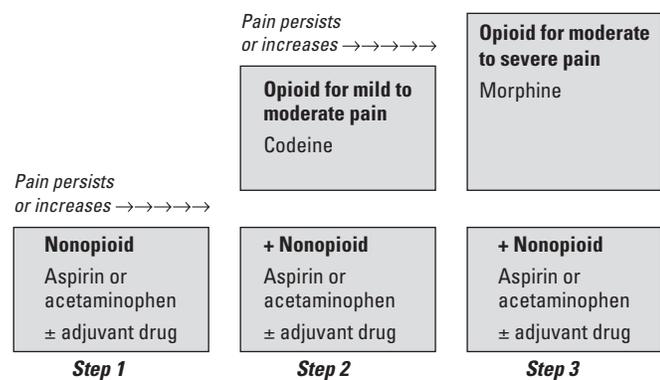

Type of procedure	Most common indications
<i>Anesthetic</i>	
Inhalation therapy with nitrous oxide	Breakthrough pain, incidental pain in patients with diffuse, poorly controlled pain
Intravenous barbiturates (for example, sodium pentobarbital)	Diffuse body pain and suffering inadequately controlled by systemic opioids
Local anesthetic by intravenous, subcutaneous, or transdermal application	Neuropathic pain in any site with local application to the area of hyperesthesia or allodynia
Trigger point injections	Focal muscle pain
<i>Nerve block</i>	
Peripheral	Pain in discrete dermatomes in chest and abdomen or in distal extremities
Epidural	Unilateral lumbar or sacral pain Midline perineal pain Bilateral lumbosacral pain
Intrathecal	Midline perineal pain Bilateral lumbosacral pain
<i>Autonomic</i>	
Stellate ganglion	Reflex sympathetic dystrophy
Lumbar sympathetic	Reflex sympathetic dystrophy of the lower extremities Lumbosacral plexopathy Vascular insufficiency of lower extremity
Celiac plexus	Midabdominal pain from tumor infiltration
Intermittent or continuous epidural infusion with local anesthetics	Unilateral and bilateral lumbosacral pain Midline perineal pain Neuropathic pain from the midthoracic region down
Intermittent or continuous epidural or intrathecal with local opioid analgesics	Unilateral and bilateral pain below the midthoracic region; often combined with local anesthetics
Intermittent or continuous intraventricular infusions with opioid analgesics	Head and neck pain and upper chest
Chemical hypophysectomy	Diffuse bone pain
<i>Neuroablative</i>	
Nerve root: rhizotomy	Somatic and neuropathic pain from tumor infiltration of the cranial and intercostal nerves
Spinal cord: dorsal root entry zone lesion	Unilateral neuropathic pain from brachial, intercostal, and lumbosacral plexopathy and postherpetic neuralgia
Spinal cord: cordotomy	Unilateral pain below the waist; often combined with local neurolytic blocks in perineal and bilateral lumbosacral plexopathy; may be performed bilaterally
Spinal cord: myelotomy	Midline pain below the waist, but rarely used because it involves extensive surgery
Brain stem: mesencephalic tractomy	Pain in the nasopharynx and trigeminal region
Thalamus: thalamotomy	Unilateral neuropathic pain in the chest and lower extremity
Cortex: cingulotomy	Useful through a stereotactic approach for diffuse pain
Pituitary: transsphenoidal hypophysectomy	Bone metastases in endocrine-dependent tumors, breast, and prostate
<i>Neurostimulatory</i>	
Peripheral nerve: transcutaneous and percutaneous electrical nerve stimulation	Dysesthesias from tumor infiltration of nerve or trauma
Spinal cord: dorsal column stimulation	Of limited use in neuropathic pain in the chest, midline, and lower extremities
Thalamus: thalamic stimulation	Of rare use in neuropathic pain in the chest, midline, or lower extremity
<i>Radiotherapy</i>	
External beam	Bone and brain metastases Nerve and spinal cord compression

(Continues on the following page.)

Table 52.1 Continued

Type of procedure	Most common indications
<i>Physical</i>	
Cutaneous stimulation (superficial heat, cold, massage)	Dysesthesias from tumor infiltration of nerve or trauma
Transcutaneous electrical nerve stimulation	Cutaneous nerve injury pain
Acupuncture	For focal or diffuse pain syndrome
Bed rest	Reduced movement–related pain syndrome
<i>Psychological</i>	
Hypnosis	Provides distraction and cognitive approach to reduce pain
Relaxation, imagery, biofeedback, distraction, reframing	Provides distraction and cognitive approach to reduce pain
Patient education

Figure 52.1 The Three-Step Analgesic Ladder

to the World Health Organization (WHO), “A palliative care programme cannot exist unless it is based on a rational national drug policy,” and this includes “regulations that allow ready access of suffering patients to opioids” (WHO 2002, 87).

WHO Three-Step Analgesic Ladder and Its Effectiveness

WHO has developed a “three-step analgesic ladder” (figure 52.1) for cancer pain and its treatment (WHO 1986), which includes a strong opioid (morphine) (table 52.2). The ladder is equally appropriate for patients with HIV/AIDS (O’Neill, Selwyn, and Schietinger 2003).

The steps in the ladder represent increasing pain severity and the drugs that should be used in each case:

- Step 1 is limited to nonopioids, including drugs that are widely available (for example, acetaminophen, aspirin, or nonsteroidal anti-inflammatory drugs, or NSAIDs).
- Step 2 describes moderate pain that requires a combination of a nonopioid and opioid for relief.

- Step 3 is for pain requiring a strong opioid. No specific dosages are recommended for opioid drugs because the concept of a standard dose does not apply: effective doses of oral morphine range from as little as 5 mg to more than 1,000 mg every four hours. Adjuvant drugs are also essential to treat side effects of analgesics or to provide additive analgesia (table 52.2).

Controlled field testing and clinical experience has demonstrated that 70 to 90 percent of cancer patients can achieve pain control using the ladder (Goudas, Carr, and Bloch 2001). Although the ladder has not been validated in formal studies for patients with AIDS, recent clinical reports describe its successful application (Anand, Carmosino, and Glatt 1994; Kimball and McCormick 1996; McCormack and others 1993; Newshan and Lefkowitz 2001; Newshan and Wainapel 1993; Schofferman and Brody 1990).

In an ideal world, a trained professional would prescribe pain medication throughout the course of illness, in accordance with the ladder. However, most patients self-medicate pain with analgesics and traditional medicines that they buy over the counter until they have late-stage disease and severe pain that can be treated only with a strong opioid. That is when they are most likely to seek formal medical care, which would start on step 3 of the ladder. Unfortunately, the opioid they need is unlikely to be unavailable in LMICs, even from health professionals.

Adequacy of and Barriers to Pain Control and Palliative Care in Developing Countries

The adequacy of pain control in populations is not easily measured. A useful and available surrogate is the per capita consumption of morphine (Joranson 1993), a figure based on mandatory annual reports by national governments to the International Narcotics Control Board (INCB). Of the 27 million grams of morphine used legally in 2002, 78 percent went to six countries—Australia, Canada, France, Germany,

Table 52.2 Basic Drug List for Cancer and AIDS Pain Relief: Analgesics and Adjuvant Drugs

Category Analgesics	Basic drugs	Alternatives
Nonopioids	Acetylsalicylic acid (aspirin)	Choline magnesium trisalicylate
	Acetaminophen	Diflunisal
	Ibuprofen	Naproxen
	Indomethacin	Diclofenac
Opioids for mild to moderate pain	Codeine	Dihydrocodeine
		Hydrocodone
		Tramadol
Opioids for moderate to severe pain	Morphine	Methadone
		Hydromorphone
		Oxycodone
		Pethidine
		Buprenorphine
		Fentanyl
Opioid antagonists	Naloxone	Nalorphine
<i>Adjuvant drugs for analgesia and symptom control</i>		
Antiemetics	Prochlorperazine	Metoclopramide
		Ondansetron
Laxatives	Senna	Cisacodyl
	Sodium docusate	Bran
	Mineral oil	Dantron
	Lactulose	Sorbitol
	Magnesium hydroxide	
Antidiarrheal agents	Loperamide	Paregoric
	Diphenoxylate hydrochloride and atropine sulfate	
Antidepressants (adjuvant analgesics)	Amitriptyline	Imipramine
		Paroxetine
Antipsychotic	Haloperidol	Thorazine
Anticonvulsants (adjuvant analgesics)	Gabapentin	Valproic acid
	Carbamazepine	
Corticosteroids	Prednisone	Prednisolone
	Dexamethasone	
Anxiolytics	Diazepam	Clonazepam
	Lorazepam	
	Midazolam	
Psychostimulants	Methylphenidate	Pemoline

Source: Foley, Aulino, and Stjernsward 2003.

the United Kingdom, and the United States. The rest went to the other 142 countries that reported. Morphine is largely unavailable in Africa, the eastern Mediterranean, and Southeast Asia (figure 52.2).

The major barriers to palliative care in LMICs are scarce resources, lack of national policies or low priority for pain relief, lack of awareness by health professionals and the public that cancer and AIDS pain can be relieved, concern that medical

use of opioids will lead to drug abuse and addiction, and legal restrictions on opioids. Medical, religious, gender, social, and cultural factors also present barriers (see box 52.2). With AIDS, social and self-stigmatization work against adequate care of any kind. In addition, most of the emphasis in poor countries has been on prevention and, more recently, on antiretroviral drugs. In all cases, even less care is in place for children than for adults (Joranson, Rajagopal, and Gilson 2002).

Box 52.2

Living with and Dying from Cancer in Scotland and Kenya

Physical suffering dominates the lives of people with advanced cancer in rural Kenya. In contrast, the concerns of cancer patients in Scotland, whose physical needs are met, focus on the prospect of death. A recent study compared these two groups.

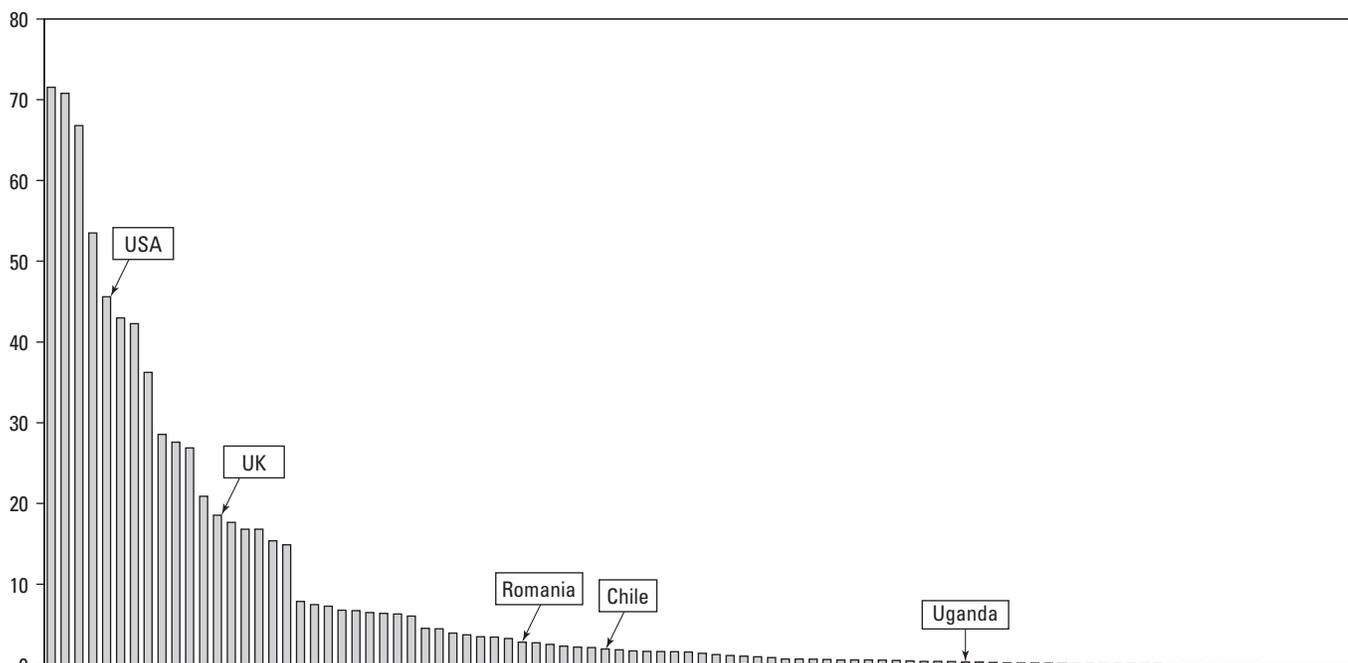

The suffering in Kenya stems largely from poverty and the high cost of basic health care. Hospital care is limited, and patients feel happier at home. Families care for patients without drugs or supplies or even the knowledge of what to expect and how to help the patient. Patients are concerned about the physical and financial burden on

their families. They are comforted and inspired by religious beliefs and by the support of their communities. They accept their fate.

In Scotland, health care is free and of high quality. Patients are able to get primary treatment for the cancer and, when needed, palliative care. They are likely to be angry about their illness rather than accepting, and many feel isolated from family and friends. Although patients' physical needs are met routinely, psychosocial needs are met only for some.

Figure 52.2 Global Morphine Consumption, by Country (Per Capita, 2002)

Legal Controls on Opioid Drugs

The Single Convention on Narcotic Drugs of 1954, amended by the 1972 Protocol (United Nations 1954), is an international treaty that aims both to prevent the illicit production of, trafficking in, and use of narcotic drugs and to ensure their availability for medical and scientific needs. The INCB, established

in 1968 by the Single Convention, is the independent, quasi-judicial organization that implements the Single Convention.

The Single Convention requires that all countries (even nonsignatories) intending to make opioids available for medical use estimate national opioid needs and report annually on imports, exports, and distribution to the retail level. It also

Box 52.3

Pain Control in Romania and Chile

Palliative care has developed in Romania since the early 1990s, largely through the Romanian Association for Palliative Care. Support has come predominantly from U.K. charities and from the Open Society Institute. Services are provided throughout the country by paid staff and volunteers in 10 hospital-based inpatient services, 9 hospice home care teams, 2 day care services, and 1 palliative care training center that provides services. Coverage is still low: only 15 percent of cancer patients are treated with opioid analgesics. Morphine is available (paid for by the government) only for terminally ill cancer patients. Prescription restrictions and extra authorization needed for releasing morphine to each patient are still so burdensome that patients may die before the paperwork is completed. The situation is improving gradually, however.

Sources: International Observatory on End of Life Care 2005.

Palliative care has developed in Chile over the past 15 years, largely through nongovernmental organizations. The Ministry of Health's cancer program has also played a role by including palliative care in its National Cancer Control Program initiative and by moving to reform drug laws. As a result, morphine consumption increased from less than 5 kg in 1990 to 55 kg in 2000. Despite these efforts, only a minority of patients have access to oral morphine for chronic pain related to cancer or AIDS. The remaining barriers include inadequately trained clinicians, a lack of national standards and guidelines, cure-oriented cancer treatment policies, fear of addiction on the part of both professionals and the public, and a lack of resources to improve the health care infrastructure.

sets out the following principles on which countries can develop their own policies and regulations:

- Individuals must be authorized to dispense opioids by virtue of their professional license or be specially licensed to do so.
- Opioids may be transferred only between authorized parties.
- Opioids may be dispensed only with a medical prescription.

Many governments have imposed even tighter restrictions, such as limiting the number of days for which an opioid prescription can be written.

COSTS AND COST-EFFECTIVENESS

This section describes the costs and benefits of providing oral morphine and essential adjuvant drugs to terminally ill cancer and AIDS patients who require it. It assumes the drugs are used according to the WHO analgesic ladder. We recognize that other analgesics can also contribute significantly to patients' costs and pain relief, but at least some such drugs (acetaminophen, for example) are available relatively cheaply in most places. Although not everyone has access to such drugs, we are unaware of any data that could be used to estimate that proportion. Costs are estimated for three countries at differing income levels and with different patterns of cancer and AIDS deaths: Chile, Romania, and Uganda (see box 52.3).

Costs Included in the Estimates

The quantitative analysis presented here is restricted to the costs, before such drugs reach the patient, of oral morphine and the adjuvant drugs needed to treat its side effects. We mention other costs associated with delivering oral morphine to terminal AIDS and cancer patients later in this section, but for reasons we discuss, we have not assigned dollar values to them.

Costs of Oral Morphine. The appropriate measure of drug cost is the sum of costs to all payers—governments, insurers, charities, and patients—for the drug itself, but that sum does not include the costs of personnel to administer the drug or otherwise care for the patient.

Oral morphine can be purchased in bulk powder or finished form and administered as a tablet or liquid (De Lima and others 2004; Rajagopal and Venkateswaran 2003). The cost to the final payer is influenced by import taxes, if any; requirements to document the chain of custody of the product; costs to local manufacturers of excipients, salts, diluents, and other materials required to produce finished forms; and price markups. The actual cost of oral morphine in LMICs is difficult to document because it is unavailable in so many places or is manufactured for finished use at different points in the distribution chain. The price of a 30-day supply of immediate-release oral morphine in 2003 ranged from US\$10 in India to US\$254 in Argentina, among the few countries for which prices were reported (De Lima and others 2004).

Morphine is likely to cost less where it is produced locally and used in easy-to-reach, urban locations. Liquid preparations made by mixing morphine powder will cost less than tablets. Even with these variations, if barriers to access to oral morphine are removed, a total drug cost of 1 cent per milligram or less for immediate-release oral morphine should be achievable for most countries. A realistic and conservative estimate of the cost of oral morphine is 0.5 cent to 1.0 cent per milligram in the countries in our analysis.

The cost of morphine per patient depends on the number of days that opioids are required and the average daily dose, recognizing that the required dosage typically increases with increasing pain nearer to death. An average daily dose in palliative care programs in developing countries is roughly 60 to 75 mg per day, and patients require this dose for an

average of three months. (Merriman 2002; personal communication, L. De Lima, International Association for Hospice and Palliative Care, June 2004; personal communication, M. R. Rajagopal, Amrita Institute of Medical Sciences, Kochi, Kerala, India, June 2004).

Using the inputs above, we estimate the cost of oral morphine for a cancer or AIDS patient with severe pain near the end of life at about 30 to 75 cents per day, or US\$9.00 to US\$22.50 per month, which is needed for an average of three months.

Costs of Other Necessary Drugs. Morphine's most common side effects are constipation, nausea, and (less frequently) psychosis. Representative drugs to treat these conditions are senna, a laxative, available to some government purchasers for

Table 52.3 Background Data, Assumptions, and Results of Cost Analysis

Item	Uganda	Chile	Romania
<i>Economic, demographic, and health characteristics</i>			
Population, 2001	22,800,000	15,400,000	22,400,000

Total incremental annual cost of oral morphine (US\$ millions)	2.2–4.9	0.6–1.2	1.1–2.6
Incremental annual cost per capita (US\$)	0.10–0.21	0.03–0.07	0.05–0.11
Incremental number of pain days per year avoided with use of oral morphine (millions)	3.6	0.9	1.9
Incremental cost per person per day of pain avoided (US\$)	0.60–1.35	0.60–1.35	0.60–1.35
Incremental cost per year of pain-free life added (US\$)	216–420	216–420	216–420

Sources: Income and demographic data, World Bank 2003; cancer deaths, Ferlay and others 2001; AIDS deaths, UNAIDS and WHO 2002a, 2002b, 2002c; per capita morphine use, INCB 2003; authors' calculations.

about 3 cents per day; prochlorperazine, an antiemetic, about 8 cents per day; and haloperidol, an antipsychotic, about 15 cents per day (Management Sciences for Health 2003). Retail prices after markups would add 20 to 30 percent.

Under the assumptions of this analysis, oral morphine for all dying cancer and AIDS patients would cost between 3 cents and 21 cents per capita per year (table 52.3) in Chile, Romania, and Uganda. The cost per pain day avoided by oral morphine is the same in all three countries, assuming that each country can acquire and dispense morphine equally efficiently.

Cost-Effectiveness

The analysis indicates that the drug costs of oral morphine come to about US\$216 to US\$420 per year of pain-free life gained in the three sample countries. The next question is whether the pain relief that could be achieved would be worth the cost. We know that patients value pain-free days highly. A day lived with the certainty of experiencing severe pain is of very low value, perhaps even lower than death itself (Furlong and others 2001; Le Gales and others 2002). Bryce and others (2004) find that people are willing to give up several months of healthy life for access to good end-of-life care. Patients in low-income countries place as great or even greater value on pain relief as patients in high-income countries (Cleland and others 1988; Murray and others 2003).

Costs Not Included in the Analysis

The analysis presented includes only the most basic costs—the costs of oral opioids and associated drugs—that would be incurred in a pain control program. Clearly, there are many other costs, ranging from the costs of services at the individual patient level to the costs of changing drug laws and policies at the national level. The most significant additional costs are discussed below.

Incremental Costs of Care Delivery. In addition to requiring the drugs themselves, implementation of the three-step ladder requires trained individuals to assess and monitor patients. Where health care systems are well developed, the incremental cost of adding oral morphine will be low. If it involved one additional health center visit, the cost per patient would increase by about US\$8 in Chile, US\$6 in Romania, and US\$4 in Uganda, amounting to less than 1 cent per capita in all three countries.

Where primary health care is weak, widespread access to oral opioids depends on the development of new systems, such as community- or hospital-based palliative care networks. Clearly, allocating the full cost of upgrading the health care system, or even the development of new palliative care programs, to oral morphine alone, would be inappropriate.

Other Costs. Security and recordkeeping related to stocking and distributing opioids, required by the Single Convention, entail additional fixed and ongoing costs. Because most hospitals handle injectable opioids (for example, pethidine), these costs would be less for hospital-based programs than for community-based programs.

Professional training and education is required for all personnel involved in the use of opioids for dying patients, in part to overcome fears and in part to ensure proper use. These costs are likely to be highest where the health care system is most deficient.

The costs of changing national policy toward opioids is substantial in terms of cost, time, expertise, and leadership (see, for example, Pain and Policy Studies Group 2003 and 2004 and other annual reports at <http://www.medsch.wisc.edu/painpolicy/publicat/annrepts.htm>). The time expended is an opportunity cost, but it may be amortized over a long time if the effort succeeds.

Potential Cost Savings. In some circumstances, making oral morphine available through a palliative care system could actually save money—for example, if it enabled some terminally ill patients who would otherwise be admitted to the hospital for pain control to die at home, or if it shortened their period of hospitalization. This outcome is more likely in places with good medical infrastructure, but even in low-income countries, patients in unbearable pain are often brought to hospitals by distressed relatives who are willing to go into debt to ease the suffering.

IMPLEMENTATION OF STRATEGIES TO IMPROVE PAIN CONTROL

Providing adequate oral morphine involves medical, political, legal, and societal change. Model programs, such as Hospice Uganda and efforts in India, have demonstrated the feasibility of providing good palliative care, including oral morphine, even for poor rural dwellers. WHO and the INCB have supported these efforts.

WHO Guidance on Palliative Care and Pain Relief

WHO has affirmed the need for palliative care and has defined the elements of model programs in several reports. In 2002, WHO's executive board called for the integration of pain and palliative care into national cancer control programs (box 52.4; WHO 2002). The Joint United Nations Programme on HIV/AIDS and the WHO AIDS Program consider pain and palliative care to be essential and pain management to be integral to AIDS care (Foley, Aulino, and Stjernsward 2003). WHO, in collaboration with the INCB and the WHO

Box 52.4

WHO Pain Relief and Palliative Care Recommendations Based on Resource Level

WHO's recommendations are as follows:

- Countries with low levels of resources should ensure that minimum standards for pain relief and palliative care are progressively adopted at all levels of care throughout the country. Countries also should ensure that patient coverage is high through services provided mainly by home-based care. Home-based care is generally the best way to achieve good-quality care and coverage in countries with strong family support and poor health care infrastructure. However, many patients are cared for in large cancer hospitals, and these institutions should have pain relief and palliative care available to all patients.
- Countries with medium levels of resources should ensure that minimum standards for pain relief and palliative care are progressively adopted at all levels of care and that, nationwide, coverage of patients is increasing through services provided by health care workers and home-based care.
- Countries with high levels of resources should ensure that national pain relief and palliative care guidelines are adopted by all levels of care and that, nationwide, patient coverage is high through a variety of options, including home-based care.

Collaborating Center (WHOCC), has developed guidelines for national authorities to self-diagnose their regulatory systems for problems that might lead to a lack of access to needed drugs (WHO 2000). These organizations also sponsor national and international workshops to help national authorities evaluate their policies, develop action plans, implement policy change, and evaluate outcomes. In addition to WHO and the INCB, a number of programs and organizations are making resources and expertise available to assist countries in various ways (box 52.5).

Hospice Uganda. Hospice Uganda began in 1993 with an old Land Rover, a grant to last three months, and a mandate to become Africa's model home-based hospice for dying cancer and AIDS patients (Ramsay 2001). By July 2004, the original Kampala location had served about 4,500 nearby patients. Two additional sites—Mobile Hospice Mbarara and Little Hospice Hoima—had served about 2,500 patients (Merriman 2004). Hospice Uganda's influence has spread across Africa through its reputation and the training programs it runs (Merriman 2004).

At the beginning, morphine was largely unavailable, and the law required that a physician prescribe it. Hospice Uganda's founder, Anne Merriman, convinced the government to amend the law to allow specialist palliative care nurses and clinical officers to prescribe morphine (Merriman 2003). Now, morphine, paid for by the government, is available for dying patients in about 15 of Uganda's 56 districts (Merriman 2003). In 1998, Uganda became the first nation in Africa to list palliative care as an essential clinical service.

The cost of treating a patient in Kampala and Mbarara is about US\$7 per week, including one home visit. For patients who come to the hospice, the cost is about US\$4 per week (personal communication, A. Merriman, Hospice Uganda, February 2003). Even at those prices, most patients cannot afford even the medicines, which are subsidized by contributions.

India. For decades, the only morphine available in India was injectable and used for postoperative pain. The enactment of a strict, national narcotics law caused morphine use to decline even further, from a high of 573 kilograms in 1985 to 18 kilograms in 1997, among the lowest per capita in the world. During the period of declining use, international efforts to promote pain control and palliative care programs began to reach India. In 1992, pain relief and the availability of morphine were designated priorities in the National Cancer Control Programme (Joranson, Rajagopal, and Gilson 2002; Rajagopal, Joranson, and Gilson 2001; Rajagopal and Venkateswaran 2003).

The Ministry of Health convened national workshops from 1992 to 1994 to ascertain why morphine use continued to decline. The following experience from a referral hospital, recounted by a former narcotics commissioner of India, is instructive:

the Institute has not been able to procure a single tablet [to] date, primarily due to the stringent state laws and multiplicity of licenses. After a lot of effort, the Institute had been able to obtain the licenses in 1994 and had approached [a manufacturer] for a supply of tablets . . . [but] by the time the tablets

Selected Resources for Developing National Palliative Care Programs

Resources available to countries include the following:

- The WHOCC for Policy and Communications in Cancer Care at the University of Wisconsin serves as a critical resource for palliative care education and country policy makers interested in assessing their opioid drug regulations and developing strategies for change. Its Web site links to WHO guidelines in several languages and provides articles and reports on efforts to improve national policy and opioid availability in Africa, Asia, Eastern Europe, and Latin America. See <http://www.medsch.wisc.edu/painpolicy/>.
- The WHOCC publishes *Cancer Pain Release* every quarter. The journal includes topical analysis of current issues in cancer pain management and palliative care and reviews recent international research and educational resources. See <http://www.whocancerpain.wisc.edu/>.
- The Open Society Institute sponsored workshops in cooperation with WHO's Essential Drug and Cancer units to bring together pain and palliative care experts and drug policy makers from Central and Eastern Europe and the former Soviet Union to develop strategies for implementing regulatory change to improve opioid availability. The Open Society Institute also supports the development of implementation strategies in 12 of these countries. That effort involves experts in pain and palliative care, cancer, and AIDS and representatives from ministries of health and financing and health insurance programs. See http://www.soros.org/initiatives/health/focus_areas/international.
- The *Journal of Pain and Symptom Management* has published three special supplements over the past nine years in association with the International Association for the Study of Pain. The supplements describe countries' efforts to advance opioid availability and palliative care. See http://www.elsevier.com/wps/find/journaldescription.cws_home/505775/description#description.
- The International Observatory on End of Life Care is a clearinghouse on palliative care in resource-poor countries that is aimed particularly at policy makers. The initial focus has been on Eastern and Central Europe, but the intent is to cover all resource-poor countries. See http://www.eolc-observatory.net/global_analysis/index.htm.

Source: Authors.

could be arranged, the licenses had expired. The doctors at the Institute and the associated pain clinic have stopped prescribing morphine tablets. (Joranson, Rajagopal, and Gilson 2002, 153).

In 1999, the INCB called on the government of India to take measures to make morphine available for medical uses. In 1994, an initiative begun by the WHOCC, the Indian Association of Palliative Care, and the Pain and Palliative Care Society systematically studied the reasons for the lack of morphine. In 1997, the WHOCC developed a proposal to reduce the number of licenses and extend their period of validity, and the following year all state governments were instructed to adopt a model rule based on the proposal. Gradually, rules have begun to change. By 2002, 7 of 28 states or territories had adopted the model rule, but it has been implemented successfully only in Kerala.

The success in Kerala can be attributed to three things: (a) the state government simplified the licensing process and stipulated that for oral morphine to be available from a center, it must have at least one doctor with at least one month of practical experience in palliative care; (b) the national drugs

controller exempted palliative care programs from needing a drug license, thereby eliminating the need for a pharmacist; and (c) a palliative care network was established, which consists of about 50 small programs. Statewide, coverage has increased to about 20 percent of those needing palliative care.

RECOMMENDATIONS FOR RESEARCH AND DEVELOPMENT

Policy makers and program implementers need practical tools to improve pain control and palliative care. They need survey instruments, guidance on how to effect policy and legal changes, and palliative care models for resource-poor settings. Many tools exist, but those could be made more accessible through the use of toolkits, distance learning, Web sites, and so on. Each country also should gather information to assess its own capabilities and needs, such as the following:

- In relation to the national level:
 - Study the incidence and prevalence of pain related to major causes of illness and death using methodologies

adapted from developed countries (Breivik, Collett, and Ventafridda forthcoming).

- Survey existing pain and palliative care programs to identify national and local leaders in pain control and palliative care and to catalog national guidelines and standards for acute and chronic pain. For hospice and palliative care services, assess the extent of available care, service delivery models, national and local policies, and professional and public knowledge about pain control and palliative care.
- Assess national and local regulatory barriers to opioid availability using WHO (2000) guidelines and needs assessment protocols (Higginson 1997) to help countries identify the patient-related, physician-related, and institutional issues that impede drug distribution.
- Study costs that affect opioid availability in several countries to document the costs of licensing, obtaining, storing, keeping records for, and dispensing opioid drugs.
- Study the costs of alternative delivery models for pain control medications in LMICs.
- Assess the offsetting savings achievable by reducing hospital days by means of better outpatient access to oral morphine, to document potential savings in representative countries, which might help reduce barriers to access.
- In relation to model programs:
 - Construct an inventory of model programs for pain control and palliative care. Include their infrastructure and personnel needs, their operating costs, and so on, in easy-to-use formats such as toolkits and education and training programs for policy makers and implementers. Regularly add new information from ongoing and new initiatives.
 - Devise additional models, particularly for poor rural communities, for providing palliative care and pain control practically, efficiently, and sustainably.

CONCLUSIONS

Unrelieved acute and chronic pain is a serious public health problem worldwide, and 80 percent of cancer patients and 50 percent of AIDS patients experience severe pain during the last months of life. Relief for these patients is possible only with oral morphine or another opioid, but developing countries face many barriers in this respect. Nevertheless, model pain and palliative care programs have demonstrated the feasibility of providing opioid treatment safely, effectively, and inexpensively in resource-poor settings. To this end, national governments must resolve the legal and regulatory barriers to opioid availability, but they need the expertise and support of the global community to make pain relief a reality.

Chapter 53

Public Health Surveillance: A Tool for Targeting and Monitoring Interventions

Peter Nsubuga, Mark E. White, Stephen B. Thacker, Mark A. Anderson, Stephen B. Blount, Claire V. Broome, Tom M. Chiller, Victoria Espitia, Rubina Imtiaz, Dan Sosin, Donna F. Stroup, Robert V. Tauxe, Maya Vijayaraghavan, and Murray Trostle

What gets measured gets done.
—Anonymous

Public health surveillance is the ongoing systematic collection, analysis, and interpretation of data, closely integrated with the timely dissemination of these data to those responsible for preventing and controlling disease and injury (Thacker and Berkelman 1988). Public health surveillance is a tool to estimate the health status and behavior of the populations served by ministries of health, ministries of finance, and donors. Because surveillance can directly measure what is going on in the population, it is useful both for measuring the need for interventions and for directly measuring the effects of interventions. The purpose of surveillance is to empower decision makers to lead and manage more effectively by providing timely, useful evidence.

Increasingly, top managers in ministries of health and finance in developing countries and donor agencies are recognizing that data from effective surveillance systems are useful for targeting resources and evaluating programs. The HIV and severe acute respiratory syndrome (SARS) epidemics underscored the critical role of surveillance in protecting individual nations and the global community. For example, in 2005, China rapidly began to expand its surveillance and response capacity through its Field Epidemiology Training Program (FETP); Brazil and Argentina chose to use World Bank loans to develop surveillance capacity; and the U.S. Agency for International Development (USAID) redesigned its surveillance strategy to

focus on the use of data to improve public health interventions (USAID 2005). Additionally, the guidelines for implementing the 2004 draft revised International Health Regulations require World Health Organization (WHO) member states to have key persons and core capacities in surveillance (<http://www.who.int/csr/ihr/howtheywork/faq/en/#draft>).

Just as decision makers require competent, motivated economists to provide quality technical analyses, they also need competent staff members to provide scientifically valid surveillance information and communicate the results as information for action. Competent epidemiologists and surveillance staff members are not a luxury in developing countries; they are a necessity for rational planning, implementation, and intervention (Narasimhan and others 2004).

DEFINITIONS AND BASIC CONCEPTS

In this chapter, we use the following definitions:

- *Indicator*: a measurable factor that allows decision makers to estimate objectively the size of a health problem and monitor the processes, the products, or the effects of an intervention on the population (for example, the number of new cases of diarrhea, the proportion of children fully

immunized in a district, or the percentage of high school students who report that they smoke at least one cigarette a day).

- *Active surveillance*: a system employing staff members to regularly contact health care providers or the population to seek information about health conditions. Active surveillance provides the most accurate and timely information, but it is also expensive.
- *Passive surveillance*: a system by which a health jurisdiction receives reports submitted from hospitals, clinics, public health units, or other sources. Passive surveillance is a relatively inexpensive strategy to cover large areas, and it provides critical information for monitoring a community's health. However, because passive surveillance depends on people in different institutions to provide data, data quality and timeliness are difficult to control.
- *Routine health information system*: a passive system in which regular reports about diseases and programs are completed by public health staff members, hospitals, and clinics.
- *Health information and management system*: a passive system by which routine reports about financial, logistic, and other processes involved in the administration of the public health and clinical systems can be used for surveillance.
- *Categorical surveillance*: an active or passive system that focuses on one or more diseases or behaviors of interest to an intervention program. These systems are useful for program managers. However, they may be inefficient at the district or local level, at which staff may need to fill out multiple forms on the same patient (that is, the HIV program, the tuberculosis program, the sexually transmitted infections program, and the Routine Health Information System). At higher levels, allocating the few competent surveillance experts to one program may leave other programs underserved, and reconciling the results of different systems to establish the nation's official estimates may be difficult.
- *Integrated surveillance*: a combination of active and passive systems using a single infrastructure that gathers information about multiple diseases or behaviors of interest to several intervention programs (for example, a health facility-based system may gather information on multiple infectious diseases and injuries). Managers of disease-specific programs may be evaluated on the results of the integrated system and should be stakeholders. Even when an integrated system is functioning well, program managers may continue to maintain categorical systems to collect additional disease-specific data and control the quality of the information on which they are evaluated. This practice may lead to duplication and inefficiency.
- *Syndromic surveillance*: an active or passive system that uses case definitions that are based entirely on clinical features without any clinical or laboratory diagnosis (for example, collecting the number of cases of diarrhea rather than cases

of cholera, or "rash illness" rather than measles). Because syndromic surveillance is inexpensive and is faster than systems that require laboratory confirmation, it is often the first kind of surveillance begun in a developing country. However, because of the lack of specificity (for example, a "rash illness" could be anything from the relatively minor rubella to devastating hemorrhagic fevers), reports require more investigation from higher levels. Also an increase in one disease causing a syndrome may mask an epidemic of another (for example, rotavirus diarrhea decreases at the same time cholera increases).

In the specialized area of surveillance for biologic terrorism, syndromic surveillance refers to active surveillance of syndromes that may be caused by potential agents used by biologic terrorists and sometimes refers to alternative measures such as increases in the use of over-the-counter drugs or increases in calls to emergency departments.

- *Behavioral risk factor surveillance system (BRFSS)*: an active system of repeated surveys that measure behaviors that are known to cause disease or injury (for example, tobacco or alcohol use, unprotected sex, or lack of physical exercise). Because the aim of many intervention program strategies is to prevent disease by preventing unhealthy behavior, these surveys provide a direct measure of their effect in the population, often long before the anticipated health effects are expected. These surveys are useful for providing timely measures of program effectiveness for both communicable and noncommunicable disease interventions.

OBJECTIVES OF SURVEILLANCE SYSTEMS

Public health surveillance provides the scientific and factual database essential to informed decision making and appropriate public health action. The key objective of surveillance is to provide information to guide interventions. The public health objectives and actions needed to make successful interventions determine the design and implementation of surveillance systems. For example, if the objective is to prevent the spread of epidemics of acute infectious diseases, such as SARS, managers need to intervene quickly to stop the spread of disease. Therefore, they need a surveillance system that provides rapid early warning information from clinics and laboratories. In contrast, chronic diseases and health-related behaviors change slowly. Managers typically monitor the effect of programs to change risky behaviors such as tobacco smoking or chronic diseases once a year or even less often. A surveillance system to measure the population effects of a tuberculosis control program might provide information only every one to five years—for example, through a series of demographic and health surveys. The principle is that different public health objectives and the actions required to reach them require different information

Box 53.1

Different Objectives, Different Data, Different Systems

<i>Objective</i>	<i>Action</i>	<i>Data</i>	<i>System</i>
Detect epidemics	Epidemic response	Early warning information	Active surveillance
Monitor intervention programs	Program monitoring	Program indicators	Health information
Monitor impact of policy change	Health policy	Health indicators	Health information
Monitor health system	Resource allocation	Administrative data	Health information and management

systems. The type of action that can be taken, when or how often that action needs to be taken, what information is needed to take or monitor the action, and when or how frequently the information is needed should determine the type of surveillance or health information system (box 53.1).

PRINCIPLES AND USES OF SURVEILLANCE

Foege, Hogan, and Newton (1976) state that “the reason for collecting, analyzing, and disseminating information on a disease is to control that disease. Collection and analysis should not be allowed to consume resources if action does not follow.” The fundamental principle of public health surveillance is that the surveillance should be designed and implemented to provide valid (true) information to decision makers in a timely manner at the lowest possible cost. Because managers are unlikely to need to make interventions to address small differences between areas, sacrificing precision makes sense to improve timeliness and save resources that can be used for public health interventions. The utility of surveillance data can be viewed as immediate, annual, and archival, on the basis of the public health actions that can be taken (table 53.1; Thacker and Stroup 1998b).

ESTABLISHING AND MAINTAINING A SURVEILLANCE SYSTEM

What is worth doing is worth doing right. Managers who decide to use public health surveillance as a management tool must recognize that they will need to commit political support and human and financial resources. As with every health system, competent, motivated health workers need to be found or trained and provided with career paths and supervision. After a manager decides to create a surveillance system, there are six steps to establishing the system. Because the system must adapt constantly to changes in the population and the physical

Table 53.1 Utility of Surveillance Data

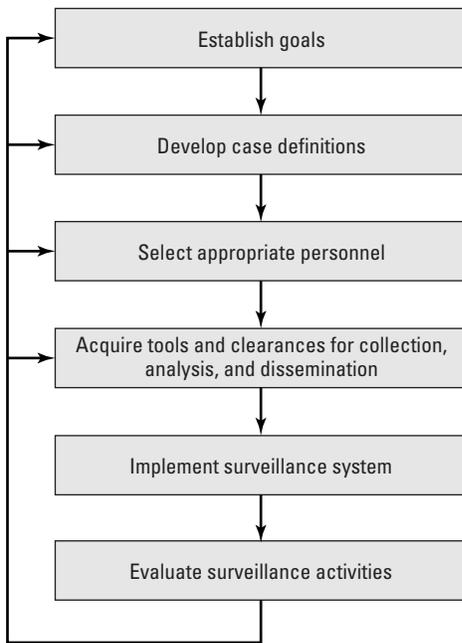

Immediate detection of	Epidemics Newly emerging health problems Changes in health practices Changes in antibiotic resistance Changes in distribution of population at risk for disease

and social environment, these steps are linked continuously (figure 53.1; Thacker and Stroup 1998a).

ANALYSIS AND DISSEMINATION OF SURVEILLANCE DATA

Surveillance information is analyzed by time, place, and person. Knowledgeable technical personnel should review data regularly to ensure their validity and to identify information

Source: Adapted from Thacker and Stroup 1998a, 119.

Figure 53.1 Elements in Establishing and Maintaining a Surveillance System

of use to top managers. Simple tables and graphs are most useful for summarizing and presenting data. Timely dissemination of data to those who make policy and implement intervention programs is critical to the usefulness of surveillance data.

The rapidly evolving field of public health informatics, which deals with collection, classification, storage, retrieval, analysis, and presentation of large amounts of health data, offers the potential for truly integrated public health surveillance based on data standardization, a communications infrastructure, and policies on data access and sharing. Surveillance will benefit by incorporating a systematic approach to standards for data content. For example, the U.S. Centers for Disease Control and Prevention (CDC) has used standards-based systems to support automatic electronic reporting of diagnostic laboratory results of notifiable diseases, thereby both increasing the number of cases reported and receiving results more rapidly (Effler and others 1999). Use of data standards facilitates comparability of surveillance information over time (for example, measurement of effect of program interventions), across different surveillance approaches (for example, facility-based reporting compared with sample surveys), and across countries and regions. To be credible, a standard should be developed through an open, participatory process, by an internationally recognized accredited standards-development organization that is also capable of long-term

maintenance and evolution of the standard. Public health data needs extend into multiple areas beyond clinical medicine (for example, environmental toxins, unintentional injury, and food safety).

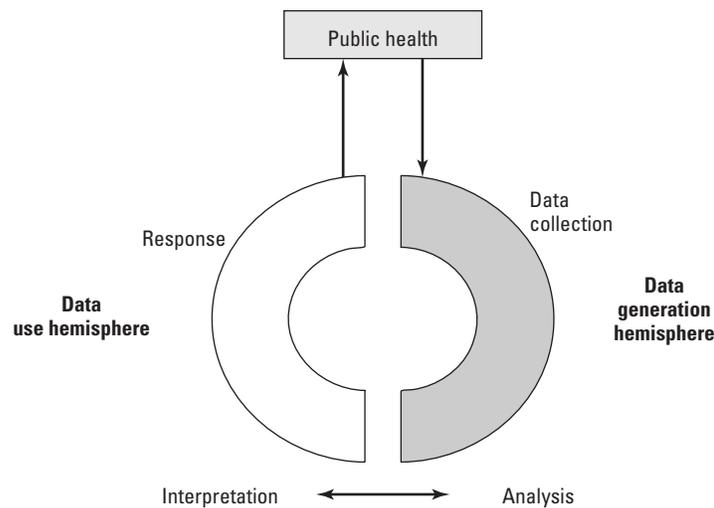

One international standard computer program used in many countries' information systems is Epi Info, an epidemiology surveillance and biostatistics program widely used around the world for the analysis of surveillance data (<http://www.cdc.gov/epiinfo>). CDC created, maintains, and distributes Epi Info at no cost to users.

SURVEILLANCE AS A COMPONENT OF NATIONAL PUBLIC HEALTH SYSTEMS

WHO and the World Bank cite public health surveillance as an essential function of a public health system (World Bank 2001). When linked to policy and program units, surveillance information improves the efficiency and effectiveness of health services by targeting interventions and documenting their effect on the population.

A critical challenge in the health sector in developing countries is to ensure quality and effectiveness of surveillance and public health response in an environment of decentralization. National-level program and surveillance system managers may lose control of the quality and timeliness of locally collected data. This situation can be avoided by training local decision makers in how to use information to meet their needs and negotiating with them over the core information collected by each district local unit. National-level managers or donors can also improve information quality by sponsoring national surveillance scientific and quality assurance networks, linking funding to provision of adequate data, and performing periodic surveys to confirm the results of local reporting. If the responsibility for implementing programs is devolved to local managers, then national-level managers need only a few summary indicators, rather than the detailed information they may be used to. District or local managers tend to prefer integrated systems to minimize filling out redundant forms.

Donors need surveillance data to target and evaluate their investments. If they perceive weakness in the national system, they may create parallel nongovernmental surveillance systems to gather data directly to meet their needs. These systems invariably pay workers more than government jobs do, so the most competent people in the government system may leave to work for the parallel system. Although this system meets donors' short-term needs, it invariably weakens government systems. Parallel systems may weaken the very ministries that they are meant to help and may not be sustainable after external funding ends. Therefore, parallel systems are inherently inequitable and should be used only as a last resort.

Figure 53.2 Surveillance and Response Conceptual Framework

SURVEILLANCE AS A TOOL TO IMPROVE PUBLIC HEALTH

Managers need focused, timely, scientifically sound information that provides evidence to make decisions on interventions for improving the health of the population in their jurisdiction. Simply collecting data and presenting them are not enough.

Using Surveillance Information for Evidence-Based Decisions

A major gap in promoting effective surveillance lies between the production of data and the ability to convert those data into usable information and then initiate the appropriate public health action. Surveillance and response can be described in terms of a *data generation hemisphere* and a *data use hemisphere* (USAID 2005). The data generation hemisphere is the traditional view of surveillance, whereas the data use hemisphere is the public health response that begins with interpretation of the data from the surveillance system (figure 53.2).

Substantial attention and the accompanying resources in surveillance have been devoted to the prompt and complete production of surveillance data. Although developing countries experience weaknesses in both hemispheres, more attention is needed to creating and strengthening the local capacity within developing countries to identify and manage effective responses to disease outbreaks and public health conditions of national and international concern. In some disease-specific programs, this capacity has to be imported through short-term expatriate assistance. Even when local capacity is developed, it is often specific to the disease program, making transfer of skills to other areas problematic. The failure to develop this indigenous

capacity has limited the ability of developing countries to build national surveillance systems that respond to both international public health threats and local health concerns. This capability is essential to the sustained development of countries.

Role of Field Epidemiologists in Providing Evidence

Developed countries have constructed their public health and disease control strategies by using the principles of field epidemiology. Developing countries need to build and sustain human capacity in field epidemiology. Strengthened field epidemiologic capacity can serve a country in the following specific areas:

- providing a response to acute problems
- providing the scientific basis for program and policy decisions
- implementing disease surveillance systems
- supporting national health planning
- making resource allocation decisions
- allocating the human capacity base for national health priorities.

Specific competencies that should be developed include, but are not limited to, the ability to accomplish the following:

- design, implement, and evaluate surveillance for a health event
- identify and assess an actual public health problem
- design and conduct a scientific investigation
- analyze and interpret data from an investigation
- recommend logical and practical public health actions after the analysis and interpretation of data

- be proficient in all aspects of diseases of public health importance (for example, HIV and AIDS, sexually transmitted diseases, malaria, tuberculosis, and zoonoses).

These competencies need to be tailored to the various levels of the health care system.

Since 1975, CDC and WHO have collaborated with more than 30 countries to strengthen health systems and address training needs for disease detection and response in a country-specific, flexible, and sustainable manner. More than half of the world's population now lives in a country where surveillance, investigation, and response are carried out by staff members and trainees of FETPs and allied programs, which include the Epidemic Intelligence Service in the United States, the European Program for Intervention Epidemiology Training, and Public Health Schools without Walls (PHSWOWs). These programs generally function within central ministries of health and may not be visible outside the public health system. It can be argued that these programs provide most of the surveillance of and response to emerging infections in the world, in addition to training most of the public health workers who manage surveillance systems at the top level. FETPs are two-year courses designed to provide a ministry with a motivated, professional group of field epidemiologists with the expertise to respond to managers' needs for evidence, perform surveillance, respond to outbreaks, and train and supervise technical personnel at other levels (White and others 2001).

Other models have evolved. Guatemala's marriage of its FETP (part of a larger, Central American FETP) with the Data for Decision Making program (Pappaioanou and others 2003) exemplifies this successful local adaptation. Data for Decision Making recruits health workers from the community and sub-district levels to receive training in surveillance and outbreak investigation in the context of their daily work. This training is delivered as a series of linked workshops with practical field-based projects, providing short-term service at the local levels. The most promising graduates of the course are selected for further training in an FETP. India, with its decentralized system, complex cultural and population dynamics, and wide variance in the sophistication of public health institutions, provides another model for strengthening national surveillance. The World Bank initiated the Integrated Disease Surveillance Project, which develops the capacity of local and midlevel surveillance workers in India. Additionally, FETP graduates are recruited as the project's surveillance officers at the state level to coordinate the surveillance activities of the hundreds of local health workers throughout the states.

SELECTED SURVEILLANCE STRATEGIES

Surveillance systems need to be designed and implemented to meet top management's needs for focused, reliable, timely

evidence gathered efficiently and presented effectively. Because these needs differ, depending on management's needs, a number of different strategies have been developed. Here are some of the most useful.

Sentinel Surveillance

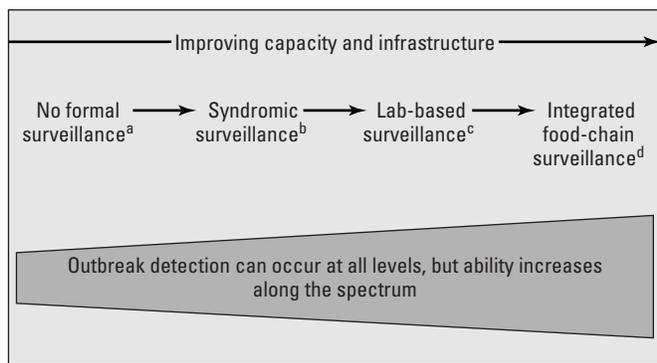

In a sentinel surveillance system, a prearranged sample of reporting sources agrees to report all cases of defined conditions, which might indicate trends in the entire target population (Birkhead and Maylahn 2000). When properly implemented, these systems offer an effective method of using limited resources and enable prompt and flexible monitoring and investigation of suspected public health problems. Examples of sentinel surveillance are networks of private practitioners reporting cases of influenza or a laboratory-based sentinel system reporting cases of certain bacterial infections among children. Sentinel surveillance is excellent for detecting large public health problems, but it may be insensitive to rare events, such as the early emergence of a new disease, because these infections may emerge anywhere in the population.

Periodic Population-Based Surveys

Population-based surveys can be used for surveillance if they are repeated on a regular basis (Thacker and Berkelman 1988). Examples of population-based surveys in surveillance include the BRFSS in the United States, HIV-prevalence surveys, household surveys, and the demographic and health surveys that many developing countries conduct every five years (<http://www.orcmacro.com>). Population-based surveys require careful attention to the methodology, particularly the use of standard protocols, supervision of interviewers, comparable sampling strategy, and standard questionnaires. These surveys require a clear definition of the target population to which the results can be generalized, and they need careful attention to the sample size, based on efficiency and the epidemiologic characteristics of the health condition under surveillance (for example, rare conditions require substantial samples). Supervising interviewers and maintaining high response rates are critical to avoid bias. Because the surveys are repetitive, population changes (caused, for example, by mortality or mobility) might bias results.

Laboratory-Based Surveillance

The methods used for infectious disease surveillance form a spectrum that evolves with the economic development of a country. Foodborne disease (FBD) surveillance, for example, is divided into four distinct levels of surveillance. Each level is more complex and has greater capacity for controlling and detecting disease, but it also depends on more resources and infrastructure (figure 53.3).

Source: Authors.

- a. Without a formal surveillance, only large or unusual outbreaks can be detected.
- b. Syndromic surveillance is based on groups of signs or symptoms indicative of a common diagnosis, such as acute gastroenteritis.
- c. Laboratory-based surveillance relies on laboratory-confirmed pathogens, such as *Salmonella* or *Shigella*.
- d. Integrated food-chain surveillance uses data from across the food chain.

Figure 53.3 Spectrum of Case-Based Foodborne Disease Surveillance

For FBD, surveillance for clinical syndromes is the most common method of surveillance in the developing world. Surveillance of FBD outbreaks that are investigated by public health authorities is often a useful means of monitoring both the safety of the food supply and the activities of the public health system. Although both surveillance for clinical syndromes and outbreak surveillance will remain important, the future in FBD is in laboratory-based surveillance. If microbiologic diagnosis is sought routinely for a sample of patients with acute gastroenteritis, then surveillance based on those diagnoses is possible. For enteric bacterial pathogens such as *Salmonella* or *Shigella*, determining the serotype of the strains in central reference laboratories allows more rapid and complete identification of epidemics, which may otherwise lead to preventable death and disability.

Laboratory-based surveillance systems require resources, facilities, and training. A central public health reference laboratory is essential for quality assurance and quality control and support. Such a laboratory-based system might begin with systematic referral of a sample of strains isolated at a sample of sentinel clinics, plus those strains that are part of outbreaks. A systematic sampling scheme provides better data than a more haphazard attempt at universal reporting. Regular sharing of information between the public health microbiology laboratory and epidemiologists is critical for the information to be used successfully.

The utility of serotyping as an international language for *Salmonella* subtypes has led to its widespread adoption. In a recent survey, 61 countries reported that they used *Salmonella* serotyping for public health surveillance (Herikstad, Motarjemi,

and Tauxe 2002). A collaborative WHO program called Global Salm-Surv promotes the use of *Salmonella* serotyping internationally among countries that wish to upgrade their national capacity for FBD surveillance (<http://www.who.int/salmsurv/en>).

Molecular subtyping is now expanding the power of laboratory-based surveillance to detect outbreaks in the background of sporadic cases by distinguishing the molecular “fingerprint” of an outbreak strain. CDC maintains PulseNet, an Internet-based network of all U.S. public health laboratories that uses a standardized genotyping method called pulsed-field-gel-electrophoresis (PFGE) as the basis for a national database of PFGE subtypes (Swaminathan and others 2001). Standardized subtyping protocols have now been developed for seven pathogens, and next-generation, gene-based technologies are under development for the future. Similar networks are developing around the world, with PulseNet Europe and PulseNet Canada already active and discussions rapidly advancing for PulseNet Asia Pacific and PulseNet Latin America. As with *Salmonella* serotyping itself, the global use of standard genotyping will facilitate the detection of multicontinent clusters.

Integrated Disease Surveillance and Response

The Integrated Disease Surveillance and Response (IDSR) strategy, first developed in Africa, links epidemiologic and laboratory data in communicable disease surveillance systems at all levels of the health system, with emphasis on integrating surveillance with response (WHO 1993, 1998). Districts were identified as a focus for strengthening efforts in collecting timely data, analyzing the collected data, and using the generated information for public health responses. The IDSR strategy is based on core activities, including case-patient detection, registration, and confirmation; reporting, analysis, use, and feedback of data; and epidemic preparedness and response (for example, outbreak investigations, contact tracing, and public health interventions). Support functions include coordination, supervision or performance evaluation, training, and resource provision for infrastructure, including communication (Nsubuga, Eseko, and others 2002).

Key steps in implementing the IDSR strategy include sensitizing key health authorities and stakeholders; conducting situational analysis; preparing a strategic IDSR plan; identifying and training a motivated, competent workforce; developing national IDSR technical guidelines; implementing the plan; and monitoring and evaluating implementation to improve performance (WHO 2000b). Assessment of the existing national surveillance and response activities provides baseline data to measure progress; to identify and build consensus on the national priority communicable diseases; to identify surveillance gaps of the selected priority diseases; to document

Table 53.2 Steps in the Development of the Philippine National Epidemic Sentinel Surveillance System

Steps	Data side	Human capacity side
1.	Identify the health problems thought to cause burden disease.	Consult top managers, donors, international agencies, and experts.
2.	Determine who will make interventions.	Involve users in design.
3.	Determine information users' need to make interventions.	Involve users in design.
4.	Decide how often decision makers need reports.	Involve users in design.
5.	Identify who collects, tabulates, and analyzes reports and who disseminates information.	Identify manager and staff to analyze, report, and enter data.
6.	Design report.	Involve users and staff in design.
7.	Make table shells.	Involve staff in design.
8.	Design questionnaire.	Involve staff in design.
9.	Pilot questionnaire.	Involve staff in implementation and evaluation.
10.	Pilot data flow and analysis.	Involve staff in implementation and evaluation.
11.	Pilot system.	Train staff in system and involve them in evaluation.
12.	Run system.	Involve staff in ongoing training and quality assurance monitoring.
13.	Evaluate system: Was information used? Are data and analysis of good quality?	Involve staff and users in design of external evaluation and in review of evaluator's report.

the strengths, weaknesses, and opportunities of the existing systems; and to make appropriate recommendations. The WHO Regional Office for Africa, collaborating with its partners, has prepared tools and guidelines for implementation of IDSR at the country level. Indicators to monitor the performance of the surveillance and response systems have been prepared and field tested and are now in use in Africa.

Example: The Philippine National Epidemic Surveillance System

In the late 1980s, the Philippine Department of Health (PDOH), relying on its integrated management information system, detected less than one outbreak per year in a population of more than 60 million people. In 1989, the PDOH designed the National Epidemic Sentinel Surveillance System, a hospital-based sentinel surveillance system that encompasses both the flow of data and the personnel requirements needed to make the surveillance system work effectively (table 53.2). After the pilot study demonstrated promising results, the PDOH created personnel positions and a supervisory structure for sentinel physicians, nurses, and clerks in regional epidemiology and surveillance units (RESUs) integrated into the public health system. In 1995 alone, the system detected and formally investigated about 80 outbreaks, including 25 bacteriologically confirmed outbreaks of typhoid and 5 of cholera. As the Philippines developed HIV serological and behavioral risk surveillance, the RESU staff conducted surveys in their communities. By integrating surveillance functions that were based

on the skills of the workforce, PDOH was able to avoid the duplications, inefficiencies, and sustainability problems of multiple vertical systems (White and McDonnell 2000).

Informal Networks as Critical Elements of Surveillance Systems

WHO and other agencies frequently receive telephone calls or informal reports about urgent health events. WHO publishes an informal list of these “rumors,” which allows public health workers to respond to health risks promptly rather than waiting for formal reports (<http://www.who.int/csr/don/en/>). The graduates of FETPs, PHSWOWs, and similar programs that provide competency-based on-the-job training in ministries of health make up one of the most important informal networks.

FETPs and allied programs both train epidemiologists and provide service to their ministries of health. For example, a student in the Brazilian FETP was assigned to review routine data on patients with leishmaniasis. She noted that some patients had symptoms of heavy metal poisoning, and further study indicated that a drug being used to treat leishmaniasis was contaminated with heavy metals. The drug was reformulated, and the problem was resolved. When this study was presented at a regional meeting of the Training Programs in Public Health Interventions Network (a network of FETPs and allied training programs), other countries banned the drug until it was reformulated (CDC 2004a).

Large categorical surveillance systems are expensive, and staff members might become complacent, especially if the

disease under surveillance is rare. For example, the polio surveillance system for acute flaccid paralysis in the Western Hemisphere detected no cases in July 2000. A trainee from the FETP of the Dominican Republic, while investigating a case of suspected poisoning in a child, documented the first outbreak of circulating vaccine-type poliovirus in the Western Hemisphere since 1991. There were 13 confirmed cases in the Dominican Republic and 8 cases in Haiti. Her investigation led to national immunization days in both countries, which raised immunization levels and stopped the outbreak (Kew and others 2002).

THE ROLE OF SURVEILLANCE IN MAJOR OUTBREAKS

It seems incredible that a disease as devastating as AIDS could have spread silently to many countries over many years before it was detected and before effective control measures were implemented in the 1980s. In recent years, surveillance and response systems at all levels have been more effective at identifying and preventing spread of infectious diseases.

Example: Surveillance and Global Response to SARS

An epidemic of severe pneumonia of unknown etiology was detected in Guangdong province, China, in November 2002, and control measures were instituted on the basis of the way the disease spread from person to person. In February and March 2003, the disease spread to Hong Kong (China) and then to Vietnam, Singapore, Canada, and elsewhere (WHO 2003b). This new disease was named *severe acute respiratory syndrome*, and a preliminary case definition was established on the basis of initial epidemiologic investigations. A novel coronavirus (SARS-CoV) was identified as the causative agent in March, and mapping of the full genome was completed in April. This global pandemic ended in July 2003, as transmission was interrupted in Taiwan (China), after more than 8,000 patients in 26 countries and five continents were affected and 774 deaths were confirmed (Peiris and others 2003).

WHO spearheaded the global effort to control this pandemic, working with national and subnational health workers. In China, the FETP, which was initiated in October 2001 in the China Center for Disease Control, mobilized all 20 of its trainees, and they contributed substantially to the surveillance, investigation, and control of the SARS outbreak, working with local health officials (CDC 2003a). In Canada, which had the most cases of SARS outside Asia, 8 of the 10 FETP residents were involved in the SARS outbreak. They instituted surveillance, conducted epidemiologic investigations, designed prevention and control guidelines, responded to inquiries from the media and the public, and planned and implemented

epidemiologic studies (http://www.phac-aspc.gc.ca/cfep-pcet/outbreaks_e.html).

The success of this global effort to control the first new epidemic disease of the 21st century depended on a combination of open collaboration among scientists and politicians of many countries and the rapid and accurate communication of surveillance data within and among countries. Rapid global spread was recognized, and a global surveillance network was established on the basis of an agreed-upon case definition that was sufficiently specific to ensure effective reporting.

Public health surveillance is critical to recognizing new cases of SARS and differentiating this disease from other causes of severe respiratory illness, especially influenza (Heymann and Rodier 2004). Ongoing research into sources in the environment as well as clinical, laboratory, and epidemiologic concerns will improve surveillance for this critical public health problem. Notably, this highly contagious disease—for which there is neither a vaccine nor a cure—was controlled by competent, dedicated health workers with access to excellent communications. SARS presented a greater challenge than smallpox, for which long incubation periods and vaccine facilitate control (Mack 2005). Although it is reassuring that national, regional, and global systems were effective in controlling SARS, there is no reason to rest on our laurels. The only certainty is that there will be more new challenges, very possibly including further outbreaks of SARS.

Example: Avian Influenza in Thailand

The disastrous pandemic (worldwide epidemic) of influenza in 1918 is thought to have originated from epidemics in birds, as were the influenza pandemics of 1957 and 1968 (Ungchusak and others 2005). In early 2004, large epidemics of avian influenza were recognized in birds in eight Asian countries; by November, the disease had spread from birds to 44 humans, 73 percent of whom died (Ungchusak and others 2005). This contagion sparked fears that the highly lethal avian virus might be adapting to spread from person to person, which could cause extensive health and economic damage around the world. In Thailand, avian influenza was investigated by FETP graduates and others in the Thai Ministry of Health in partnership with CDC. By applying field epidemiologic techniques supported by laboratory studies, they detected that the virus was being spread from human to human in a family. It is likely that person-to-person transmission may have occurred in other countries, where field epidemiology was not used.

The Thai example is important for achieving the following: (a) raising global awareness of the potential of a global catastrophe early enough that plans can be made to avert or decrease harm and (b) demonstrating that, as with SARS, the disease could be controlled with proven field epidemiologic methods supplemented by good communications, without vaccines,

drugs, or a high-technology laboratory or surveillance system (Mack 2005).

Example: Ebola in Uganda, the Role of the PHSWOW

On October 8, 2000, a second-year student in the Ugandan PHSWOW returned to Gulu district in northern Uganda for his field project. He found a hospital jammed with patients with high fevers, diarrhea, and bleeding. He diagnosed viral hemorrhagic fever. He called the Ministry of Health in Kampala, where that weekend a graduate of the PHSWOW was in charge of taking calls about epidemics. She agreed with his diagnosis and arranged for samples to be rushed to the National Institute for Virology in South Africa, the nearest WHO reference center for viral hemorrhagic fevers. When the minister of health arrived at his office the next day, the graduate briefed him. Recognizing the gravity of the situation, the minister sent the graduate to head the public health team surveillance and control team in Gulu, and the student headed the clinical team that established infection control in hospitals and treated patients.

Laboratory tests quickly confirmed that the illness was Ebola hemorrhagic fever, which usually kills more than 50 percent of those infected (Heymann 2004). Public health surveillance was difficult for several reasons. Because the disease was severe and rapidly fatal, rural villagers feared that they might be stigmatized if the government knew about cases in their area. Some sought out traditional healers; others fled as soon as they realized they had been exposed, which prompted outbreaks in two other districts. Gulu was a politically unstable area, and some villages were difficult to reach because of rebel or bandit activity. The Ugandan government mobilized its military to help with case finding and invited WHO, CDC, and other international teams to assist. Patients with Ebola infection require intense nursing and medical attention to control bleeding, diarrhea, and fevers. Some patients bleed easily, and all their secretions can be highly infectious. Hospitals in Gulu were desperately short of supplies to control the spread of infection from so many patients simultaneously. In spite of this situation, Ugandan health workers selflessly cared for the sick. By January 23, 2001, a total of 425 cases had occurred, the largest Ebola outbreak recorded. Only 53 percent of the patients had died, a proportion far less than the 88 percent reported in the 1976 Ebola outbreak in the Democratic Republic of Congo (formerly Zaire) and other previous epidemics (WHO Report of an International Commission 1978). Sadly, 22 health care workers were infected. Because the team from the Ugandan Ministry of Health set up active surveillance nationwide, the other two outbreaks, started when infected Gulu residents fled to distant villages, were quickly detected and controlled. International observers commented, “National notification and surveillance efforts led to the rapid identification of these foci and to effective containment” (CDC 2001).

The Ugandan Ministry of Health invested in developing competent, motivated health workers through the PHSWOW, an active partnership with Makerere University, the Rockefeller Foundation, CDC, and WHO. Both students and graduates contributed to the ministry’s ability to rapidly identify and control this dangerous epidemic. Because the minister had timely evidence, he was able to notify other countries quickly and to bring in international teams before the disease spread further. Partially because of the lessons learned from this epidemic, Uganda has become one of the leading countries in implementing the IDSR program.

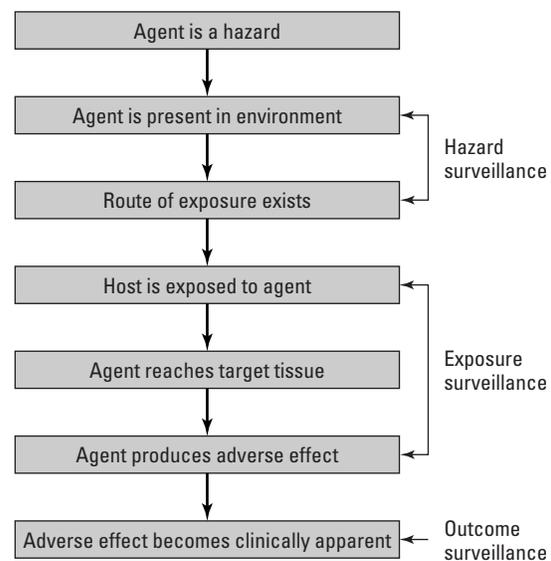

SURVEILLANCE FOR SPECIFIC CONDITIONS

Surveillance systems are important tools for targeting, monitoring, and evaluating many health risks and interventions. Because managers need a wide variety of information for specific interventions, systems have been developed and tested to meet those needs.

Environmental Public Health Surveillance

Surveillance for environmental public health practice requires the collection, analysis, and dissemination of data on hazards, exposures, and health outcomes (figure 53.4; Thacker and others 1996).

Health outcomes of relevance include death, disease, injury, and disability. However, relating those outcomes to specific environmental hazards and exposures is critical to

Source: Thacker and others 1996.

Figure 53.4 The Process of Adverse Effects and the Corresponding Surveillance

environmental public health surveillance. Hazards include toxic chemical agents, physical agents, biomechanical stressors, and biologic agents that are located in air, water, soil, food, and other environmental media. Exposure surveillance is the monitoring of members of the population for the presence of an environmental agent, its metabolites, or its clinically inapparent (for example, subclinical or preclinical) effects.

Four challenges complicate environmental public health surveillance. First, the ability to link specific environmental causes to adverse outcomes is limited by our poor understanding of disease processes, long lead times, inadequate measures of exposure, and multiple potential causes of disease. Second, data collected for other purposes rarely include sufficient information to meet a case definition for a condition caused by an environmental agent. Third, public alarm is often out of proportion to the hazard of concern, and sentiment will often influence public policy disproportionately to scientific information. Fourth, biologic markers will become increasingly critical elements of environmental exposure surveillance.

Obtaining data on exposure, which can include estimates derived from hazard data through sophisticated modeling or direct measurements of individual exposure obtained from use of personal monitors (for example, passive air samplers), is generally impractical in developing countries. Childhood blood lead levels are the only biomonitoring data that are collected routinely in several countries, either in national surveys or from screening programs for children at high risk.

Health outcome surveillance as applied to environmental public health is similar to traditional surveillance efforts. In the United States, the focus is on surveillance for birth defects; developmental disabilities (for example, cerebral palsy, autism, and mental retardation); asthma and other chronic respiratory diseases (for example, bronchitis and emphysema); cancer; and neurological diseases (for example, Parkinson's disease, multiple sclerosis, and Alzheimer's disease) (McGeehin, Qualters, and Niskar 2004). Other nations have different sets of priority conditions for surveillance. Disease registries, vital statistics data, annual health surveys, and administrative data systems (for example, hospital discharge data) are sources that have been used for monitoring health conditions. The challenges mentioned previously have constrained our ability in all nations, regardless of level of development, to establish and maintain effective and comprehensive environmental public health surveillance systems. As we invest in understanding the enlarging threats in the global environment, we must overcome these challenges and establish improved surveillance systems. The health of the global community depends on this investment.

Injury Surveillance

Injuries are a major public health problem and are among the 10 leading causes of death worldwide, killing an estimated

5 million persons each year and causing high rates of disability. People from all economic groups are at risk for injuries, but death rates caused by injury tend to be higher in developing countries (Peden, McGee, and Sharma 2002). Injury surveillance includes monitoring the incidence, causes, and circumstances of fatal and nonfatal injuries. Injuries are classified by the intention of the act into two groups: unintentional injuries and violence-related injuries. WHO (Holder, Peden, and Krug 2001) and the Pan American Health Organization (Concha-Eastman and Villveces 2001) have developed guidelines for establishing injury surveillance systems in developing countries.

If the range of fatal and nonfatal injuries, as well as the risk factors that can lead to injury, are to be fully captured, surveillance systems need to be established in multiple settings. Fatal injuries can be captured by using forensic or death certificate data. A far greater number of injuries are nonfatal and can be tracked through hospital- or primary care-based systems. Systematic information on nonfatal injuries, including prevalence, incidence, and related risk behaviors can also be obtained through ongoing population-based surveys.

Critical points should be addressed when planning an injury surveillance system in a developing country. First, data sources need to be clarified. In some developing countries, routine data on injuries are not always captured in health information systems. It is therefore necessary to consider other sources of data—for example, law enforcement agencies, coroners, or medical examiners. Next, the events and variables in an injury surveillance system should be defined according to the objectives of the system. Criteria such as the intentionality (violence-related injuries versus unintentional injuries); the outcome (fatal injuries versus nonfatal injuries); and the nature of violence-related injuries (physical, sexual, psychological, deprivation, or neglect) should be considered when establishing the system. Finally, case definitions and coding procedures should be defined before implementing the system.

For example, the Nicaraguan Ministry of Health, in collaboration with CDC and the Pan American Health Organization, began developing and implementing an injury surveillance system in 2001 (Clavel-Arcas, Chacon, and Concha-Eastman 2004). The system, based on the medical facility emergency department (ED), collects data on injuries in keeping with the *Injury Surveillance Guidelines* established by WHO (Holder, Peden, and Krug 2001). Under the system, a reportable case is defined as a patient who died from or was treated for an injury in the ED. Cases include patients with unintentional and violence-related injuries.

ED staff members identify cases and collect data in five hospitals in Nicaragua. Information used to complete the instrument is collected directly from the patients or their representatives. An ED admission clerk collects basic demographic data on the patient's arrival. ED medical staff members (physicians and nurses) collect the remaining information

(for example, location, mechanism of injury, nature, severity, and circumstances surrounding the injury) during triage and assessment.

The hospital epidemiologist collects data collection forms daily from the ED, reviews the quality of data, and requests data from the ED staff if the forms are incomplete. The statistician reviews data daily. The country project coordinator also monitors the quality of the data periodically. Using Epi Info 2002 programs developed specifically for this project, the project coordinators analyze trends and identify potential risk factors (Noe and others 2004). The information is used to produce monthly reports for dissemination. Information is reported at both the regional and the country levels.

Injury prevention programs in Nicaragua use surveillance data to assess the need for new policies or programs and to evaluate the effectiveness of existing policies and programs. For example, the municipality of León is using the information from the hospital to monitor the increase in suicide attempts among youths abusing pesticides and to evaluate an intersectoral campaign to promote life that includes primary through tertiary prevention strategies.

Surveillance for Biologic Terrorism

Surveillance for biologic terrorism is conducted primarily for outbreak detection and management. Surveillance must support early detection of an incident of biologic terrorism and its characterization in the same manner as for the detection and control of naturally occurring outbreaks of infectious diseases. Early detection of outbreaks can be achieved by the following (Buehler and others 2004):

- timely and complete receipt, review, and investigation of disease case reports, including the prompt recognition and reporting to or consultation with health departments by physicians, health care facilities, and laboratories
- improvement of the ability to recognize patterns indicative of a possible outbreak early in its course (for example, by using analytic tools that improve the predictive value of data at an early stage of an outbreak or by lowering the threshold for investigating possible outbreaks)
- receipt of new types of data (such as purchases of health care products, absences from work or school, symptoms presented to a health care provider, or orders for laboratory tests) that can signify an outbreak earlier in its course.

Environmental detection systems for microbial pathogens and toxins of concern for biologic terrorism might also be categorized as new types of data early in the course of an outbreak, before infection (Meehan and others 2004). The primary surveillance tools for event detection and management are the traditional disease-reporting systems for notifiable diseases

discussed elsewhere in this chapter. These core surveillance tools should be robust before new data types can be considered for supplementing public health surveillance.

Syndromic surveillance is an investigational approach by which health department staff members, assisted by automated data acquisition and generation of statistical signals (computerized algorithms), monitor disease indicators continually to detect outbreaks of disease earlier and more completely than might otherwise be possible with traditional reportable disease methods (Buehler and others 2004).

CDC's list of biologic terrorism agents and diseases can be found at <http://www.bt.cdc.gov> and an updated list of references dealing with syndromic surveillance is at <http://www.cdc.gov/epo/dphsi/syndromic/>.

Complex Emergency Surveillance

The key elements in planning a disaster surveillance system are establishing objectives, developing case definitions, determining data sources, developing simple data collection instruments, field testing the methods, developing and testing the analysis strategy, developing a dissemination plan for the report or results, and assessing the usefulness of the system. The surveillance needs are different in the preimpact, impact, and postimpact phases (Binder and Sanderson 1987).

The role of surveillance in disaster situations has included the following broad framework of activities:

- predisaster activities (for example, hazard mapping, provision of guidelines, and training for medical and rescue teams)
- continuous monitoring and surveillance for priority health problems in affected populations (for example, in the post-tsunami surveillance in Tamil Nadu, India, a one-page instrument was used for 10 priority health conditions for daily active surveillance in displaced populations at camps)
- prospective surveillance of affected populations focusing on the natural history of exposure and health effects and long-term effects of stress disorders among survivors.

Surveillance in Refugee Populations

Support of relief efforts following national and global disasters has been a relatively new application of epidemiologic practice for the public health professionals. Nevertheless, since the initial CDC involvement with the United Nations in a large-scale relief effort concerning approximately 20 million displaced people affected by the 1967–70 civil war in Nigeria, CDC staff members have participated in several assessments of the health needs, damage, and nutrition in refugee populations resulting from man-made and natural disasters. The more notable and extended actions were conducted in the 1979–82 Khmer

Thailand-Cambodia refugee-relief action, followed by long-term public health surveillance of Somalian refugees (1980–83), periodic but comprehensive health and nutritional assessments of Afghan refugees in Pakistan (1980–2002), and growth and nutritional assessments of internally displaced populations—especially children—in the Democratic People’s Republic of Korea (1990s) and southern Sudan. Although these relief efforts occurred many years and many thousands of miles apart, they shared several important characteristics:

- Large numbers of people were in fixed camps or on the move searching for food and shelter. These needs were usually addressed by external aid agencies and many times caused local environmental degradation (fuel, temporary housing, water pollution, and so on).
- Refugees, after the initial phase, competed with indigenous populations for scarce jobs, leading to social strife and stress. Refugees were also exploited and suffered violence—additional factors leading to stress and social maladjustment.
- No administrative structure to provide and coordinate assistance of the necessary magnitude existed before the crisis, and thus, it had to be created after the fact.
- Assistance was complicated by the uncertainty associated with military activity, crime, and hostile governments.
- Data that were relatively simple to gather and analyze provided health workers and administrators information needed to plan and monitor assistance and its impact.
- Close collaboration with other local and international relief organizations (such as the United Nations High Commissioner for Refugees, the International Red Cross, the United Nations Children’s Fund, WHO, and USAID) was essential to instituting and sustaining a meaningful surveillance system for refugees that led to interventions.

The major goal of these activities is to identify and eliminate preventable causes of morbidity and mortality. Planning requires effective use of existing knowledge about characteristic or predictable demographic patterns, easily applied health indicators, and avoidable errors of omission or commission. As in disasters, the principles of surveillance (data collection, data analysis, response to data, and assessment of response) and other public health techniques should be an integral part of relief efforts. Retrospective evaluation of these efforts has also proved useful (CDC 1983).

Chronic Disease Surveillance Systems

Development and evaluation of policies for health improvement require a reliable assessment of the burden of disease and injury, an inventory of the disposition of resources for health, assessment of the policy environment, and information on the

cost effectiveness of interventions and strategies. In all these areas, consideration of noncommunicable (mostly chronic) conditions becomes critical. In 1999, noncommunicable diseases were estimated to cause approximately 60 percent of the deaths in the world and 43 percent of the global burden of disease (WHO 2000a). WHO forecasts that by 2020 the burden of disease from noncommunicable diseases for developing and newly industrialized countries will have increased more than 60 percent (Murray and Lopez 1996).

Some developing countries have found it difficult to acquire and analyze accurate mortality statistics regularly, let alone morbidity and quality-of-life information. Ensuring development, implementation, and widespread use of noncommunicable disease data for better decisions on resource allocation is critical to improving the quality of lives and promoting a more equitable future for health within and between countries.

Hypertension, elevated blood cholesterol, tobacco use, excessive alcohol consumption, obesity, and the multiple diseases linked to these risk factors are a global public health problem. In one study, smoking, high blood pressure, and high cholesterol alone explained approximately two-thirds to three-fourths of heart attacks and strokes (Vartiainen and others 1995). Until recently, surveillance for risk factors was an activity commonly associated with developed countries (Holtzman 2003). However, recently WHO has increased attention to noncommunicable disease surveillance by developing tools and working to achieve data comparability between countries (WHO 2003c). Data on key health behaviors, obesity, hypertension, lipids, and diabetes are collected inconsistently in developing countries, especially in Africa. Data on tobacco use are available through the Global Youth Tobacco Survey (<http://www.cdc.gov/tobacco/global>).

Incidence data (the number and proportion of new cases in a population) are limited in developing countries. However, India’s National Cancer Registry program may serve as a notable exception (http://icmr.nic.in/ncrp/cancer_regoverview.htm). In 1981, the Indian Council of Medical Research, recognizing that there was a lack of information on follow-up of cancer patients to assess quality of care, instituted a cancer registry network. The network provides data on the magnitude and patterns of cancer in eight areas of India to enable studies of the histologic features correlating with prognosis and association studies (for example, whether a history of vasectomy is associated with cancer of the prostate). Another important example relates to the widespread use of folic acid in China and the resultant reduction in incidence of birth defects (Kelly and others 1996; Wald 2004).

Surveillance data have been critical in establishing the importance of obesity as a public health priority in the United States. Data for individual states provided by CDC’s BRFSS have enabled individual health departments to document their obesity epidemic (Sturm 2003). These data provide a measure

of the effectiveness of interventions to meet the control objectives. The BRFSS is a practical tool for developing and middle-income countries, as Jordan demonstrated when it implemented a BRFSS in 2002; the first survey documented substantial levels of obesity, especially among women, combined with low levels of physical activity (CDC 2003b).

ECONOMICS OF PUBLIC HEALTH SURVEILLANCE SYSTEMS

The outbreak of SARS in 2003 demonstrates the far-reaching economic impact of not having an effective global public health surveillance system in place, with an estimated reduction in real gross domestic product of more than US\$1.0 billion in Canada (Darby 2003) and estimated income losses in the range of US\$12.3 billion to US\$28.4 billion for East and Southeast Asia as a whole (Fan 2003).

Public health surveillance is considered a global public good (Zacher 1999), particularly when it is used for eradication of such diseases as poliomyelitis. As eradication campaigns decrease the number of cases, maintaining systems to find the last few cases becomes more expensive. Often, the majority of the costs for these systems fall on hard-pressed developing countries. This factor raises questions of fairness and equity. For example, as poliomyelitis becomes rare, it ceases to be a significant risk to national populations, whereas other diseases, such as malaria and diarrhea, typically are major causes of morbidity and mortality. In such countries, it seems most fair and efficient for the global community to finance eradication campaigns, leaving national systems free to address the diseases that most affect their populations. The negative impact of globally mandated eradication surveillance systems can be mediated or reversed by leveraging on the eradication program's infrastructure to gather surveillance data for diseases of concern to local governments (Nsubuga, McDonnell, and others 2002). A similar case can be made for influenza early warning systems in countries that gather information that will be used to create vaccines that will benefit other populations but not their own. Equity demands that the countries that benefit from such systems finance them.

Public health surveillance systems serve an essential function in preventing and controlling disease spread within and across national borders. Although the private sector benefits, it lacks the incentive to invest in public health surveillance systems, and sovereign states depend on the contribution of others (WHO 2002); this situation has important implications for the financing of public health surveillance systems. Even within national borders, the difficulty of quantifying the benefits of surveillance systems for individual communities leads to neglect by local authorities, providing the economic rationale for funding by the national government. Developing countries

Table 53.3 Health Expenditures by National Income Level of Countries, 2001

Income group ^a	Government expenditures on health as a percentage of gross domestic product	Total expenditures on health as a percentage of gross domestic product
High income	6.30	10.74
Upper-middle income	3.68	6.41
Lower-middle income	2.58	5.63
Low income	1.22	4.78

Source: World Bank 2004.

a. All World Bank member economies with populations of more than 30,000 are classified into income groups, divided according to 2003 gross national income per capita, calculated using the World Bank Atlas method. The groups are low income, US\$765 or less; lower-middle income, US\$766 to US\$3,035; upper-middle income, US\$3,036 to US\$9,385; and high income, US\$9,386 or more.

are reportedly the weak link in the global surveillance framework, although they bear the greatest burden of disease, emerging and reemerging old pathogens, and drug-resistant pathogens (U.S. GAO 2001). The greatest need for surveillance systems is in these countries, but most lack both the resources and the political will to build human capacity and finance the systems (table 53.3). Resource constraints and intense pressure to provide care and treatment services lead public health authorities in the poorest countries to spend resources on surveillance (U.S. GAO 2001). Because the costs and benefits derive from surveillance systems spilling across national borders, donors should assist with capacity building in countries that have been unable to invest the human and material resources required.

An interesting and unresolved feature of these global public goods—the solution to their adequate provision and supply rests at local, national, and sometimes regional levels—has prompted the international health community to advocate for capacity building in developing countries rather than for consolidation of the fragmented systems at the global level (WHO 2002).

Standard tools of economic evaluation (Meltzer 2001) have been used to compare the benefits and costs of several public health interventions. The public good characteristics of surveillance systems, with benefits that are not easy to quantify, make the use of such tools difficult to implement in practice. However, economic evaluation of laboratory surveillance systems to detect specific disease-causing organisms have been undertaken in the developed world by comparing benefits and costs now and in the future (Elbasha, Fitzsimmons, and Meltzer 2000). These evaluations have not been done in developing countries and are needed. At best, an analysis of the benefits and costs of existing or proposed surveillance systems is feasible. This analysis requires an estimate of the cost of illness and answers the

question of how many cases of a particular disease need to be prevented by the surveillance system to be exactly equal to the expenditure on the system.

Given expenditures on specific health interventions or programs, one can, by using traditional econometric tools, apply the data on health outcomes from the surveillance systems as inputs to economic analysis. Surveillance also clearly leads to a cost saving if it prevents the need for expenditure on treating patients.

FUTURE OF SURVEILLANCE

Public health agencies, ministries of finance, and international donors and organizations need to transform surveillance from dusty archives of laboriously collected after-the-fact statistics to meaningful measures that provide accountability for local health status or that deliver real-time early warnings for devastating outbreaks. This future depends in part on developing consensus on critical surveillance content and developing commitment on the part of countries, funding partners, and multilateral organizations to invest in surveillance system infrastructure and to use surveillance data as the basis for decision making. This vision of the future assumes a coherent, integrated approach to surveillance systems that is based on matching the surveillance objective with the right data source and modality and on paying attention to country-specific circumstances while maintaining global attention to data content needs.

Information technology and informatics can help in attaining this vision. Specifically, technology can facilitate the collection, analysis, and use of surveillance data, if data standards are developed and compatible systems are established. Data collection for surveillance would be an automatic by-product of any electronic systems used to support clinical care. Under this scenario, an automatic electronic message would be sent to the responsible public health jurisdiction with information about a health event (for example, death, disease, or injury), including all relevant information from the electronic health record about the patient, provider's name, patient's home address, risk factors, previous immunizations, and treatments. Even before this ideal capacity becomes widespread, technology such as cell phone-based systems could accelerate collection of key data (for example, occurrence of a viral hemorrhagic fever outbreak). The rapid penetration of cell phones in developing countries might obviate the need for prohibitively expensive landline-based systems. An accelerated system of wireless Internet access might also transform the capacities to which a local health post or a district health official might have access. These systems should also be considered as means for collecting information beyond traditional data. For example, telemedicine access can permit views of a rash illness to be shared with national or international medical specialists.

Analysis of surveillance data can also be transformed by using available technology. Software that is Web-enabled, together with the advances in geographic information system software and global positioning devices, means that anyone with Internet access can potentially apply the latest version of software running on a distant server in the national capital to local data to generate up-to-date maps and graphs describing health status in that jurisdiction.

Use of surveillance data can also be transformed. Sophisticated algorithms can be applied to data as it is collected to determine when (and how) an alert should be sent to local, national, or even international health officials to indicate a need for immediate investigation. Increasingly sophisticated visual display techniques and creation of custom channels with data of particular relevance to groups of data users are just some of the tools already being used to put public health content on the desktop of anyone with broadband, secure Internet access.

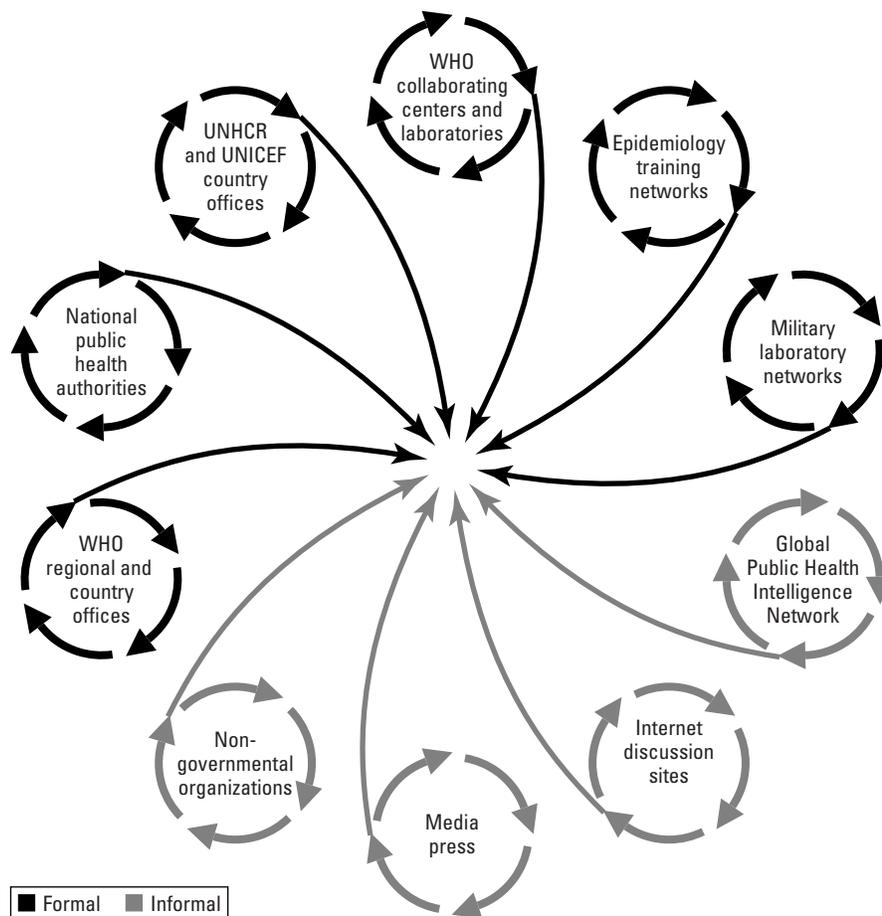

Realization of this future vision does not require technology beyond what is already feasible, but the following factors are needed:

- the organizational and political will to develop and coordinate the needed systems and standards that will enable those systems
- appropriate attention to individual privacy and system security
- removal of the financial and logistical barriers to broadband Internet access
- a strategic multisectoral approach to accelerating national infrastructure among the poorest developing nations.

GLOBAL SURVEILLANCE NETWORKS

Globally, infectious disease surveillance is implemented through a loose network that links parts of national health care systems with the media, health organizations, laboratories, and institutions focusing on particular disease conditions. WHO has described a "network of networks" (U.S. GAO 2001) that links existing regional, national, and international networks of laboratories and medical centers into a surveillance network (figure 53.5).

Government centers of excellence (for example, CDC, the French Pasteur Institutes, and FETPs) along with WHO country and regional offices also contribute to disease and health condition reporting. Military networks, such as the U.S. Department of Defense's Global Emerging Infectious Disease System, and Internet discussion sites, such as ProMed (<http://www.promedmail.org>) and Epi-X (<http://www.cdc.gov/epix>), also supplement the reporting networks. In 1997, WHO started the Global Outbreak Alert and Response Network, and

Figure 53.5 Global Infectious Disease Surveillance Frameworks

it was formally adopted by WHO member states in 2000. The network has more than 120 partners around the world and identifies and responds to more than 50 outbreaks in developing countries each year (Heymann and Rodier 2004).

The International Health Regulations are the only binding international agreements on disease control. The regulations provide a framework for preventing the international spread of disease through effective national surveillance coupled with the international coordination of response to public health emergencies of global concern by using the guiding principle of maximum protection, minimum restriction (WHO 2003a). The current regulations apply only to cholera, plague, and yellow fever; they require WHO member states to notify WHO of any cases of these diseases that occur in humans within their territories and then give further notification when the territory is free of infection. The regulations are being revised to include the development of national core capacities and national focal persons who have the competencies of graduates of FETPs and allied training programs. Programs established to improve the

capacity of both epidemiologists and laboratorians to collect, use, and interpret surveillance and outbreak data (for example, the collaborative WHO program in foodborne diseases called the WHO Global Salm-Surv) are also important components in developing global surveillance networks.

RESEARCH AGENDA IN PUBLIC HEALTH SURVEILLANCE

Developing nations share surveillance needs with the rest of the world, yet they are challenged by economic limitations, weak public health infrastructure, and the overwhelming challenges of poverty and disease. As a result, countries in the developing world often depend on the research efforts of others, or they collaborate with others to conduct the research necessary for their surveillance needs. Within individual countries, surveillance systems are essential in measuring disease and injury burden as a first step in establishing public health priorities that lead to policies and programs.

The major research question for surveillance is how to develop and maintain a cadre of competent, motivated surveillance and response workers in developing countries. Other questions include how to design and maintain surveillance systems for these problems, especially morbidity systems for chronic diseases. Standard methods can be used to evaluate existing surveillance systems, which, in turn, will help define surveillance needs (Romaguera, German, and Klaucke 2000). Developing countries have used the IDSR strategy, which provides an efficient approach to data collection and analysis. Unfortunately, the majority of developing countries have limited surveillance systems for noninfectious diseases; instead, existing data systems (for example, vital records, motor vehicle crash records, or insurance claims data) are potential sources of surveillance data. In other settings, even these data sources are scarce, and approaches such as verbal autopsies and recurrent surveys might be alternatives (White and McDonnell 2000).

Surveillance for risk factors is another challenge, and BRFSSs need to be validated and applied more widely in developing countries. Surveillance for injuries, environmental hazards (such as traffic intersections that are associated with high rates of injuries), and exposures to chemical or biological agents is a key public health concern with few examples of effective application anywhere in the developed or less developed parts of the world. Rigorous research is required in this field (Thacker and others 1996).

The burgeoning use of electronic data systems and the almost universal availability of the Internet provide a tremendous opportunity for more timely and comprehensive surveillance in all parts of the world. Yet in this rapidly emerging field, critical needs exist, including the following:

- competent, motivated health workers
- data standards (Lober, Trigg, and Karras 2004)
- global policies and practices for international surveillance
- useful software (Dean 2000)
- evaluation of the effectiveness of all these applications.

New approaches that must be evaluated by using standard methods (Romaguera, German, and Klaucke 2000) include the following:

- IDSR for infectious diseases
- syndromic surveillance (CDC 2004b) for terrorism and emergency response
- laboratory-based surveillance methods to enhance diagnostic accuracy and increase timeliness of recognition of outbreaks and interventions (Swaminathan and others 2001).

Many research questions remain about surveillance methodology, including how to do the following:

- use data for forecasting or temporal and spatial analysis for aberration detection

- conduct surveillance for multiple competing risk factors that lead to a single condition (for example, smoking, cholesterol, hypertension, and overweight for heart disease)
- conduct surveillance for the adverse effects of drugs
- interpret ecologic data relative to data collected on individuals (Greenland 2004)
- measure cost-effectiveness of alternative approaches to surveillance (for example, integrated compared with categorical approaches)
- link data sources effectively (for example, hazard, exposure, and outcome data for environmental diseases)
- build and sustain human infrastructure in developing countries
- strengthen evidence-based decision-making cultures in ministries of health and finance.

CONCLUSION

Public health surveillance is an essential tool for ministries of finance, ministries of health, and donors to effectively and efficiently allocate resources and manage public health interventions. To be useful, public health surveillance must be approached as a scientific enterprise, applying rigorous methods to address critical concerns in this public health practice (Thacker, Berkelman, and Stroup 1989). Although the surveillance needs in the developing world appear to differ from those in the developed world, the basic problems are similar. In a time when we are confronted with SARS and avian influenza, the need to integrate global networks is undeniable, and research in how these concerns are addressed is essential. Collaboration among practitioners, researchers, nations, and international organizations is necessary to address the global needs of public health surveillance.

ACKNOWLEDGMENTS

The authors would like to acknowledge ORISE Fellow Danielle Backes of the Division of International Health, Coordinating Office for Global Health, U.S. Centers for Disease Control and Prevention, for her invaluable help in preparing this chapter.

Chapter **54****Information to Improve Decision Making
for Health**

Sally K. Stansfield, Julia Walsh, Ndola Prata, and Timothy Evans

*The new source of power is not money in the hands of a few, but information in the hands of many.
—John Naisbitt and Patricia Aburdene, Megatrends 2000*

This chapter focuses on the collection and management of public health information, in contrast to clinical information, which concerns individual patient care encounters. Even when aggregated, clinical data are necessary, but not sufficient, to inform efforts to improve the health of populations. While substantial attention has been focused on these facility-based clinical consultations and the health management information system (HMIS) used to track the relevant data, we focus here on the broader health information system (HIS) needed to inform decisions at individual, facility, district, and national levels. Considered here are the routine data collection systems upon which program management, planning, monitoring, and evaluation depend. Information needs for specific tasks, such as for research or for program evaluation, are discussed in the chapters on research (chapters 4 and 7). Other chapters in this volume refer to information needs to enable disease control or to evaluate programs and improve the delivery of interventions. Those interested in these issues should also pay special attention to chapter 53 and chapters 70–73. This chapter bridges the global and the local issues; it makes the case for strengthening the evidence base for action through comprehensive health information systems that include census, vital events, monitoring, public health surveillance, resource tracking, facility-based service statistics, and household surveys.

INTRODUCTION

From infancy on, we receive information that gives form to our thinking and problem solving. The method by which a phenomenon is measured shapes societal perceptions of it and the collective efforts to affect it. Likewise, the choices we make in the collection and use of information for health will determine our effectiveness in detecting problems, defining priorities, identifying innovative solutions, and allocating resources for improved health outcomes. Despite those fundamental realities, there has been little awareness to date of the ramifications that greater information use can have for advancing health, and even less attention has been given to systems needed to provide timely, accurate, and relevant information.

An example of the formative power of information for policy change lies in the history of the United Nations' Standard System of National Accounts, created by Richard Stone more than 50 years ago. The annual reporting of these accounts by most countries shapes our impressions of the relative position of nations, defines our views of the differential opportunities offered to their citizens, and drives the content of national and global political discourse (Jolly 2002). Another example is the measurement of disability-adjusted life years (DALYs), which has shaped priorities for investment in global health over the past decade.

However, data or information alone will not transform outcomes. *Data*, which are simple measures of characteristics of people and things, have little inherent meaning or value. Analysis of the data enables the identification of patterns, thereby creating *information*. Finally, the use of information to generate recommendations, rules for action, and behavior change signifies the creation of *knowledge* that is used to make decisions and change human behavior.

Good decisions on effective policies, services, and behaviors require timely, accurate, and relevant information. Health information is required for strategic planning and the setting of priorities; clinical diagnosis and management of illness or injury; quality assurance and quality improvement for health services; detection and control of emerging and endemic disease; human resource management; procurement and management of health commodities (including drugs, vaccines, and diagnostics); regulation of toxic exposures; program evaluation; research; and other types of policies and programs (Walsh and Simonet 1995). Citizens require such information to choose healthy behaviors, to demand effective policies and services, and to hold their governments accountable for the allocation and use of resources for health. Internationally, information is required to meet transnational needs, such as for the detection and control of consequences of epidemics and infectious diseases, results-based management of development assistance programs, and advocacy for increased financing for health.

Several recent trends further enhance the pressures to deliver better health information. Global epidemics, such as of severe acute respiratory syndrome (SARS) and “bird flu,” have amply demonstrated the need and potential benefits of sensitive and transparent systems for tracking health events. Donors, including the Global Fund and the Global Alliance for Vaccines and Immunization (GAVI), increasingly demand performance measures and detailed evidence to justify new requests for support. “Basket” funding and sectorwide approaches place further responsibilities on countries to define their own priorities. Decentralization and devolution of budgetary controls have shifted much of this growing burden to the periphery, requiring districts to provide local evidence as a basis for decisions. Tracking progress toward the Millennium Development Goals for health requires empowering countries to measure key indicators and produce evidence-based strategic plans to achieve and document that progress. Furthermore, nearly every chapter in this volume cites the need for better information, including through research dependent on a health information system, to accelerate improvements in health.¹

Yet there is a striking disconnect between the need for information and the ability to respond to that need. To collect, collate, analyze, and communicate the necessary information in a timely and understandable fashion requires organized processes and procedures and a comprehensive HIS. However,

donor-driven and disease-specific initiatives have actually undermined efforts to develop a comprehensive HIS by creating separate, parallel, and often duplicative systems to meet the need for each funding source.

Health information and the systems for its supply are a public good, meeting the defining criteria of being *nonexcludable* (in that, once the information is in the public domain, it is difficult to withhold from users) and *nonrival* (in that consumption of the information does not lessen its availability for use by others). As a public good, the supply of health information is the primary responsibility of governments: national governments for information within these jurisdictions, and international agencies and national governments together for international comparative information and global summary data.

Harmonizing the data collection, standards, best practices, and other elements of a national and global HIS has several advantages. Standardization enables economies of scale for training, hardware and software, and processes. Routine health information is a summative good in that the collation of each contribution produces a cumulative increase in the value of the public good, strengthening the credibility and importance of that information. Furthermore, standardization of systems improves the reliability and comparability of information, both within nations and across national and regional boundaries (Cibulskis and Hiawalyer 2002).

SYSTEMS AND SUPPLY OF HEALTH INFORMATION

To create an effective HIS, governments must finance the system, create the necessary policy environment (for example, through legislation and regulation), and develop systems and services for the collection, collation, dissemination, and use of health information. A substantial portion of the national health information is fully within the control of government health officials. However, information from the private health sector and other parts of the government is also required. Table 54.1 lists some of the data required and their sources. A principal challenge is the integration of these intra- and extrasectoral functions into a single, comprehensive HIS.

Direct Expenditures for Health Information

As for most public goods, the production of health information is mostly financed by government appropriation. Budget support for the HIS comes through both the ministry of health and a national statistics office (NSO) in most countries. The NSO is usually responsible for collecting information through the national census and most household surveys. For the least developed countries especially, bilateral and multilateral donors are essential sources of finance, particularly for HIS planning, infrastructure development, and training. In Africa, it has been estimated that grants or loans from donors account for between 20 and 70 percent of the financing for statistical

Table 54.1 Health Information from Sources Outside the Health Sector

Health information	Responsible agency
Census and national surveys: Income and poverty distribution Household expenditure for health Coverage with health interventions	National statistical office
National expenditures for health, economic development indicators, and industrial production and distribution data	Ministry of finance
Employment data: Human resources for health Occupational health information	Ministry of labor
Import data: Pharmaceuticals and vaccines Capital equipment and health commodities	Ministry of trade
Food production and security information and nutritional status data	Ministry of agriculture
Military health service statistics	Ministry of defense
Patterns of transportation injury (including motor vehicle accidents)	Ministry of transportation
Literacy rates and school health program information	Ministry of education

Source: Authors.

systems overall. Revenue generated by selling statistical products and services accounts for 10 to 20 percent of the financing for national statistical systems (Economic Commission for Africa 2003). User fees or taxes for use of information products and services can partially offset the costs of developing and maintaining the information system. In many countries, taxes and tariffs on computer equipment and government regulation of communications and Internet use remain barriers to public access to health information. Cost must not be a barrier to use of health information for the public good.

Information Policy

Sound information systems require a legislative and regulatory environment that encourages and supports effective HIS development. At the global level, many efforts have been made to establish international standards and policy frameworks for statistical data (United Nations Statistical Commission 1994). These policy frameworks are used to establish mandates for collection of basic health data (such as a decennial census or surveillance for reportable infectious diseases), to ensure the independence of official statistical agencies, to reinforce professional ethics, and to create norms for data quality and dissemination.

Another key policy intervention, less tangible though equally critical, is the creation of a culture of quality and transparency

in the management of health information. There should be protection from political interference and full empowerment of the health statistics office to make public statements in response to criticisms of reports and the underlying methods. Ethical practices for protecting privacy and confidentiality must be well understood, and procedures should be in place to deal with breaches in these standards. Accuracy and reliability should be stated as expectations and ensured through periodic review of data collection methods and through benchmarking with internationally credible definitions of indicators. A client orientation should be instilled and users of data regularly consulted in defining outputs and formats for the presentation of data.

Systems for Collection, Management, and Analysis

Most developing countries have no comprehensive strategy for information management, reflecting the fractal nature of donor and national investments in these systems. Interventions to improve the HIS in the least developed countries, often donor driven, have often focused only on a specific subsystem, primarily for health service statistics, and have neglected other components of the HIS.

An effective HIS requires an overarching architecture that defines the data elements, processes, and procedures for collection, collation, presentation, and use of information for decision making throughout the health sector (see box 54.1). This information architecture promotes comparison and integration of data elements from a variety of subsystems. As O'Carroll (2003) points out, such a comprehensive design enables phased system development, reduces redundancy, increases efficiency, and improves interoperability. Interoperability is critical to ensuring, for example, that census data, vital statistics, and health facility data can be integrated to generate rates, ratios, cost-effectiveness estimates, and other information required to compare options for health investment.

The Pan American Health Organization (PAHO) has led the Regional Core Health Data Initiative "to facilitate speedy access to basic information on the health situation in the countries of the Region." This initiative has involved an international consultation and agreement on the priority data, collection methods, and indicators. The initiative has shown that it is possible to create a regional database of essential, consistent, valid, standardized, timely, and regular information. PAHO has used the information to set its priorities, whereas countries have applied the results to design health programs and to allocate resources to upgrade their information systems. In the future, the plan is to expand the systems to subnational districts (PAHO 2004).

Other WHO regions, including the Asia Pacific, are instituting similar initiatives with Web-based publication of core health indicators.

Data Collection. No single mechanism for data collection is adequate to meet the needs for public health decision making.

Box 54.1**The Health Metrics Network: Harmonizing Investment in HIS Development**

Developing countries, multilateral agencies, bilateral donors, and technical resource agencies have recently come together to form a global Health Metrics Network (HMN) that is designed to provide guidance for the development of the HIS, both in meeting national information needs and in producing the required indicators for tracking progress toward global goals. The HMN will provide the first consensus technical framework for HIS

Source: Authors.

architecture and a plan for development of national health information systems. This HMN Framework includes a blueprint for iterative improvements in the HIS; descriptions of core data collection subsystems (census, surveys, vital events monitoring, service statistics, and resource tracking); and procedures for management and dissemination of information.

These needs can be met using a combination of the six key health information subsystems: census, household surveys, public health surveillance, vital events monitoring, health service statistics, and resource tracking. Surveys are conducted on a sample in order to limit costs, whereas the other subsystems are more often designed to cover the entire population. In most developing countries, public health surveillance—except for certain disease-specific efforts—is conducted through passive reporting from health facilities. Especially where utilization rates are low, this facility-based surveillance may be considered a sample or “sentinel” surveillance strategy. Vital events monitoring is, ideally, universal; however, many countries use a phased introduction of vital events monitoring that makes it functionally a sentinel or sample-based data collection effort during the transition to universal coverage.

A *national census* every 10 years is an irreplaceable component of a national information system because it provides denominator data for so many indicators and sampling frames for subsequent sample surveys. The major costs of a census come from activities to establish the census maps, enumerate populations, enter data, and analyze the results. The cartographic costs can often be shared with other government departments, because the resulting updated maps can be instrumental in carrying out other critical public functions.

Sample surveys of households are a mainstay of health information collection in the developing world. They provide data on service utilization; coverage of health interventions (for example, immunization); morbidity (self-reported illness or disability); pregnancy outcomes; mortality levels, differentials, and trends; and causes of death (through associated *verbal autopsy*; that is, expanded interviews in the case of death to determine cause on the basis of signs and symptoms before death).

Surveys are, almost without exception, funded externally in the least developed countries and are not seen within the country as being part of a health information “system.” They are, in

fact, generally undertaken to compensate for the lack of information available through routine systems (AbonZahr and Boerma 2005). The investment in surveys has thereby enabled donors and developing countries to sustain their neglect of the development of comprehensive and sustainable national health information systems. The United Nations Population and Statistics Divisions and the European Statistical Office (EUROSTAT) also support household survey work. Differences in methodologies among these surveys are currently a barrier to the comparison of results. The World Bank’s Managing for Development Results Roundtable, held in Marrakech, Morocco, in 2004, recommended harmonization of these surveys to eliminate duplication.

Nonetheless, surveys offer an important source of information that transcends most of the selection bias that is inherent in service statistics. Especially in the least developed countries, where vital events registration systems and census taking are embryonic or nonexistent, surveys represent the only source of unbiased information about demography, socioeconomic status, coverage, morbidity, mortality, health expenditures, and other characteristics of the population. Where substantial proportions of the population use private health services, household surveys are particularly important. Even industrial countries rely on periodic community-based sample surveys for immunization coverage, for health service utilization rates, and for information on household health expenditures (Perrin, Kalsbeek, and Scanlan 2004).

The World Health Organization (WHO) recommends using periodic surveys to monitor coverage, such as for immunization programs, especially in view of the shortcomings of service statistics for obtaining these measures (Murray and others 2003). Some household surveys collect biological and clinical specimens, such as blood, saliva, urine, and self-collected vaginal swabs, or they check swabs for anemia, HIV, disease antibodies, vitamin A, and other conditions. However, the performance characteristics of most diagnostic technologies (for example,

cost, ease of field use, sensitivity, and specificity) are designed for clinical use and do not lend themselves readily to use in population surveys, especially in remote areas of developing countries. Moreover, the collection of diagnostic information along with individual identifiers introduces complex ethical issues in the notification of people with treatable conditions, the financing of any required treatments, and the use of the specimens for other studies (Ties Boerma, Holt, and Black 2001).

Public health surveillance has been defined as the “ongoing systematic collection, analysis, and interpretation of data on specific health events affecting a population, closely integrated with the timely dissemination of these data to those responsible for prevention and control” (Thacker and others 1996). In developing countries, surveillance usually focuses primarily on a set of notifiable diseases, mainly infectious, which health care providers and laboratories are often required by law to report. Some nations also track risk factors for important diseases, injury events, adverse drug reactions, cancers, and pregnancy outcomes. Surveillance may be intensified over a period of years to enable targeting of special interventions for the control or elimination of diseases such as polio, tetanus, or measles. Active surveillance or screening of populations for target diseases may also be used in specific circumstances, such as during peak seasons for the disease or during natural disasters, when the potential for epidemics may be high.

Most passive surveillance data, however, are incomplete. Reliance on surveillance for reportable diseases diagnosed in health facilities omits diseases diagnosed among those who go to private providers or who are too poor to go to any health facilities. Even in health facilities, reportable diseases are often underrecognized or cannot be confirmed in laboratories that have inadequate resources. Sentinel surveillance methods and registries maintained in a few selected sites may be more representative of the entire population and more cost-effective in identifying and reporting the target diseases or health conditions; however, an outbreak may go undetected in a geographic area without a sentinel site. Special regional surveillance may also be used where populations are vulnerable to special health risks. The Vigisus project in Brazil, for example, has developed a system of epidemiologic and environmental surveillance for the prevention and control of disease among indigenous populations in the Amazon region (<http://www.br.undp.org/propoor/BRA97028a.htm>). Despite the methodological hazards, public health surveillance is essential for both national and global planning and preparedness, especially in view of the risks of regional expansion (for example, of meningitis and polio) or global spread of recent epidemics (for example, of SARS and bird flu).

Vital events monitoring is the continuous, compulsory, and (in most cases) universal civil registration of key vital events, such as births, deaths (sometimes including fetal deaths), marriages, divorces, and migrations. In many countries, vital events

monitoring systems function poorly and may be found only as remnants of past colonial administrations. In 2003, 115 of 192 WHO member states reported mortality data with causes of death, capturing about one-third of global deaths, or 18.6 million deaths per year. In South Asia, only 60 percent of births are registered (22.5 million), and in Africa, only 30 percent (17 million). Alternatives to universal registration include the sample registration systems used in China and India and the demographic surveillance sites in Tanzania. The International Network of Field Sites with Continuous Demographic Evaluation of Populations and Their Health in Developing Countries (INDEPTH), an association of longitudinal vital and health statistics surveillance sites in 17 countries, can provide technical support and training for development and management of these demographic surveillance sites (<http://www.indepth-network.org/>). The UN Statistics Division has developed principles and recommendations for vital statistics systems to guide countries in their development (<http://unstats.un.org/unsd/demographic/sources/civilreg/civilregmethods.htm>).

Vital events monitoring systems may also be enhanced to determine causes of death, whether those deaths occur within health facilities or in the community. When deaths occur outside the health care system, a *verbal autopsy*, or structured interview of the relatives of the deceased, can assist in determining the cause of death. Verbal autopsies can, however, be used reliably to diagnose only those few conditions that have characteristic clinical signs or patterns of signs that can be recognized by family members or by the health workers who review the interview data. WHO is now developing standardized tools for verbal autopsy that will enhance the sensitivity and specificity of these instruments and permit comparisons over time and across geographics.

Health service statistics are critical management tools for both preventive and curative services. The statistics are collected at each level: community outreach service points, primary care facilities, and district and regional referral hospitals. Information from clients and providers documents the quantity and quality of services and enables managers to detect and solve problems in order to improve health outcomes and efficiencies. This health information subsystem must be “flexible and capable of adapting to local needs, while at the same time allowing for standardization of health care quality assurance indicators, and subsequent ability to measure and compare the quality performance of health facilities nationwide” (Duran-Arenas and others 1998). A principal barrier to improving service quality in many health care facilities is the lack of reliable systems for managing and retrieving individual patient records.

Service statistics are especially powerful when they can be compared with population-based measures from censuses and surveys to estimate rates and ratios, such as disease incidence or

service coverage rates. Most service statistics subsystems track data only from public sector providers and facilities. Future improvements must implement systems and incentives to ensure reporting of service data from the private sector.

The *resource-tracking subsystem* must enable measurement and management of human resources; facilities; commodities (pharmaceuticals, vaccines, and other consumables); and finances. Human resource tracking provides a mechanism for licensing health service providers and accrediting health facilities. Licensure and accreditation can be paired with incentives to ensure service quality and private sector contributions to achieving public health goals.

The national health account (NHA) framework provides methods for measuring total national expenditures for health from household, public, private, and donor sources. NHA data document the sources of health financing, the amount spent for services, the distribution of funds across services and interventions, and the distribution of health benefits from those services and interventions. An NHA framework tracks the flow of funds, for example, from the ministry of health to health providers and government service programs or from households to pharmacies and private providers. These internationally comparable data enable benchmarking of performance among countries (Peters and others 2000).

Of the 68 countries that have implemented NHAs, only one-third have used the framework more than once. However, 19 of 21 countries studied can report at least one instance in which the NHA system has informed and shaped policies (De and others 2003). For example, South Africa's NHA analysis documented a higher per capita health expenditure in the richest districts, leading to intensified efforts to mitigate these inequities (Abt Associates 2003).

Information and Communications Technologies. The rapid evolution of information and communications technologies (ICT) over the past 30 years has immense implications for the potential speed, cost, and effectiveness of an HIS. But a "digital divide" persists, with poor countries failing to benefit fully from these ICT advances. Lack of access to reliable power sources, absence of Internet connectivity, inability to procure computer equipment and appropriate software, and inadequate technical support are some of the barriers. African users account for only 1 percent of the world's Internet traffic, 80 percent of which is in South Africa (<http://www3.sn.apc.org/africa>). Although less than 0.001 percent of the Internet use in Africa is among health professionals, this usage is growing rapidly.

Internet access in health facilities can make the HIS more effective and efficient by enabling instantaneous transmittal of data to central locations. Internet access in facilities can also speed data transmission and improve clinical outcomes by providing access to evidence-based decision support for clinical care (Godlee and others 2004; McLellan 2001). Even in remote

areas where no telephone or cable access exists, satellite technology can provide access to e-mail. Several countries, such as Bolivia and Peru, have successfully used satellite telephone technologies to enable continuous Web-based updating of health databases. Because the effectiveness of epidemic control often depends on timely detection and reporting of outbreaks, e-mail and telephone technologies have shown particular promise for use in disease surveillance. In Peru, for example, 100 percent reporting was achieved and sustained within six months of rollout of a pilot surveillance system using cellular telephones (Lescano and others 2003). The system is to be expanded to national coverage this year.

Although individual citizens will not soon have equal access to ICT, these technologies can immediately be better used to improve public health. Automation of data entry and analysis can ease data capture, validation, analysis, and transmittal of health information. District managers can generate reports with tables and charts and transmit them to central levels, which can then apply this knowledge to improve local management. Special prompts and "exception reports" can alert managers to unexpected findings that require double-checking or immediate interventions (for example, outbreaks of infectious disease, low immunization coverage, or other management problems).

Use of free software, such as the U.S. Centers for Disease Control and Prevention's Epi Info, can lower costs, but often these software packages require substantial adaptation to local needs, along with additional training and technical support. Acquisition of computer equipment should be viewed not as a one-time capital expenditure but as a long-term commitment to buy periodic upgrades, maintenance, and technical support. Experience shows that purchase of inexpensive software and computers, such as in the Eastern Cape Province of South Africa, may actually increase overall costs when they require early replacement with more adequate alternatives.

Geographic information system (GIS) technologies have also been successfully used in districts in several countries to enable mapping and visual representation of the geographic distribution of risk factors, disease, and services. A desktop GIS viewer and mapping software are available in several shareware versions, including the WHO's "Health Mapper," so that maps can be produced at little cost. Other potentially promising technologies include electronic scanners and personal digital assistants for data capture (<http://www.healthnet.org>) and global positioning systems to facilitate the mapping process.

The principal barriers to improved information systems, however, are human, not technological. Substantial investment in training and technical support must accompany the introduction of any new technology. If the HIS is not functionally solid, introducing ICT will likely only worsen existing problems.

Dissemination and Use of Health Information

Information is a means to the end of improving health, but the availability of reliable information does not guarantee its use or improved decision making. Because decisions are often driven as much by politics as by evidence, it is critical to design information systems to meet the needs of decision makers and to create a culture of evidence that provides incentives and accountability for evidence-based decision making. Extensive dissemination promotes widespread use and accountability. The many users of information include the following:

- health ministries at national, regional, and district levels
- researchers and evaluators
- legislative and policy analysts
- nongovernmental organizations and consumer organizations
- advocacy groups
- private sector health providers and insurers
- communities, including groups of patients
- journalists
- donors and international agencies concerned with health
- individuals and families.

The literature on health information systems is replete with complaints of the neglect of existing information, yet remarkably little is known regarding the effectiveness of interventions to improve the use of information. The NHA experience (De and others 2003) suggests that policy makers are most likely to use information when it contributes to and informs a preferred government direction, especially if that information is not available to stakeholders outside the health ministry. But systems and dissemination patterns for information can be engineered to ensure that clients, providers, and managers will seek and use information to inform decisions. Standard procedures can be developed to ensure analysis and use of data at the level at which it is collected. Training of health workers can be designed to include both basic and refresher training in the analysis and interpretation of data that are relevant to each job. Expectations of information use can be built into routine job requirements, including use of evidence for planning, data requirements for periodic reporting to supervisors, and use of information during performance reviews. Groups of managers can be convened across districts or regions for benchmarking, in which each manager presents and compares performance data and is rewarded for transparency and learning. These practices will result only from intense training in analysis and use. For example, Loevinsohn (1994) demonstrated that fewer than half of midlevel managers were able to use the information system even to identify best- and worst-performing districts. Nonetheless, if managers use the information, and if improved efficiency and coverage with interventions is the result, the HIS becomes exceedingly cost-effective.

Information will “allow the public, their elected representatives, or donors to determine whether they are obtaining value for money” (Cibulskis and Hiawalyer 2002; see also Mackay 1998). Providing full access to the media will help to accelerate expectations of evidence-based decision making and accountability. Civil society, including nongovernmental organizations, should be the principal users of information to create and sustain citizen demand for quality services. The Healthy Communities Foundation’s “dashboard” of lead indicators of health system performance exemplifies one promising example of the visual display of data (<http://whatcom.healthycities.org/demo/aboutus.htm>). Such dissemination and use of health information has enhanced government accountability for improved health in Papua New Guinea, where reports of local government performance in improving health systems transformed election results (G. Hiawalyer, personal communication).

BENEFITS, COSTS, AND COST-EFFECTIVENESS OF IMPROVED INFORMATION

There is broad agreement that information—plus the knowledge it enables—creates value. Yet it is challenging, indeed, to quantify the added value of information. Information, after all, is necessary but never sufficient to achieve improved outcomes. Other resources—human, material, and financial—are required for change. Nonetheless, it is possible to define the interventions necessary to improve health information and to draw on a few studies to estimate the cost and cost-effectiveness of these investments.

Strengthening of Systems

The steps involved in strengthening HIS include securing funding for a review of the current HIS and planning reforms and then using that plan to secure funding for implementing the reforms. The reforms depend on legislation and regulations that delineate the requirements, incentives, and disincentives for collecting the needed information. Finally, the review of the current HIS includes a situational analysis and outline of a plan that involves a comprehensive information architecture that is linked to both national and international needs.

The HMN Framework includes assessment and planning tools and HIS standards that will guide strengthening of systems. Full implementation will likely take at least 36 months, and the effects on decision making and health outcomes will be detectable only after approximately five years.

Benefits and Effectiveness of Improved Information

The value of health information can be characterized in terms of cost savings; system efficiencies (for example, increased coverage or quality of services); or improved health outcomes

(for example, DALYs saved or improved health equity). Information can also be used to increase overall resources for health. Publications such as this volume, *World Development Report 1993: Investing in Health* (World Bank 1993), and the report of the Commission on Macroeconomics and Health (2000), are important examples of evidence that has been used to change health policies and increase resources for health.

The industrial world holds examples of the use of information to make service provision more effective and efficient. A quality improvement and evidence-based decision assistance program for diabetes patients in the United States created a net savings of US\$510,133,² primarily by averting hospitalizations (Petraikos 1998). The U.S. Institute of Medicine estimates that a computerized system for managing physician orders for medications costing US\$1 million to US\$2 million could “pay for itself in three to five years” and prevent injury to hundreds of patients per year (Kohn, Corrigan, and Donaldson 2001).

There are also promising examples of the benefits and effectiveness of improved information from developing countries. Quality improvements driven by better information in Bolivia resulted in a 300 percent increase in hospital utilization rates (Pappaioanou and others 2003). In rural Mali, populations enrolled in a community-based information system calculated delivery costs for childhood immunization to be US\$1.47 per child, compared with US\$2.79 per child among populations not registered (Zayan, Berggren, and Doumbia 1992).

Better information can also improve efficiencies in the management of pharmaceutical resources. For example, implementing a subnational information system in the Eastern Cape province of South Africa led to improved access to pharmaceuticals, with a 39 percent reduction in stockouts of essential drugs. Such improvements undoubtedly lead to better health outcomes, which may result in increased productivity and consequently an increase in the growth rate of the gross domestic product (Jamison, Sachs, and Wang 2001; Nordhaus 2002).

Costs of Improved Health Information

Few studies have documented the costs of an HIS. Kleinau (2000) estimated the resource requirements for health service statistics, the most expensive of the six subsystems. Using similar assumptions, we have calculated updated costs.

This estimate includes only the public sector facilities, not private sector reporting systems. Reporting from private providers would likely include a more limited set of reported data: diseases, vaccinations, possibly staffing, and minimal utilization. Table 54.2 summarizes the total annual costs and per capita costs of the six health information subsystems.

The costs of a facility-based services statistics subsystem of the HIS (table 54.3) can be assumed in most developing countries to include routine public health surveillance, because these data are obtained at health facilities when ill patients are

Table 54.2 Cost of Essential HIS Subsystems

HIS subsystem	Total cost (US\$ million)		Per capita cost (US\$)	
	Low income	High income	Low income	High income
Health service statistics	4.8	25.9	0.16	1.66
Public health surveillance (included with health service statistics)	0	0	0	0
Census	7.5	30.0	0.25	1.0
Household surveys	0.6	1.0	0.02	0.03
Vital events surveillance	1.5	6.0	0.05	0.20
Resource tracking	1.5	3.0	0.05	0.10
Total	15.9	65.9	0.53	2.99

Source: Authors.

Note: Table is based on a population of 30 million. Household survey costs are based on the experience of the demographic and health surveys during 2001–2003 (Macro International, personal communication). Costs vary by sample size and by length of the survey instrument; Macro International estimates, an average cost of US\$100 per survey participant. A sample of 6,000 is assumed for the low-income setting, and a sample size of 10,000 is assumed for the high-income setting. Cost estimates for vital events monitoring are based on demographic surveillance sites. In the high-income setting, the annual costs are assumed to quadruple. Resource-tracking costs are based on the experience of national health accounts (Abt Associates, personal communication), and the Egyptian Budget Tracking system. Similar costs are estimated for human resources and commodities.

brought for treatment. The additional costs of program-specific surveillance (for example, in support of polio eradication or tetanus elimination programs) could be assumed with a minor marginal investment in addition to facility-based and community-based information systems, including for vital events surveillance.

The calculated range for per capita annual costs of a comprehensive HIS—US\$0.53 to US\$2.99—compares closely to the estimates from a country setting in which those data have been obtained, including a low-resource country (Tanzania) with a per capita cost of approximately US\$0.50 (Rommelmann and others 2004) and a high-resource country (Mexico) with a per capita cost of approximately US\$1.00. The Health Metrics Network (HMN) Technical Task Force South Africa has also estimated costs of the HIS at approximately US\$26 million (165 million rand) for a population of 43 million, yielding a per capita cost of US\$0.60. The highest range of the estimate would apply in countries with higher salaries and a more comprehensive HIS.

Estimations of the Cost-Effectiveness of Interventions to Improve Health Information

The Tanzania Essential Health Interventions Program (TEHIP) is perhaps the best source of evidence for the cost-effectiveness of improved health information. The project was designed to

Table 54.3 Annual Costs of the Facility-Based Services Statistics Subsystem of an HIS

HIS cost	Low-resource setting	High-resource setting
<i>Personnel</i>		
Primary care facility	One person (salary US\$4,514/year) spends 10 percent of time at each of 6,000 facilities (US\$2,708,400)	Two people (salary US\$10,351/year each) spend 20 percent of time at each of 6,000 facilities (US\$24,842,400)
First referral level	One person (salary US\$4,514/year) spends 25 percent of time at each of 1,000 facilities (US\$1,128,500)	Two people (salary US\$10,351/year each) spend 75 percent of time at each of 1,000 facilities (US\$15,526,500)
District hospital	Two people (salary US\$4,514/year each) spend 20 percent of time at each of 300 facilities (US\$541,680)	Two people (salary US\$10,351/year each) spend 100 percent of time at each of 300 facilities (US\$6,210,600)
Regional level	Three people (salary US\$10,962/year each) spend 50 percent of time at each of 15 facilities (US\$246,645)	Three people (salary US\$25,134/year each) spend 100 percent of time at each of 15 facilities (US\$1,131,030)
National level	Six people (salary US\$10,962/year each) spend 50 percent of time (US\$32,886)	Ten people (salary US\$25,134/year each) spend 100 percent of time (US\$251,340)
Subtotal (personnel)	US\$4,658,111	US\$47,961,870
<i>Data collection instruments and supplies</i>		
Primary care facility	US\$100/year	US\$400/year
First referral level	US\$250/year	US\$1,000/year
District hospital	US\$500/year	US\$2,000/year
Regional	US\$1,500/year	US\$5,000/year
National	US\$5,000/year	US\$30,000/year
Subtotal (supplies)	US\$7,350	US\$38,400
<i>Information technology: computers and software</i>		
Primary care facility	0	0
First referral level	0	0
District hospital	0	20 percent use of each of two computers with software at US\$1,100 at each of 300 facilities (US\$132,000)
Regional level	0	Two dedicated computers with software at US\$1,100 at each of 15 facilities (US\$33,000)
National level	50 percent use of each of four computers with software at US\$1,100 (US\$2,200)	10 dedicated computers with software at US\$1,100 (US\$11,100)
Subtotal (information technology)	US\$2,200	US\$176,100
Training cost	US\$180,000	US\$1,730,000
Total cost	US\$4,847,661	US\$49,906,370
Per capita cost	US\$0.16	US\$1.66

Note: Based on a model country with a total population of 30 million.

test how evidence can be used to decentralize health sector planning at the district level and to what extent evidence-based priority setting would result in improved health outcomes. The project budgeted for a marginal investment of US\$2.00 per capita for the information and for health interventions, although only US\$0.80 per capita was actually spent. The slightly increased investment covered training in the use of the information to set priorities and to better manage the most

cost-effective interventions. The information systems included a district burden-of-disease intervention priority profile, district health accounts, a district cost information system, and district health service mapping. Management and technical support strengthened the district and regional health sector use of the information for management and administration. Communities participated in the ownership and management of health facilities. The cost-effectiveness estimates in this

Box 54.2**The Tanzania Essential Health Interventions Program**

TEHIP is a partnership between Tanzania's Ministry of Health and the International Development Research Centre. The project was established to determine the feasibility of an evidence-based approach to health planning at the district level. Testing the premise of the World Bank's (1993) *World Development Report 1993: Investing in Health*, TEHIP enabled district health planners in two of Tanzania's 117 districts to collect and use burden-of-disease and cost-effectiveness data to get the best value for

money from national investments in health. Interventions included door-to-door collection of data and training or technical support for managers in the analysis and use of the data for decision making. TEHIP districts allocated services to high-burden diseases, resulting in a tripling of clinic utilization rates and increased treatment effectiveness. With a per capita increase in spending of only US\$0.80, district health managers achieved a 47 percent reduction in child mortality rates.

Table 54.4 The Effectiveness of Evidence-Based Resource Allocation in Improving Health

Year	Number of children < 5 years	Probability of dying (birth to 5 years)	Mortality rate (< 5 years)	Total deaths	Deaths averted	DALYs gained/death	Total DALYs	DALYs discounted at 3 percent
1999	31,000	135.5	34	1,054	—	—	—	—
2000	31,500	119.0	25	791	263	41	10,850	11,511
2001	32,000	110.0	25	803	251	41	10,332	10,643
2002	32,661	114.0	26	853	202	41	8,303	8,304
Total DALYs gained							29,487	30,458

Source: Authors.

Note: 1999 is baseline year; therefore, no deaths were averted.

section are based solely on the declines in mortality of children under five years of age, even though adult mortality also decreased. To ensure a conservative estimate of the costs of the HIS, we used a per capita cost of US\$2.00—higher than the actual investment for TEHIP and at the high end of the range of costs for a comprehensive HIS estimated in table 54.2—US\$0.53 to US\$2.99. All costs were ascribed to the information system, because there were no improvements in the interventions themselves. Expenditures and deaths before 2002 were discounted by 3 percent annually (see box 54.2).

The demographic and epidemiologic data were taken from the Rufiji district, where the most complete data were available. The estimate of the number of children under age five (32,661) is based on the 2002 census results. The Ministry of Health, census, and Rufiji Demographic Surveillance System estimates range from 31,000 to 36,000 children for 2003. Because of this discrepancy, the decline in the total fertility rate, from 5 to 4.7 (5 percent), is taken into account in estimating the number of children less than five years of age for 1999 to 2001. The probability of dying before five years of age declined by 15.6 percent, and because of declining fertility, each year has 1.5 percent

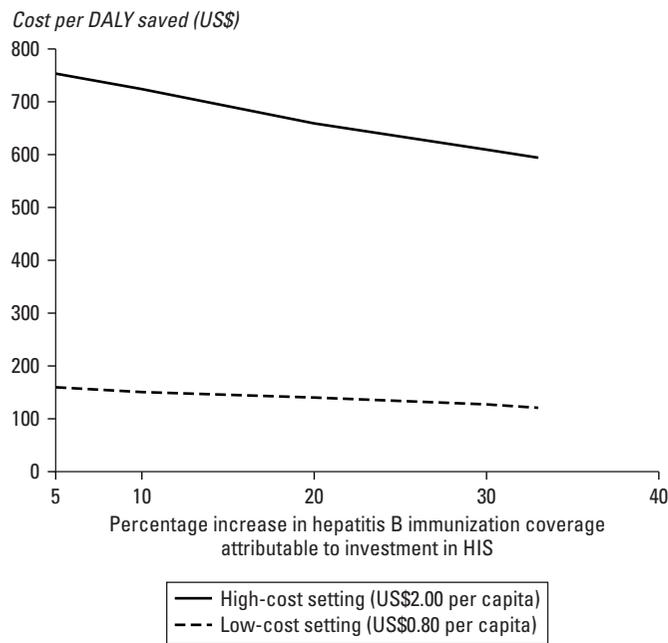

Table 54.5 Costs of Evidence-Based Resource Allocation for Improving Health

Year	Population	Total cost at US\$2 per capita (US\$)	Discounted cost (US\$)
1998	186,809	373,618	420,510
1999	191,012	382,024	417,448
2000	196,515	393,030	416,966
2001	202,176	404,352	416,482
2002	208,000	416,000	416,000
Total costs		1,969,024	2,087,406

Source: Authors.

fewer children than the preceding year. DALYs saved from each child death averted is estimated at 41.2. The resulting calculations of effectiveness are summarized in table 54.4.

The estimates of cost are based on population size projected back from the 2002 census results, assuming an average annual growth rate of 2.8 percent. Costs incurred in 1998 are included because we assume that it takes at least two years (1998 to 2000) of improving the HIS before health benefits accrue.

Source: Authors.

Figure 54.1 Cost-Effectiveness of Health Information Systems: Cost per DALY Saved Because of Increases in Coverage Attributable to HIS

Using these figures for effectiveness (table 54.4) and cost (table 54.5), we find that the cost-effectiveness of the HIS that results in improved evidence-based resource allocation and child health may be conservatively estimated at US\$68.50 per DALY gained (US\$2,087,406 to gain 30,457 DALYs). Even in the poorest countries, this is well below the gross national product (GNP) per capita benchmark for what is considered worthwhile for government investment in health.

This analysis for the TEHIP project is based solely on child deaths averted. But the improvement in health information would also yield substantial benefits for adult populations. For example, HIS-driven increases in coverage with hepatitis B vaccine have varied between 5 and 33 percent (Miller and McCann 2000). These increases in coverage with hepatitis B immunization will result in incremental reductions in death and disability among adults attributable to hepatitis B-induced cirrhosis and liver cancer, thereby averting the loss of substantial numbers of DALYs in low-income countries (World Bank 2002). Hepatitis B vaccine is a cost-effective addition to an existing immunization program, with a cost per death averted of US\$11 to US\$15 (US\$193 to US\$262 per DALY saved). But efficiency and coverage can be substantially improved with an additional investment in the HIS. The cost per DALY saved by incremental investment in the HIS can be calculated using estimates of costs of the HIS from table 54.2, plus the estimates of cost and deaths averted because of immunization from Miller and McCann (2000) for populations in all low-income countries (GNP per

capita less than US\$997; World Bank 2002). Figure 54.1 shows that, for the high-prevalence countries (Miller and McCann 2000), the investment in a comprehensive HIS is highly cost-effective (US\$159 to US\$126 per DALY saved for low-cost settings and US\$757 to US\$597 per DALY saved for high-cost settings), even if the investment results in only minor increases in immunization coverage. A similar analysis for countries with a lower prevalence rate of hepatitis B demonstrates that the cost per DALY saved is higher, but the investment in an HIS still yields a savings of DALYs at a cost that is well below the GNP per capita for the majority of the low-income countries.

These calculations of the cost-effectiveness of investments in an HIS are highly conservative, because they consider health benefits within a single population group (children, in the case of TEHIP) or a single disease problem (hepatitis B). They therefore underestimate the true cost-effectiveness of investment in an HIS, which can drive improvements in program efficiency and effectiveness across a broader range of health interventions.

FINANCING OF IMPROVED HEALTH INFORMATION

The annual per capita cost, estimated earlier, of US\$0.53 to US\$2.99 for a comprehensive HIS, represents a substantial portion of the current per capita health expenditure for many developing countries. These figures include capital and recurrent costs, although they do not include the costs of any external technical assistance. Because most countries have already made a substantial investment in a HIS, the actual incremental costs to improve the existing HIS likely are much less. Salaries, which account for more than 90 percent of HIS costs, are expenditures that are already being made in most settings, so the marginal cost of HIS improvements would be primarily the initial development costs of planning, training, technical assistance, and information technology upgrades. Furthermore, the costs of HIS improvements may be fully offset or even exceeded by the savings from the resulting improvements in efficiencies in the health care system.

Existing funding is adequate to strengthen systems substantially in all low-income and lower-middle-income countries primarily through the major international initiatives (Global Fund to Fight AIDS, Tuberculosis, and Malaria; President's Emergency Plan for AIDS Relief; and Multi-country AIDS Program of the World Bank). All these funders recommend that 3 to 7 percent of grants and loans be allocated to monitoring and evaluation. Several bilateral development agencies and the multilateral development banks will provide financing for HIS reform, including the U.S. Agency for International Development (USAID) through the MEASURE (Monitoring and Evaluation to Assess and Use Results) Project, which is

designed to improve and institutionalize the collection and use of data for health policy development and program monitoring. The HMN offers some financial assistance to countries that are preparing for and planning HIS reform and will assist countries in negotiating financing packages that blend loan funding with grants from bilateral donors to implement those reforms.

Several international agencies support strengthening systems for national statistics that extend beyond the health sector. STATCAP (Statistical Capacity Building), which is a new lending program offered by the Partnership in Statistics for Development in the 21st Century (PARIS21) through the World Bank, supports the development of national statistical systems. The separate Trust Fund for Statistical Capacity Building offers smaller amounts of grant funding to prepare the statistical master plan that is required for obtaining a STATCAP loan. Although short-term project funding can often be secured for system development, the resulting system and its recurrent costs must be within the country's capacity to sustain it, both technically and financially.

IMPLEMENTATION OF CHANGE: LESSONS OF EXPERIENCE

Underinvestment is the root cause of the nearly universal weaknesses in the HIS in developing countries. This failure is reflected in the poorly paid and undervalued HIS staff; in the irregular and unreliable transmittal of data from the periphery; in the underreporting of events, including births, deaths, and morbidity; and in the failures to base planning and decision making—at both the district and the central levels—on credible evidence (Azubuike and Ehiri 1999).

When the need for HIS improvement is identified, ministries of health should explicitly state the characteristics they need in a reformed system and quantify the expected benefits. A common mistake made in implementing HIS change is failing to recognize the associated need for change in management processes and organizational culture. In contrast, recent HIS reforms in Niger (Mock and others 1993) and Uganda (Gladwin, Dixon, and Wilson 2003) have had unprecedented success because they have been aligned with broader management reforms and changes in organizational culture. Failure to adjust management roles with HIS changes can constrain effectiveness, such as when HIS managers are not given the necessary increased status and authority to demand reports and trigger corrective actions (Gladwin, Dixon, and Wilson 2003). Failure to invest adequately in training, especially in skills for presentation and communication of results, may also inhibit the use of health information. The demand from international organizations and global programs, such as the Expanded Program on Immunization and Stop TB, for reports on vast numbers of indicators has retarded the smooth devel-

opment of the district-level HIS. The HMN will create an alliance of countries committed to a parsimonious consensus technical framework and encourage donors to cooperate with and strengthen the HMN-sanctioned HIS architecture in participating countries.

The predictors of success in developing and maintaining an HIS are as follows:

- high-level commitment to HIS development and the linked changes in management
- a champion of HIS reform who engages the stakeholders and can work across sectors
- an information architecture that is simple, is structured to drive decision making at the level that data are collected, provides incentives and accountability for performance, and links health information subsystems
- investment in training and increased status for the people who manage the HIS.

RESEARCH AND DEVELOPMENT

An effective HIS delivers routine information that enables informed policy making and management but also promotes health research. Routine information systems may serve as a research platform, but the HIS itself should also be a subject of research. Research should drive the continual refinement of HIS methods and tools, thereby ensuring expanding and well-documented returns on our investments in health.

The instruments and methods of the HIS must be continually refined to improve its effectiveness and reduce its costs. For the phased introduction of vital events monitoring, for example, there is a pressing need for the development and validation of methods for projecting subnational results to national rates of birth and death. More research is needed to develop and test new methods for rapid assessment in order to obtain timely and affordable information to solve management problems. As field-appropriate and cost-effective diagnostic technologies are developed, research should be performed to document the utility of obtaining biomarkers in household surveys.

Documenting improved outcomes and lower costs will provide evidence for policy makers on the effectiveness of HIS investments. To better decide how to improve the HIS, decision makers will need documentation of the costs and effects of introducing ICT in support of the HIS. Existing and emerging technologies should be tested for their cost and effectiveness in assisting field-based data capture, instantaneous data transmission, GIS-based mapping of indicators, and compelling presentation for decision making by policy makers, managers, and other stakeholders. Research and development efforts are needed to devise software—or preferably shareware—that is specifically tailored to support the consensus technical framework developed by the HMN.

Bailey and Pang (2004) point out the need for more research in the developing world to better understand users' information needs. In fact, research is needed to better document the entire information value chain, with special attention to improving the identification of information needs, to overcoming the natural disincentives to information sharing, and to enabling better use of information for constructive change. At present, there is still a need to improve the access to information and knowledge in the developing world. However, the future will bring the larger challenge of improving the management and use of information and the knowledge such information can bring. Research in the HIS will be instrumental in both accelerating equitable access to information and improving the management and use of knowledge for improved health.

CONCLUSIONS

More than ever before, it is in the mutual interest of the developing and industrial worlds to invest in strengthening systems for collection and management of health information (Stansfield 2005).

The trend toward "basket" funding for health and sector-wide approaches makes the need for priority setting all the more acute. Priority setting depends on accurate information. The success of efforts to reduce poverty and health inequity will depend on the existence of information systems to detect those problems, facilitate the design of solutions, and track progress toward eliminating the problems. Countries and donors must, therefore, accelerate and harmonize their investments in information systems.

Within countries, the trend toward decentralization of authority for management of health resources has led to further challenges for the HIS, as well as to greater reliance on the information it provides to inform decision making. It is clear from the instructive failures of underresourced systems that the accuracy and value of information reported to the national level will depend on that information's perceived value in the periphery. Information is relevant only if it is used to solve a local problem or if it helps to generate innovation that solves a local problem (Bailey and Pang 2004). Therefore, the decentralization of authority will be successful only with better information systems to support decisions at the periphery, and evidence-based decision making will be possible only if authority can be devolved to the periphery. This decentralization, along with increasing cooperation and collaboration across sectors to improve health outcomes, makes it all the more critical to present data in simpler ways that are understandable and compelling to a broader and nontechnical audience.

Although historically neglected, investments in comprehensive development of the HIS will clearly deliver good value for money. Improvements in the HIS can accelerate broad

improvements in health if they are engineered to reflect, reinforce, and even drive health sector reforms. Even more compellingly, investments in the HIS can make health the "thin edge of the wedge," giving governments and politicians a positive experience with information sharing and overcoming the natural disincentives to transparency and accountability. HIS investments hold the promise, therefore, not only of transforming public health, but also of accelerating progress toward good governance in every sector.

NOTES

1. Sauerborn and Lippeveld (2000) have defined a *health information system* as the "set of components and procedures organized with the objective of generating information that will improve health management decisions at all levels of the health system."

2. The dollar amounts given are quoted from the references and are not adjusted for current dollar value.

Chapter 55

Drug Resistance

Ramanan Laxminarayan, Zulfiqar A. Bhutta, Adriano Duse, Philip Jenkins, Thomas O'Brien, Iruka N. Okeke, Ariel Pablo-Mendez, and Keith P. Klugman

The control of infectious diseases is seriously threatened by the steady increase in the number of micro-organisms that are resistant to antimicrobial agents—often to a wide range of these agents. Resistant infections lead to increased morbidity and prolonged hospital stays, as well as to prolonged periods during which individuals are infectious and can spread their infections to other individuals (Holmberg, Solomon, and Blake 1987; Rubin and others 1999). The problem is particularly severe in developing countries, where the burden of infectious diseases is relatively greater and where patients with a resistant infection are less likely to have access to or be able to afford expensive second-line treatments, which typically have more complex regimens than first-line drugs. Furthermore, the presence of exacerbating factors, such as poor hygiene, unreliable water supplies, civil conflicts, and increased numbers of immunocompromised patients attributable to the ongoing HIV epidemic, can further increase the burden of antimicrobial resistance by facilitating the spread of resistant pathogens. In this chapter, we discuss the causes and burden of drug resistance and evaluate interventions that address the resistance problem in developing countries. Although a number of the interventions we discuss are relevant to drug resistance in HIV/AIDS and other forms of antiviral resistance, chapter 18 includes a more in-depth discussion of this subject.

RISK FACTORS

Drug Use in Humans

The evolution of drug resistance is facilitated by a number of factors, including increasing use of antibiotics and antimalarials;

insufficient controls on drug prescribing; inadequate compliance with treatment regimens; poor dosing; lack of infection control; increasing frequency and speed of travel, which lead to the rapid spread of resistant organisms; and insufficient incentives for patients, physicians, or even governments to care about increasing resistance. It is important to distinguish between risk factors for the emergence of resistance (*de novo resistance*) and those for the spread of resistance (*primary resistance*).

The molecular basis of resistance may give a clue to the likelihood of resistance emerging. If a single DNA base pair mutation leads to the development of resistance, then its selection is likely to be widespread, especially if the biological fitness cost of the mutation is low. *De novo* or acquired resistance results in the appearance of a resistant strain in a single patient. Subsequent transmission of such resistant strains from an infectious case to other persons leads to disease that is drug resistant from the outset, a phenomenon known as primary resistance (IUATLD 1998). Independent, cumulative events result in multidrug-resistant bacteria or tuberculosis (MDR-TB). Both the creation and the transmission of drug resistance contribute to its prevalence in a given population. This mechanism also holds true in the case of antimalarials; that is, resistance develops when malaria parasites encounter drug concentrations that are strong enough to eradicate the susceptible parasite population, but they fail to inhibit the multiplication of naturally occurring resistant strains. Commonly used antimalarial drugs are not mutagenic.

In the case of tuberculosis, spontaneous mutations leading to drug resistance occur rarely in *Mycobacterium tuberculosis*,

and multidrug regimens can prevent the emergence of clinical drug resistance (Cohn, Middlebrook, and Russell 1959). Resistance is thus an avertable phenomenon resulting from inadequate treatment, which, in turn, is often the result of an irregular drug supply, prescription of inappropriate regimens, or poor adherence resulting from a lack of supervision. In the case of malaria, the widespread misuse of chloroquine as prophylaxis is believed to be an important factor in the emergence and spread of resistance to this drug.

Despite conventional wisdom, the highest rates of antibiotic resistance in the pneumococcus bacterium globally are not for penicillins or macrolides, which usually require multiple DNA mutations or the import of foreign genes, respectively, but for sulfamethoxazole-trimethoprim, which can be selected from among a population of susceptible pneumococci by a single base change in the dihydrofolate reductase gene (Adrian and Klugman 1997). The direct selection of resistance following exposure of children carrying pneumococci has been shown in a prospective study in Malawi to occur in 42 percent of children exposed to sulfadoxine-pyrimethamine for a week and in 38 percent of children a month after exposure to drug treatment for malaria (Feikin and others 2000).

Evolutionary biology suggests that drug selection pressure is an important factor in the emergence and spread of drug resistance. Although the relationship between antimicrobial use and drug resistance (in the pneumococcus, for example) is well established in developed countries (Bronzwaer and others 2002), direct evidence to support this hypothesis is less forthcoming in developing countries because of a lack of data on antibiotic use. Resistance to antimicrobials is less likely to arise in the poorest developing countries simply because of the lower levels of antibiotic use associated with poorer socioeconomic status. For instance, India—a large country with scant control over antibiotic prescribing—has very low rates of resistance among systemic isolates of pneumococci, at least in rural areas (INCLEN 1999). These low rates exist despite wide antibiotic availability, probably because extreme poverty limits the duration of antibiotic exposure for the treatment of acute pneumococcal infections. Rising incomes and increased affordability of antibiotics will likely change this low incidence of resistance; the same may be true of quinolones, which are widely available at relatively affordable prices, even in semirural and rural populations. This trend may be responsible for the emergence of nalidixic acid resistance to *Shigella* in Bangladesh and fluoroquinolone resistance to *Salmonella typhi* in India.

Recent evidence suggests that shorter courses of antibiotics may select for less resistance in the pneumococcus compared with longer courses (when patients comply with those courses) (Schrage and others 2001). Very low levels of resistance have also been found in isolated rural African communities (Mthwalo and others 1998). This observation, however, should not lead to complacency. Increased access to antibiotics in developing

countries, without controls on over-the-counter use, has led to some of the highest rates of resistance in the world, as was seen with penicillin resistance in Vietnam. Relatively wealthy countries such as the Republic of Korea and Japan also have lax control and even greater access to funds to purchase antibiotics (Song and others 1999). Patterns of resistance differ by antimicrobial class, and resistance to several classes has been linked to particular patterns of use in developing countries. Macrolide use in children in China may be preferred to the use of beta-lactams, which are known to be associated in rare instances with serious anaphylactic reactions, and in Beijing and Shanghai, the highest global rates of macrolide resistance are encountered in nasopharyngeal isolates from children (Wang and others 1998; Yang, Zhang, and McGee 2001). Tetracycline use remains widespread in developing countries, and poor African countries, such as the Central African Republic, may have higher rates of resistance to tetracycline than to beta-lactams or macrolides (Rowe and others 2000).

The relationship between compliance and resistance emergence in the treatment of acute and largely self-limiting infections is less robust than in the case of chronic infections such as tuberculosis (TB). It is likely that resistance selection occurs more readily in the commensal flora (for example, the pneumococcal flora of the nasopharynx) than among the organisms causing the acute infection. Thus, shorter courses (and reduced compliance) may reduce the selection of resistance in commensal flora. In contrast, in TB, selection takes place in the infecting pathogen, and poor compliance is associated with the selection of resistant strains.

Antibiotic Use in Animals

Many developed countries use antibiotics for veterinary uses, both for improving feed efficiency and rate of weight gain (subtherapeutic use) and for disease prevention and treatment (therapeutic use) (Levy 1992). Although the extent of antibiotic use in animals in developing countries is unknown, one study from Kenya reported that tetracyclines, sulfonamides, and aminoglycosides were the most commonly used antimicrobials for veterinary purposes (Mitema and others 2001). Over 90 percent of the antibiotics used were for therapeutic purposes, and there was no evidence of use for growth promotion.

There is strong evidence that the use of antibiotics in farm animals promotes the development of drug-resistant bacteria in animals (Aarestrup and others 2001). Because routes for the movement of these resistant bacteria to humans are available, there is sufficient circumstantial evidence that drug resistance in bacteria associated with food animals can influence the level of resistance in bacteria that cause human diseases (Wegener and others 1999). Furthermore, mathematical models indicate that the effect of subtherapeutic use on resistance in humans

is greatest when resistance levels are undetectable (Smith and others 2002). The appearance of drug-resistant strains of *Enterococcus faecium* in broiler meat products at retail outlets declined after the ban of antimicrobial growth promoters in Denmark (Emborg and others 2003). Salmonella has been recovered from chicken (35 percent), turkey (24 percent), and pork (16 percent) samples obtained from area supermarkets in Washington, D.C. (White and others 2001). There is evidence that dissemination of tetracycline-resistance-encoding plasmids between aquaculture and humans has already occurred in Europe (Rhodes and others 2000). The global nature of this problem became apparent in 2001, when authorities in some European countries found residues of chloramphenicol in tiger shrimp imported from China, Indonesia, and Vietnam (Holmstrom and others 2003).

Transmission of Resistant Pathogens

Once resistance has emerged in a population, it can spread both geographically and between age groups. Unsafe drinking water, unsanitary conditions, and poor infection control in hospitals are risk factors for the transmission of all infections, including resistant ones. The transmission of resistant strains from children to adults has been suggested by anecdotal reports as far back as the 1980s (Klugman and others 1986). That association is strongly supported by the role of conjugate pneumococcal vaccine in reducing antimicrobial resistance among adult pneumococcal bacteremic isolates in the United States (Whitney and others 2003). The association of HIV infection with pediatric serotypes and antimicrobial resistance in pneumococci suggests the potential utility of this approach in reducing the burden of antimicrobial resistance in pneumococci in developing countries where the burden of disease is overwhelmingly associated with HIV infection in both children (Madhi and others 2000) and adults (Jones and others 1998).

Disease Burden

Although no estimates of disease burden are currently available that are specific to drug resistance, the contribution of drug resistance to the burden of infectious diseases is believed to be large. Resistance has emerged in malaria, HIV, TB, and other bacterial infections that together constitute a significant proportion of the burden of disease in developing countries. An indication of the extent of the problem is provided by the burden of diseases for which drug resistance is a problem (table 55.1), as well as by the levels of drug resistance among these pathogens (table 55.2 and figures 55.1 and 55.2).

Pneumococci. Surveillance of drug resistance in pneumococci shows several general trends. The numbers of strains that are fully susceptible to penicillin-G, once nearly universal in most of the world, have declined by 30 to 50 percent in many countries and by 75 percent in some, as resistant clones have spread widely but irregularly throughout the world (Sa-Leao and others 2002). At the same time, percentages resistant to macrolides and to sulfamethoxazole-trimethoprim have increased, especially where those drugs have been widely used, and resistance to tetracycline or chloramphenicol has fluctuated widely. Linked resistance to these drugs results in a growing percentage of strains resistant to many or all of them. Resistance to fluoroquinolones is still rare but is beginning to be observed in many places (Ho and others 2001; Quale and others 2002).

Certain *Streptococcus pneumoniae* clones have been widely disseminated. A penicillin-, chloramphenicol-, and tetracycline-resistant clone (and sometimes erythromycin) of Spanish origin (Spain^{23F}-1) has, since its original description, been isolated in other parts of Europe, the United States, South and Central America, South Africa, and East Asia (McGee and others 2001). It is likely that this clone is even more widespread and that the absence of reports from other areas reflects the absence of molecular testing techniques needed to delineate

Source: Jacobs and others 2003.

Note: Drug classes were defined as follows: β -lactams (penicillin MIC \geq 0.12 mg/L), macrolides (erythromycin MIC \geq 0.5 mg/L), tetracyclines (doxycycline MIC \geq 0.5 mg/L), phenicol (chloramphenicol MIC \geq 8 mg/L), folate pathway inhibitors (co-trimoxazole MICs \geq 1 mg/L based on trimethoprim component), and quinolones (ofloxacin MIC \geq 8 mg/L).

clones, rather than an absence of the organisms themselves. Other globally disseminated *S. pneumoniae* include specific clones of serotypes 19F, 14, 19A, 9N, 9V, 3, and 6 (McGee and others 2001). Spread of these pandemic clones has continued, even in areas where successful interventions have reduced selective pressure from antimicrobial use (Arason and others 2002). With increasing international travel, the potential of

these strains to spread to areas where resistance is uncommon can no longer be considered remote.

Shigella. In many regions where *Shigella*, especially *Shigella dysenteriae*, is prevalent and an important cause of infant mortality, resistance first to sulfamethoxazole-trimethoprim, then to ampicillin, and commonly to tetracycline and

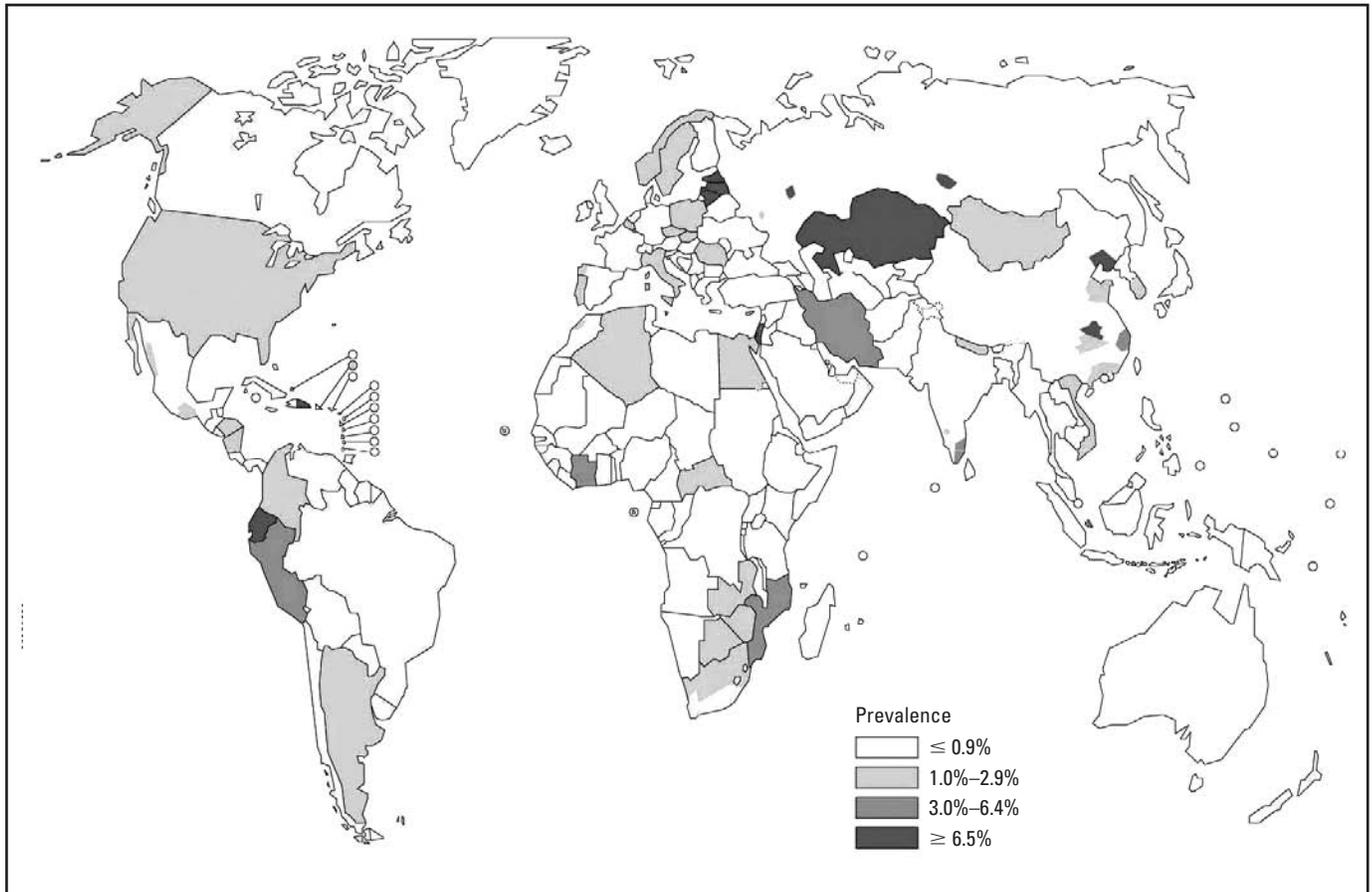

Source: WHO Regional Office for Africa, 1997–2002.

WHO has established 126 sentinel surveillance sites in 36 African countries that monitor the efficacy of locally used antimalarial drugs by following up patients in clinics. According to standard protocol (13, 14), results are expressed as I) early treatment failure (ETF); II) late clinical failure (LCF); in the future, late parasitological failure (LPF) will be considered as well. Treatment failure for policy change as shown here consists of the sum of ETF + LCF.

Note: The box indicates the 25th/75th percentile, the line limits lower/upper values, and where the lines cross, the median.

Figure 55.2 Prevalence of MDR-TB among New TB Cases, 1994–2002

chloramphenicol has emerged and, over recent decades, spread to half or more of the strains sampled. In the 1990s, resistance has begun to emerge and spread to fluoroquinolones and third-generation cephalosporins, which in many places are the last effective oral drugs available (Ding and others 1999). In the past two decades, emergence and spread of *Shigella dysenteriae* type 1 resistant to sulfamethoxazole-trimethoprim, ampicillin, tetracycline, chloramphenicol, and—increasingly—nalidixic acid has reduced the effectiveness of these inexpensive and widely available antimicrobials in the empiric management of epidemic dysentery (Cunin and others 1999; Hoge and others 1995). The alternatives, ciprofloxacin and ceftriaxone, are relatively expensive and not always available. As a consequence, high fatality rates have been observed in a number of recent dysentery outbreaks (Legros and others 1998). The emergence of fluoroquinolone-resistant strains has quickly followed. The unchecked spread of these pathogens could pose a major public health challenge (Sarkar and others 1979).

Gonorrhoea. Newly drug-resistant strains of gonococci tend to spread rapidly because of their peculiar epidemiology and the lack of control programs. Therefore, it is important to detect microepidemics of such strains, but this need is rarely met. The past half-century has witnessed the successive emergence and spread of gonococcal strains resistant to each new drug that becomes widely used to treat gonorrhoea, including sulfonamides, penicillin, tetracycline, and sulfamethoxazole-trimethoprim (Tapsall 2002). Within less than a decade, such strains have commonly come to account for half or more of the isolates in many regions. The recent emergence of resistance to fluoroquinolones leaves only less available parenteral drugs, such as spectinomycin or ceftriaxone, as the reliable therapy (Ison and others 1998; Palmer, Leeming, and Turner 2001).

Tuberculosis. The emergence and spread of *multidrug-resistant tuberculosis*, which is defined as combined resistance to isoniazid and rifampicin, threaten the control of TB globally (Kochi, Vareldzis, and Styblo 1993). Patients infected with strains resistant to multiple drugs are very difficult to cure (Espinal and others 2000; Goble and others 1993), particularly if they are HIV-infected or malnourished (Fischl and others 1992), and alternative treatment is much more toxic and expensive (Drobniewski and Balabanova 2002). A patient with MDR-TB may remain infectious much longer than a patient with drug-susceptible organisms. Among new cases, prevalence of resistance to at least one TB drug ranges from 0 percent in some Western European countries to 57.1 percent in Kazakhstan, with a median of 10.2 percent. Multidrug resistance among untreated patients ranged from 0 percent in eight countries to 10.0 to 14.2 percent in six others. In previously treated cases, resistance to at least one drug ranged in different settings from 0 to 82.1 percent, with a median of 18.4 percent. Prevalence of

MDR-TB in previously treated cases ranged from 0 to 58.3 percent, with a median of 7.0 percent (WHO 2004).

An estimated 273,000 (at a 95 percent confidence interval [CI]; 185,000 to 414,000) new cases of MDR-TB occurred worldwide in 2000. By simple extrapolation, 70 million people could be latently infected with MDR-TB, and more than 1 million active MDR-TB cases could remain among previously treated patients. Despite its threatening potential, MDR-TB is—and will probably remain—generally rare. Decades after the introduction of TB drugs, the global prevalence of MDR-TB in new patients remains less than 2 percent (Dye and Espinal 2001). Old animal studies (Cohn and others 1954) and recent analyses using molecular epidemiology (Garcia-Garcia and others 2000) suggest that MDR-TB strains might be, on average, less infectious. And unlike most other bacteria, *M. tuberculosis* replicates rather slowly (low mutation rate) and shares little if any genetic material. Thus, even in the absence of widespread treatment of MDR-TB, its prevalence may not necessarily explode (Kam and Yip 2001).

Malaria. Chloroquine-resistant strains of *Plasmodium falciparum* malaria appeared a half-century ago in Southeast Asia and South America and spread across Africa, especially East Africa, in the past quarter-century (Wellems and Plowe 2001). The use of molecular markers testing indicates the wide geographical reach of *pfcr* polymorphism for chloroquine resistance, and *dhfr* and *dhps* polymorphisms for sulfadoxine-pyrimethamine. Current levels of treatment failure of chloroquine are in figure 55.1. There is evidence that malaria mortality, especially in children under the age of five, is rising as a consequence of increasing resistance to chloroquine (Greenberg and others 1989; Trape 2001). In response to increasing treatment failure, many countries, including Malawi, South Africa, and Tanzania, adopted sulfadoxine-pyrimethamine as first-line treatment; however, resistance to this drug too is growing in many parts of Africa. In Southeast Asia, the emergence of multidrug resistance to sulfadoxine-pyrimethamine and mefloquine over the past decade and a half has prompted the use of combination treatments that include artemisinin (Wongsrichanalai and others 2001).

ECONOMIC BURDEN

Although few estimates have been made of the economic impact of drug resistance in developing countries, there is some indication that this burden is substantial. Estimates for costs associated with the loss of antibiotic effectiveness in outpatient prescriptions in the United States range from US\$378 million to as high as US\$18.6 billion (Elbasha 1999). A report by the Office of Technology Assessment to the U.S. Congress estimated the annual cost associated with antibiotic resistance in

hospitals (attributable to five classes of hospital-acquired infections from six antibiotic-resistant bacteria) to be at least US\$1.3 billion in 1992 dollars (Office of Technology Assessment 1995). The U.S. Centers for Disease Control and Prevention (CDC) estimated that the cost of all hospital-acquired infections, including both antibiotic-resistant and antibiotic-susceptible strains, was US\$4.5 billion.

Patients infected with resistant strains are more likely to be sicker, to be hospitalized for longer periods of time, and to die of the infection (Carmeli and others 2002). Both the duration of hospitalization and the attributable cost of treating methicillin-resistant *Staphylococcus aureus* were found to be nearly three times as large as those for a susceptible infection (Abramson and Sexton 1999). One problem with estimating the attributable morbidity and mortality that is caused by resistant pathogens is that patients who are infected with resistant strains are more likely to have been sicker in the first place. Therefore, the ability to appropriately control for the underlying severity of the illness that causes hospitalization is a concern.

Another important cost of resistance comes from the need to move to second-line treatments, which are often much more expensive than the first-line treatment that is no longer effective. For instance, treating the roughly 300 million cases of malaria with artemisinin-based combinations would involve an excess burden of roughly US\$200 million each year in drug costs. Periodically changing first-line treatment may also involve costs of assessing alternate treatment regimens, retraining health care providers, and restocking health care facilities. Though all these impose a significant economic burden, especially in poorer countries, they may be an inevitable consequence of past drug use. A focus on the cost of resistance alone may be misleading, because it is potentially possible to eliminate drug resistance by not using any drugs. To appropriately assess the net benefits of drug use, one must include the cost of increased resistance and the benefits of antibiotic or antimalarial use in treating infections and preventing their spread to uninfected individuals.

INTERVENTIONS

In this section, we discuss interventions to address the challenge of drug resistance (table 55.3). Many interventions to address the problem of resistance are the same as those that reduce the burden of disease (these are discussed in detail in the relevant disease-specific chapters in this volume). Reducing disease diminishes the need for drug treatment and, therefore, lowers the likelihood that resistant strains will emerge. Some interventions, such as the use of drug combinations, reduce the likelihood that resistance will emerge, whereas other interventions, such as improvements in drug prescribing and patient

compliance with dosing, reduce the likelihood that a resistant pathogen will survive and proliferate. Prolonging the effective therapeutic life of existing drugs is not sufficient, however. Increasing incentives for pharmaceutical firms to bring new drugs to markets may also be called for.

Drug Treatment Strategies

The appropriate choice of drug treatment is an important step in delaying the evolution of drug resistance. Drug combinations that include drugs with different targets were first used in the treatment of tuberculosis and have now become routine practice in the treatment of cancer and HIV/AIDS. Combinations of artemisinin and its derivatives with other antimalarials, notably mefloquine, have accelerated recoveries, increased cure rates, and reduced transmissibility. In the refugee camps on the western border of Thailand, where most of the recent studies with artemisinin combinations have been conducted, the use of combinations delayed the development of resistance and reduced the incidence of disease (Nosten and others 2000). The rationale behind drug combinations is that, if resistance results from spontaneous genetic mutations, the chance that a parasite will emerge that is simultaneously resistant to two drugs with unrelated modes of action (that is, drug targets) is the mathematical product of the individual parasite mutation frequencies multiplied by the total number of parasites exposed to the drugs (White 1998, 1999). Combinations, therefore, reduce enormously the probability that a resistant mutant will arise. Sequential deployment of the drugs is much less effective, because it does not exploit the multiplicative reduction in selection risk.

In the context of antibiotics, combinations have typically been used to broaden the spectrum of antimicrobial coverage rather than to reduce the likelihood of the emergence of resistance. With the development of new penicillins and cephalosporins with broader spectra of activity a decade ago, most serious infections have been treated with monotherapy. The use of combination therapy to preserve new classes of antibiotics from the emergence of resistance at a societal level may be rational, but it has not been implemented because of cost concerns and the potential for enhanced toxicity associated with the use of more agents than necessary to effect a cure in an individual patient.

Other strategies include periodic withdrawal of a drug or rotation between different drugs. These strategies depend on the extent of the fitness cost of resistance¹ and the extent of multidrug resistance, which may vary with the specific combination of pathogen and drug. Withdrawal or drastic decline in antimicrobial use is occasionally but not always accompanied by the replacement of resistant strains with sensitive ones. The effects of antimicrobial removal have best been assessed for antibacterial drugs in northern Europe, where drug use is

Table 55.3 Potential Nonclinical Interventions: Evidence from Developing Countries

Strategy	Intervention	Reference	Description	Study location
Treatment strategies	Combination therapy for malaria	Nosten and others 2000	Use of an artesunate-mefloquine combination was found to reduce incidence of mefloquine resistance in <i>Plasmodium falciparum</i> malaria.	Thailand
	Cycling strategy	Kublin and others 2003	Replacement of chloroquine with sulfadoxine-pyrimethamine resulted in a decline in chloroquine-resistant strains over an eight-year period to levels that permit reintroduction of the drug.	Malawi
	Drug heterogeneity	Bonhoeffer, Lipsitch, and Levin 1997; Laxminarayan and Weitzman 2002	Modeling studies demonstrated the superiority and cost-effectiveness of policies involving use of different antibiotics on different patients compared with those using the same antibiotics on all patients.	n.a.
	Directly observed therapy short course	Balasubramanian, Oommen, and Samuel 2000 Dye and others 2002	Directly observed therapy reduced the probability of treatment failure. Directly observed therapy for TB was 2.8 times cheaper to deliver and between 2.4 and 4.2 times more effective than conventional treatment.	Kerala, India South Africa
Reducing selection pressure	Training providers	Bexell and others 1996	Continuing education seminars for paramedical prescribers resulted in patients being prescribed antibiotics less frequently at intervention centers (34 percent) compared with control centers (42 percent). Drug choice and dosing were also improved.	Lusaka, Zambia
		Santoso, Suryawati, and Prawaitasari 1996	One-on-one educational interventions and seminars for medical and paramedical prescribers reduced antimicrobial prescription by 17 and 10 percent, respectively ($p < 0.001$).	Yogyakarta and Central Java provinces, Indonesia
	Training drug sellers	Agyepong and others 2002	Training drug dispensers on patient communication resulted in modest improvements in the proportion of patients showing strict, full adherence to antimalarial regimen.	Dangme West District, Ghana
	Treatment guidelines with education	Qingjun and others 1998	Blister packages increased compliance with chloroquine therapy to 97 percent, from 83 percent in the control group.	Hunan province, China
	Direct education of patients	Helitzer-Allen and others 1993 Paredes and others 1996	Introduction of a nonbitter antimalarial tablet and a new educational message were effective in improving antimalarial prophylaxis compliance among pregnant women by 57 to 91 percent. Video, radio, and printed bulletins were used to educate women in an intervention community on the management of watery infantile diarrhea. The overuse of nonindicated medicines (antibiotics and antidiarrheals) dropped 11 percent in the intervention group and only 7 percent in the control group.	Malawi Lima, Peru
Reducing spread of resistance pathogens	Hand washing	Kurlat and others 1998	Training of nursing staff in hand washing, handling of infants, and care of intravenous lines resulted in 40 percent reduction in bacteremia rates.	Argentina
	Bednets (malaria)	Maxwell and others 2002	Use of netting resulted in a 55 to 75 percent reduction in malaria morbidity and consequent conservation of antimalarial drug use.	Tanzania
	Vaccination	Klugman 2001	Pneumococcal vaccines target the serotypes most commonly encountered clinically, which are more likely to be resistant to antimicrobials.	South Africa

Source: Authors.

tightly regulated and susceptibility patterns are closely monitored (Seppala and others 1997). A recent study demonstrated that after chloroquine was replaced by sulfadoxine-pyrimethamine in Malawi because of a loss of effectiveness attributable to resistance, chloroquine-susceptible *Plasmodium falciparum* strains appear to have returned (Kublin and others 2003). Though the results of this study offer promise for stopping or reversing resistance trends, if antimicrobials are more sparingly and less indiscriminately applied, little is known about the rate at which the resistance to chloroquine may reemerge with widespread use of this drug.

Rotating between two or more antibiotics has been proposed to address the problem of nosocomial drug resistance in the United States (Bergstrom, Lipsitch, and McGowan 2000; McGowan 1986), even though there is not much supporting empirical evidence to date. In one hospital-based study, switching from gentamicin to other aminoglycosides reduced resistance to gentamicin. However, when gentamicin was reintroduced, resistance developed rapidly (Gerding 2000). Modeling studies have indicated that a superior strategy may be to increase antimicrobial heterogeneity so that different patients are treated with drugs to which mechanisms of resistance are independent (Bonhoeffer, Lipsitch, and Levin 1997; Laxminarayan and Weitzman 2002). Although this may be difficult to implement in many developing countries, the approach incorporates an evolutionary perspective that may help deal with drug resistance.

Reducing Selection Pressure

Inappropriate antimicrobial use constitutes selective pressure without a corresponding benefit to individual or public health. (Eliminating all antibiotic use could, of course, eliminate the problem of drug resistance, but this strategy is clearly undesirable.) This multifaceted problem arises from behaviors of prescribers (not always physicians), dispensers (not always pharmacists), and consumers (not always infected). An important factor in overprescription is the issue of externalities; physicians, patients, and pharmacists have few incentives to consider the effects of their prescriptions or drug use on overall levels of resistance and the burden imposed on the rest of society. Physicians, both in private practice and in hospital settings, may also derive income from drugs sold and may, therefore, prescribe antibiotics more frequently than is desirable. In China, for instance, many hospitals rely on selling drugs for the bulk of their revenue (Hu and others 2001). Patient pressure demanding a prescription is known to influence prescribing in developed countries but could be less important in developing countries.

Interventions at the Provider Level

In this section, we discuss interventions directed at health care providers and local retail pharmacies, such as education and professional accountability.

Prescribing Patterns. Studies in developing countries have shown that as much as a third of drug prescriptions, accounting for 20 to 50 percent of drug costs, are irrational and that antimicrobials are among the most frequently prescribed medications (Bosu and Ofori-Adjei 2000). Although altering prescribing behavior is an important intervention to control drug resistance, the widespread availability of drugs without a prescription limits its effectiveness. The prescribing problem may be worse among private practitioners than among public practitioners (Siddiqi and others 2002). Continuing education for practicing health workers is one type of intervention that has been tested in several countries. In the United States, a decline in antimicrobial prescribing in pediatric ambulatory care has been attributed to educational programs directed at physicians as well as the public (McCaig, Besser, and Hughes 2002). In developing countries, successful educational programs for prescribers have improved diagnostic quality, dispelled perceptions of patient pressure, reduced unjustified antimicrobial prescription (Chuc and others 2002; Hadiyono and others 1996), and reduced polypharmacy (Hadiyono and others 1996) among private as well as public providers, including nonphysicians (Chakraborty, D'Souza, and Northrup 2000; Chuc and others 2002). In general, these measurable outcomes were improved by 5 to 20 percent by a single intervention—a modest but significant change that is best combined with parallel interventions. Although cost-effectiveness was not a focus of the studies, the resultant reduction in drug use would ultimately result in cost savings. Important components of educational interventions are long-term commitment and refresher courses, and complementary interventions are also desirable (le Grand, Hogerzeil, and Haaijer-Ruskamp 1999).

Prescription guidelines, essential drug lists, and formularies are essential for defining policy and provide a useful framework on which educational interventions can be based (Laing, Hogerzeil, and Ross-Degnan 2001). The World Health Organization (WHO) recommends standard treatment guidelines as one of several approaches for promoting rational drug use. Also, guidelines proposed by pharmacy and therapeutics committees or external advisers have been applied in developing countries, with mixed results. Although standard treatment guidelines reduced antibiotic use for respiratory infections by 50 percent in Fiji (le Grand, Hogerzeil, and Haaijer-Ruskamp 1999), they did not alter prescription patterns in a Ugandan study and produced a detectable but insignificant effect in Sri Lanka (Angunawela, Diwan, and Tomson 1991). In general, follow-up was essential for success, and the use of standard treatment guidelines was more effective with nonphysician prescribers (le Grand, Hogerzeil, and Haaijer-Ruskamp 1999). Education must form part of any treatment guideline intervention, and evidence suggests that, if anything, educational programs are more effective than simply formulating guidelines (Laing, Hogerzeil, and Ross-Degnan 2001). Rigid guidelines

such as preprinted order forms or prepackaged drug kits for the management of community-acquired infections have been perceived as excessively prescriptive and have not been successful intervention tools (le Grand, Hogerzeil, and Haaijer-Ruskamp 1999). Devising incentives for compliance could potentially lower the higher prescription rates among private providers, where treatment guidelines by themselves are less likely to work.

Peer and supervisory monitoring increases professional accountability, thereby promoting the application of knowledge to practice. The requirement that antibiotic prescriptions for inpatients be countersigned by an infectious disease consultant was successful in reducing prescriptions by 50 percent, with a resultant cost savings of about US\$350,000 over two years in a Panama hospital (Saez-Llorens and others 2000). Such a program would have limited applicability in other countries and settings where the number of trained medical professionals is small. A supervisory program in Vietnam, with medical equipment incentives, reduced the number of patients for whom antibiotics were prescribed and increased the number who received a correct dose regimen (Chalker 2001).

Diagnostic Tests. Bacterial culture and susceptibility testing, a necessary component of rational antimicrobial prescribing, is uncommon in many developing countries (Okeke, Lamikanra, and Edelman 1999). Furthermore, diagnostic tests to confirm or refute infections are also commonly unavailable or unreliable, so diagnoses are made largely on the strength of clinical signs and symptoms (Berkley and others 2001). Laboratory tests are expensive and routinely cost more than an empiric drug that could be effective. In contrast, malaria dipsticks can be an inexpensive tool for case detection and may be cost-effective in low transmission settings (Rimon and others 2003). Clinicians have been known to use chemotherapy as a diagnostic tool: a cure would confirm a diagnosis. Susceptibility testing of at least some specimens will provide much-needed surveillance data to support empiric prescribing, although efforts should be made to take into account spatial heterogeneity in resistance patterns.

Retail Pharmacies and Outlets. Drug distributors, including not only pharmacists but also pharmacy attendants, patent medicine stallkeepers, and itinerant drug sellers, often sell drugs without prescription and are an important source of primary care for people in many developing countries (Igun 1994; Indalo 1997). Patients in search of convenient and accessible health care often seek treatment at drug retail premises. Many drug sellers have not been formally trained in diagnosis and prescription but often have financial incentive to perform those tasks, with varying degrees of competence. Despite the potential loss of business to storekeepers, educational interventions have been successful in increasing prescription requirement demands and promoting referral advice, all steps in the right direction (Chuc and others 2002). Models for delivering

educational interventions in developing countries vary but can be broadly classified into focus group discussions (Hadiyono and others 1996) and large seminars (Bexell and others 1996). Both models have been found to be of comparable effectiveness; however, applicability and cost are situation-specific (Santoso, Suryawati, and Prawaitasari 1996).

Drug Quality. Ensuring drug quality is important, both to benefit the individual patient and to ensure that a patient is not subjected to suboptimal doses that would promote drug resistance. The few studies that have been conducted indicate that more than half of the antimicrobials marketed in developing countries do not match their labels. Hence, even when prescribers and consumers are using the drugs responsibly, therapeutic failure and subinhibitory levels of antimicrobials may occur. Substandard drugs are those that are degraded as a result of expiration or improper storage or that are counterfeit (Okeke and Lamikanra 2001; Prazuck and others 2002; Taylor and others 2001).

Interventions at the Patient Level

Improving communication between patients and providers could improve adherence to prescribed antimalarial regimens (Agyepong and others 2002). Compliance can also be positively affected by packaging. Blister packages, when combined with proper instruction about drug use, have been shown to produce modest increases in antimalarial compliance, particularly for long-term regimens, such as with primaquine (Qingjun and others 1998). Blister packages are also time-savers for primary health care workers, potentially allowing them more time to advise patients on drug use. However, the introduction of blister packages must be accompanied by clear directions to avoid injury following ingestion of blister packages.

Reducing patient self-medication may also be desirable, although the effect on drug resistance remains to be precisely quantified. Enforcement of prescription-only regulations for most antimicrobials reduces self-medication in developed countries (Carey and Cryan 2003; Goff, Koff, and Geiling 2002; Pechere 2001) and may be desirable in developing countries as well. However, such a strategy may be difficult to implement in developing countries. There have been only rare reports of reduction in antibiotic use following blanket enforcement of prescription supply legislation in areas where antibiotics are freely available (Bavestrello, Cabello, and Casanova 2002). Opponents to enforcement demand a heavy financial and political investment, implying that a black market for medicines could emerge, particularly if the demand for these drugs is not lowered (Bhutta and Balchin 1996; le Grand, Hogerzeil, and Haaijer-Ruskamp 1999). The sale of antimicrobials is a lucrative business, even when illegal, because of high demand.

Educational interventions directed at consumers have been proposed to reduce self-medication and increase compliance, but evidence for the effectiveness of this strategy remains inconclusive, largely because so few studies have been conducted. Gonzalez Ochoa and others (1996) demonstrated that, although refresher training for health personnel managing acute respiratory infections reduced antibiotic prescribing by 9 to 19 percent in two intervention areas in Havana, no benefit was seen from community education programs when used alone or in conjunction with prescriber training. In contrast, Denis (1998) was able to show that a poster had 5 percent effectiveness alone and 20 percent effectiveness when used with a video to promote appropriate use of quinine and tetracycline regimens for malaria among Cambodian villagers. The best method to deliver information about the consequences of antibiotic resistance remains to be identified and will need to be modified to suit different cultures (Marin and others 1995).

In the case of tuberculosis, first-line directly observed therapy (DOT) remains one of the most cost-effective of all public health strategies (WHO 1994). The discovery that DOT can be administered successfully as a short course (DOTS) has been pivotal to successful implementation. Relatively simple, the DOTS approach can improve patient compliance, cure the vast majority of new TB patients, and prevent transmission of the disease and the emergence of MDR-TB (Balasubramanian, Oommen, and Samuel 2000; Dye and others 2002). Unfortunately, many countries have been slow to adopt and implement DOTS programs correctly, and only a minority of TB patients worldwide are managed according to this protocol (Dye and others 2002; Pungrassami and others 2002). Because many patients either are treated outside the DOTS regimen or do not adhere to the long-term chemotherapy necessary to eradicate the causative organism, MDR-TB is likely to emerge and treatment costs are likely to escalate to as high as 1,000 times the cost of conventional treatment of drug-sensitive infection.

A DOTS program requires good laboratory support for case identification and is highly employee intense, requiring health workers to observe the ingestion of every dose of antimicrobials over several months. However, the potential economic gains are immense because of the high costs of allowing the continued spread of the disease and of managing resistant patients and because of the benefit of reduced hospital admissions (Dye and others 2003). Several studies have investigated means for reducing the cost of conventional DOTS programs without compromising effectiveness. Lwilla and others (2003) demonstrated that both institutional and community-based DOTS programs are effective, permitting cost-effective implementation in remote areas. Furthermore, although DOTS involves supervised drug dosing, highly trained health workers are not essential. Studies in South Africa, Haiti, and Thailand have found that DOTS was effective when drug administration was supervised by appropriately trained volunteers, including

storekeepers and former TB patients (Barker, Millard, and Nthangeni 2002; Pungrassami and Chongsuvivatwong 2002).

Although DOTS was not designed to cure patients with MDR-TB, it succeeds in 50 percent of cases (Espinal and others 2000). Controversy has emerged about the best approach to MDR-TB in resource-constrained settings. Although some experts assert that standard TB control prevents the emergence of MDR-TB in a cost-effective way (Chaulet, Raviglione, and Bustreo 1996) and that expensive treatment of MDR-TB would divert scarce resources from struggling DOTS programs, others argue that it is unethical to abandon MDR-TB patients and maintain that, if untreated, MDR-TB strains will become dominant, undermining tuberculosis control in future generations (Farmer, Becerra, and Kim 1999). These arguments are of particular consequence for programs in poor countries.

Application of Antibiotics for Nonhumans

The use of antimicrobial agents in agriculture and aquaculture can contribute to the spread of antimicrobial resistance in humans, although the extent of this contribution has not been precisely quantified. It is believed that agricultural antibiotic use hastens the emergence of resistant pathogens in humans, and antibiotic use in humans contributes to the spread of resistance once it has emerged (Smith and others 2002). There are no reliable estimates of the extent to which antibiotics are being used for such nonhuman purposes even in developed countries. In developing countries, one would expect use to increase with rising incomes and greater industrialization of agriculture and food production.

WHO has recommended that antimicrobials normally prescribed for humans should no longer be used to promote growth in animals (WHO 2000). Some countries in Europe, including Denmark and Sweden, have already phased out such use, and under the current plan, the European Union will ban the use of antibiotics for growth promotion by 2006. Evidence of the effect of a ban on antibiotic use in swine production is available from Denmark. Although the ban significantly lowered the use of antibiotics in growth promotion and raised the cost of swine production by less than 1 percent, the resulting higher incidence of disease among swine increased the use of antibiotics used for veterinary therapeutic purposes (Hayes and Jensen 2003). A similar increase was noted in Sweden, where antibiotic use in animals was banned in 1986; however, this problem was temporary, and in the longer term, livestock producers were able to move to an effective production system with lower antibiotic use (Wierup 2001).

Containing the Spread of Resistant Micro-organisms

Although selection is a necessary component of the resistance archetype, the dissemination of resistant organisms may have a far greater effect on the current situation (Zaidi and others 2003).

Interventions that block this dissemination have the added benefit of improving health by interrupting disease transmission and reducing the need for antibiotics in the first place. A case in point is the reduction in drug-resistant *Streptococcus pneumoniae* infections in the United States following the introduction of a multivalent vaccine that protected against the serovars with which resistance is commonly associated (Whitney and others 2003). By contrast, a drop in antibiotic use had no detectable effect on resistance within a short period (Arason and others 2002). Because these types of interventions are easier to evaluate, and in many cases are cheaper to implement (Coast and others 2002), they are likely to be of great value to public health in developing countries.

Interventions that interfere with the spread of many infectious diseases will have a parallel effect on the dissemination of resistant micro-organisms. Because the potential health benefits are obvious, these types of interventions are likely to be sustained (Wilson and Chandler 1993). A simple, cost-effective example is hand washing, which could reduce diarrhea by 47 percent while also having beneficial effects on acute respiratory tract and other community-acquired infections (Curtis and Cairncross 2003) (see chapters 19 and 35). Similarly, insecticide-impregnated bednets are another important intervention for the control of malaria (see chapter 21).

The emergence, persistence, and intra- and interhospital spread of multidrug-resistant organisms have all been facilitated by inadequate infection control practices. Furthermore, the emergence and spread of drug-resistant nosocomial pathogens from hospitals to the community are also a concern, and a history of hospitalization has been identified as a significant risk factor for the acquisition of a resistant infection in family members (OR 4.5, $p = 0.007$) (Zaidi and others 2003). Unfortunately, we lack good clinical trials that compare the different approaches to infection control programs and their ability to control antimicrobial resistance in hospitals and other health care facilities (Duse and Smego 1999). It seems reasonable to assume, however, that if the overall frequency of nosocomial infections is decreased in a health care facility, then the need for antimicrobial agents may be reduced. Furthermore, well-structured and rational infection control strategies that balance resources with the magnitude of the local problem must surely play an important role in decreasing morbidity, mortality, and costs (direct and indirect) to the patient, his or her family, the hospital, and the health care sector in general. Hospital-acquired infections rank among the most important causes of death, either directly or indirectly, in the developing world (Duse and Smego 1999; Ponce-de-Leon and Rangel-Frausto 1993).

Global Coordination

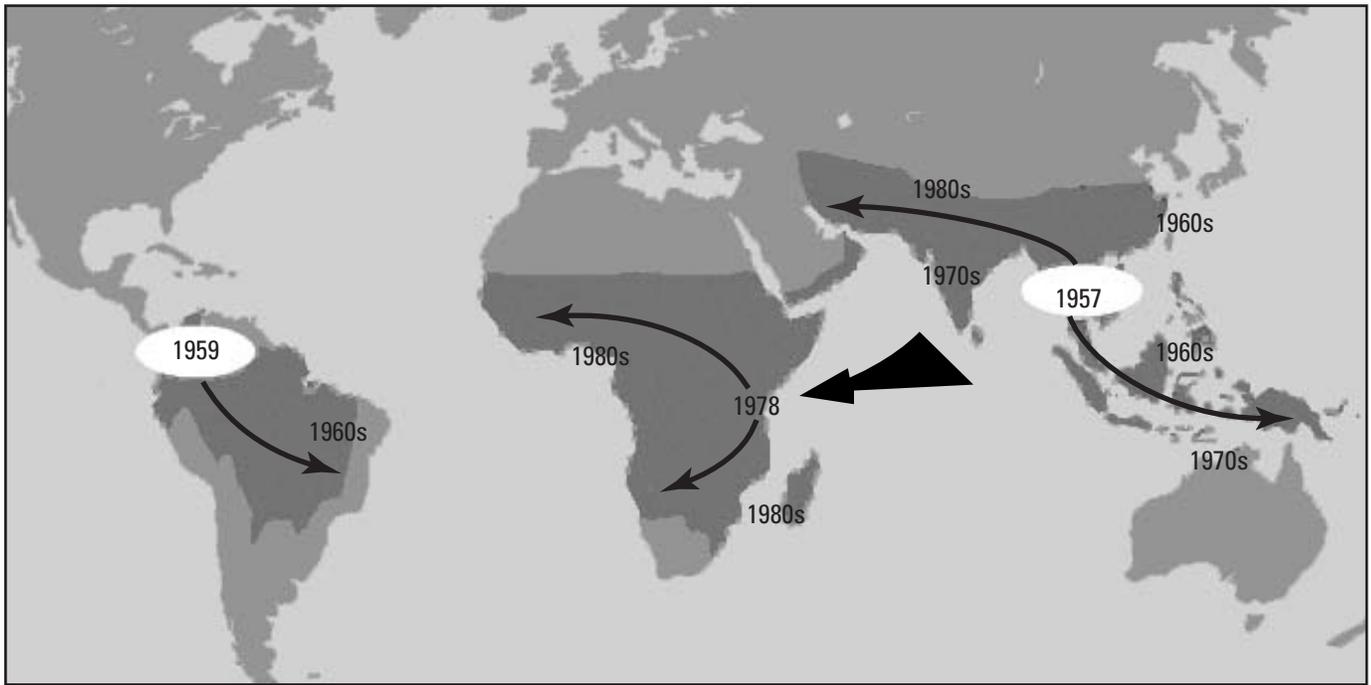

Antimicrobial resistance is a global challenge that requires urgent global action, not just across national boundaries but

also across the whole range of sectors involved. International travel and trade, particularly of food products, have facilitated the rapid globalization of resistance, and actions undertaken by any single nation have consequences for other countries. Drug resistance may threaten health gains made in other spheres of public health. Thus, coinfection with antimicrobial-resistant pathogens and HIV can lead to more rapid disease progression and enhanced dissemination of resistant pathogens. The emergence of antimicrobial resistance is considered a major threat to the future security and political stability of some regions (CIA 1999). Figure 55.3 shows the likely geography of the emergence, spread, and evolution of chloroquine resistance.

Concerted international action is needed to contain antimicrobial resistance. Failure of individual countries to act to contain resistance could lead to both national and international consequences. For instance, the use of artemisinin as monotherapy in any single country could potentially lead to the rapid evolution of resistant strains, which could threaten the use of this valuable drug in any other part of the world.

There is a considerable need for greater international collaboration on surveillance of antimicrobial resistance, both for routine surveillance and as an early warning system for unusual resistance events. Although existing laws at the international level require reporting of some infectious diseases, they do not include any systematic reporting of antimicrobial resistance. Certain multiresistant pathogens, such as methicillin-resistant *S. aureus*, are now notifiable at the national level in some countries, but the global nature of the resistance problem means that national legal measures alone are not enough. At the same time, the creation of new international duties would be undermined if they were not incorporated into national law (Fidler 1998).

To support such surveillance, the World Health Organization makes software (WHONET) available to enable clinical laboratories to enter their drug susceptibility test results into databases that can be analyzed for local management of resistance. Those results can also be merged, creating, thus far, approximately 80 national surveillance databases. Statutory notification about pathogens with new resistance phenotypes is under active discussion in several countries. Interpretation of existing surveillance data is hampered by the multiplicity of methods used to measure resistance and by the difficulties of assessing the quality of the data. Enhanced laboratory capacity is needed in many countries to provide effective diagnostic services and resistance surveillance. Multicountry external quality assurance schemes already exist but need to be extended to cover more resource-poor nations. WHO has begun establishing international surveillance standards by issuing antimicrobial resistance surveillance standards (WHO 2002a), guidelines for the management of drug-resistant tuberculosis (WHO 1997), and protocols for detection of antimicrobial drug resistance (WHO 1996). Monitoring the use of antimicrobial agents

Source: Cell 1997.

Figure 55.3 Global Spread of Chloroquine-Resistant Strains of *P. falciparum*

is an important aspect of surveillance and needs to be strengthened internationally.

Coordinated surveillance for drug resistance to TB may be a useful prototype to follow. By 2003, a global network of 20 supranational reference laboratories and five regional subnetworks, known as the World Health Organization–International Union against Tuberculosis and Lung Disease (WHO–IUATLD) Global Project, was reporting data on representative cases of TB from 62 countries. The network has monitored participants’ laboratory testing methods and developed uniform definitions, such as establishing clinical categories for new cases and previously treated cases. The WHO–IUATLD Global Project, which covers approximately 33 percent of the world’s population and 28 percent of its reported cases of TB, and other surveillance efforts reveal great variations from place to place in the prevalence of resistance to antituberculosis drugs.

The WHO Global Strategy for Containment of Antimicrobial Resistance (WHO 2001) recommends more than 60 interventions that can slow the emergence and reduce the spread of resistance in diverse settings, and it provides a blueprint for global coordinated action. A recent report by the Institute of Medicine calls for such coordinated action at a global level to subsidize artemisinin-based combination treatments for malaria for deployment in developing countries to ensure that combination treatments are available at the same or lower price

than monotherapies. The underlying rationale is that this strategy would both save lives in the short term and delay the emergence of resistance in the long term, thereby benefiting all malarious countries (Arrow, Panosian, and Gelband 2004).

Encouraging the Development of New Drugs

The development of new products has not kept pace with the problem of addressing microbial resistance to drugs that are used to treat infections in human and veterinary medicine. In the context of drug resistance, it is not sufficient to design policies that will encourage only the development of new drugs. It is also important that such policies give pharmaceutical firms (a) an incentive to invest in new classes of drugs, rather than products that belong to existing drug classes and that are, therefore, more likely to be rendered obsolete by resistance, and (b) an incentive to care about drug resistance when making decisions about how to market and sell their product. (See chapter 6 for a discussion of product development not specific to drug resistance.)

Current public and private investment in drugs, vaccines, and other products to control major infectious diseases in developing countries has recently been less than 2 percent of total health research expenditures throughout the world. Of the 1,393 new chemical entities registered by Western health authorities between 1975 and 1999, only 13 (less than 1 percent)

were intended for the treatment of tropical diseases, and half of those came from veterinary research.

Evidence suggests that in recent years, a steadily decreasing proportion of pharmaceutical company profits has been invested in antimicrobial research and development (R&D). One reason given for this decline is increased development costs, which result from more complex clinical trials, longer development times, and the relative attractiveness of returns from investing in drugs for chronic diseases, which must be taken continuously rather than just for the duration of an infection. Efforts to reduce inappropriate antibiotic use may paradoxically also reduce incentives for pharmaceutical firms to invest in developing new products (Monnet and Sorensen 2001; Philipson and Mechoulan 2003). The related issue, of using shorter treatment courses for many infections, may also affect R&D incentives (Pichichero and Cohen 1997).

Encouraging research into antimicrobial agents that will be used primarily in low-resource countries poses particular challenges, given the need for drug companies to make a profit. Various incentives to the industry, including both push and pull mechanisms, have been discussed (Kettler 2000). *Push mechanisms* consist of incentives to offset R&D costs, such as research grants, tax credits, public investment in applied research, cost-sharing between companies, and establishment of local development facilities. *Pull mechanisms* are designed to create a market, thereby improving the likelihood of a return on investments. They could include an international purchase fund for a new antimicrobial that meets specific criteria (United Kingdom Government 2001), tax credits on sales, and favorable patent policies, such as extension of patent terms or market exclusivity on new products. Time-limited exclusivities on new, clinically useful formulations might stimulate the additional pharmaceutical and clinical studies that are needed to support licensure. Better patent protection for new antimicrobial agents in areas of the world where patent laws are not enforced today would also help.

Patent policies to encourage investment in developing new antibiotics should also take into consideration the effect of those policies on incentives that would encourage pharmaceutical firms to conserve the effectiveness of their products. If effective patent lengths are too short, pharmaceutical companies will be less likely to care about growing drug resistance to their product and will be more interested in maximizing sales of their products during the period of patent production. Extending patent lengths may not solve the problem, however. If different firms make closely related antibiotics that have linked mechanisms of action, no single firm may have an incentive to care about drug resistance (Laxminarayan 2002). Increasing patent breadth, one solution to this problem, would have the added advantage of creating an incentive for firms to invest in developing new classes of drugs rather than introducing drugs that are closely related to existing products in modes of action.

IMPLEMENTATION OF STRATEGIES: TWO LESSONS FROM EXPERIENCE

Integrated Management of Childhood Illness

The program on the integrated management of infant and childhood illness (IMCI) was initiated by WHO, the United Nations Children's Fund, and other technical partners. The program, which provides a framework for stepwise assessment and management of sick children, has been successful in averting unnecessary antibiotic and antimalarial use and in reducing the cost of medications (Gove 1997). An underlying objective of IMCI is to detect, where present, conditions other than those responsible for the primary complaint. The result is that rational prescribing may actually increase, but because IMCI guidelines reduce irrational prescribing, the net effect is a reduction in drug use, including antimicrobials (Oluwole, Mason, and Costello 2000). Drug costs associated with treating children in Kenya were found to be reduced from an average of 44 cents per patient (U.S. currency) to between 16 and 39 cents per patient when IMCI guidelines were followed (Boulanger, Lee, and Odhacha 1999). A study that compared prescriptions arising from standard and IMCI-guided consultation with a health worker in Kaduna state, Nigeria, found a reduction in polypharmacy when IMCI guidelines were used, from a median of five drugs down to two drugs, and an 80 percent reduction in the cost of all medicines (Wammanda, Ejembi, and Iorliam 2003). This reduction represented savings of 93.4 and 68.6 percent for antibacterials and antimalarials, respectively, although part of the savings could be attributed to the substitution of tablets for more expensive syrup formulations.

The contribution of IMCI to promoting judicious drug use is worth noting. A study that compared four districts of Kenya—two districts that had IMCI programs (Morogoro and Rufiji) and two that did not (Ulanga and Kilombero)—found that in 73 percent (95 percent CI; 65–80) of consultations studied in the IMCI intervention districts, a child needing an oral antibiotic or antimalarial was prescribed correctly, compared with 35 percent (95 percent CI; 25–45) in the control districts (Armstrong Schellenberg and others 2004). Also, in the IMCI districts, 86 percent (95 percent CI; 80–92) of children who did not need antibiotics left the facility without an antibiotic, compared with 57 percent (95 percent CI; 48–66) in the control district.

Directly Observed Therapy

Strict compliance and cure verification make it possible to conduct directly observed therapy using shorter-term regimens (the DOTS program). Outpatient treatment of a single TB case in Pakistan, with complete compliance, was recently estimated at US\$164 and increased to US\$310 when an institution-based DOTS program was applied (Khan and others 2002). In Beijing, the cost of saving one disability-adjusted life year

(DALY) is 10 times higher when a DOTS TB program is not used (Xu, Jin, and Zhang 2000). Recent expansion of DOTS care in India has resulted in savings of about 0.2 million lives and US\$400 million in indirect costs (Khatri and Frieden 2002). Progress with DOTS in India was initially slow, but following better implementation, recent findings suggest that huge successes have been made in the past five years. The successes can largely be attributed to improved management of the program, area-specific appraisals, infrastructure, personnel, and technical support as well as continuous supervision (Khatri and Frieden 2002). This model is one that may apply in other developing countries.

In New York city, individualized chemotherapy based on drug susceptibility testing was nearly as effective in new patients with MDR-TB as in those with drug-susceptible TB (Telzak and others 1995), and the number of MDR-TB cases decreased by more than 90 percent within the decade (Fujiwara and others 1997). The relatively large number of MDR-TB cases in high-income countries made second-line drugs more available and affordable, and experience in the management of MDR-TB grew considerably over the past decade (Mukherjee and others 2004). Yet questions remained about which interventions had led to the city's success. In 1999, WHO created a working group on DOTS-plus to assess the feasibility and cost-effectiveness of treating MDR-TB in low- and middle-income countries (Espinal and others 1999). DOTS-plus has already negotiated a 90 percent price reduction from the pharmaceutical industry (Gupta and others 2001), and experience from Peru suggests feasibility and a mean cost of US\$211 per DALY gained (Suarez and others 2002).

AGENDA FOR ACTION

Although the evolution of resistance is a biological phenomenon, it is influenced strongly by the behavior of physicians, patients, and hospital administrators. In the language of economics, drug resistance is an *externality* associated with the use of antibiotics—a consequence not taken into consideration by those who use antibiotics or antimalarials. From a public policy perspective, there may be an economic case for societal intervention, because patients, physicians, and nations acting on self-interest alone may produce a higher degree of drug resistance than is ideal for society as a whole. From a global perspective, there is a case for international coordination to ensure that the actions of any single country or region do not increase the likelihood of emergence of resistance, which could then spread to other parts of the world.

Rising incomes in the developing world are likely to encourage greater use of Western medicine and, consequently, greater use of antibiotics. Moreover, the adoption of government-sponsored or employer-sponsored insurance plans in many

parts of the developing world could further increase drug use. Because developing countries will be less able to bear the costs of increasing resistance, it is important that the patterns of overuse and misuse observed in high-income countries not be repeated. The right financial incentives must be in place for both patients and physicians to face the full cost of using antibiotics and antimalarials and to ensure that these drugs are not overused.

Recommended Interventions

Sets of interventions specific to the diseases discussed in this chapter are described below.

Pneumococci. A number of affordable interventions can be considered. Data suggest that hand washing can interrupt not only the spread of pathogens causing diarrhea but also the transmission of nosocomial pathogens, and it can reduce respiratory infection-related mortality and morbidity. The promotion of a culture of hand washing requires access to clean, sufficient water—an urgent goal. Patient education to reduce demand for antibiotics for viral infections, and alteration of perverse incentives for physicians to prescribe antibiotics excessively are recommended. Pneumococcal conjugate vaccine has been shown to reduce the burden of antibiotic-resistant invasive disease, reduce transmission of resistant strains, and reduce antibiotic use in vaccine recipients and their siblings. Strategies for introducing this type of vaccine into the high-risk populations of developing countries are urgently needed. Better diagnostics are a key to more appropriate and focused prescribing, but their application is likely to be delayed in poor countries. The long-term effects of blanket recommendations for antimicrobial prophylaxis among HIV-infected populations must be closely monitored.

Shigella. Interventions must include improved strategies for case definition, clinical recognition, and appropriate therapy of dysentery. These strategies require a focus on educating physicians and caregivers as well as restrictions on over-the-counter availability of antibiotics in developing countries. Recent strategies for reducing antimicrobial prescribing for diarrhea at the community level also include coadministration of zinc with oral rehydration therapy. This strategy has been shown to lead to significant reduction in antimicrobial prescribing for diarrhea in Bangladesh and may be a useful adjunctive strategy (Baqui and others 2002).

Tuberculosis. The top priority must be the expansion of DOTS (Iseman, Cohn, and Sbarbaro 1993), which itself can prevent the emergence of MDR-TB (Dye and others 2002). In individual countries or parts of countries, however, additional strategies may be appropriate. Pablos-Méndez, Gowda, and Frieden

(2002) have grouped countries according to the proportion of TB patients completing treatment successfully and the level of MDR-TB among previously untreated patients. The resulting matrix provides a reasonable framework for deciding whether to use second-line drugs in a national program. Countries with treatment success of less than 70 percent should introduce or improve the DOTS strategy as the top priority. In settings with primary MDR-TB of less than 1.5 percent, treating MDR-TB is not a public health priority, although individual cases could be referred to clinical experts. The hotspots—those areas with primary MDR levels above 5 percent—are international public health emergencies. Infection control practices must be emphasized in such settings. Intermediate situations are ideal for additional research comparing DOTS with various individualized regimens against MDR-TB.

Malaria. With declining effectiveness of chloroquine and rapidly emerging resistance to its replacement, sulfadoxine-pyrimethamine, it is imperative that significant attention be paid not just to the choice of an appropriate first-line treatment for malaria, but also to strategies to prolong the effective therapeutic life of the new treatment. WHO has recommended that new artemisinin derivatives be used only in combinations with other drugs. There is evidence that artemisinin has already found its way into shops as monotherapy; discouraging the use of this valuable drug in monotherapy through public subsidies for combinations, by mandate, or through a combination of measures is a necessary first step. Discouraging the use of artemisinin as monotherapy is not sufficient, however. It is also important to ensure that the partner drug in the combination used with the artemisinin derivative is effective and, hence, able to protect the artemisinin. Therefore, discouraging the use of the partner drug as monotherapy, except in cases in which no safe alternative exists, such as for sulfadoxine-pyrimethamine in intermittent preventive treatment of malaria in pregnant women, is an important step in ensuring the long-term sustainability of malaria treatment. Training shopkeepers and other purveyors of antimalarial treatments to recognize symptoms of malaria and to use diagnostics to detect malaria would help reduce malaria treatment to instances for which it is appropriate and would reduce the likelihood of the emergence of resistance. Finally, steps to reduce the burden of malaria through the use of insecticide-treated bednets and, in some areas, residual household spraying would help reduce the need for antimalarial treatment and thereby reduce treatment selection pressure.

Research Agenda

A description of a research agenda to explain the full range of issues related to drug resistance is outside the scope of this

chapter and has been accomplished by other groups. Here, we restrict our focus to the following five priorities:

- accounting for attributable morbidity and mortality and the economic burden of drug resistance in the developing world
- measuring the cost-effectiveness of interventions to improve prescribing and patient compliance
- researching incentives for firms to invest both in developing new drugs and in maintaining the effectiveness of existing drugs
- identifying socioeconomic, demographic, and cultural factors that determine antibiotic use and misuse and projecting how antibiotic use will change in future years
- designing international coordinating mechanisms for surveillance to report resistance outbreaks and coordinate strategies for appropriate drug use, recognizing the global nature of drug resistance.

CONCLUSION

Modern medicine rests on the bedrock of effective anti-infective drugs. Unfortunately, the use of drugs creates selective pressure for resistance to arise, and thus, the growth of resistance may be an unavoidable consequence of our actions in treating disease. It is, however, important for governments to intervene to ensure that the effectiveness of our current arsenal of anti-infectives is not depleted at an excessively rapid rate. Given the potential for international spillovers of resistant pathogens and the ability of actions taken in one region or nation to affect other parts of the world where a disease is prevalent, a strong case can be made for coordinated international action—similar to another urgent global situation, the depletion of the ozone layer and the subsequent Montreal Protocol to phase out the use of chlorofluorocarbons—to manage the evolution of resistance.

Some interventions that we recommend, such as more restrictive prescribing policies and the use of combinations, could, in the absence of subsidies from the state, place a burden on the poorest patients. For instance, an overly restrictive policy on drug sales at the retail level could harm those who have less access to formal medical care and prescriptions. There may be similar effects from mandating that antimalarial drugs be sold in combinations that the poor cannot afford. Efforts to manage resistance should not be balanced on the backs of the poor, however, because the rationale for these efforts is that society as a whole gains from them. It is important that state subsidies be used to ensure that interventions to manage for resistance do not reduce patients' access to effective and affordable drugs.

Huge gains in life expectancy have come from the introduction of effective drugs to treat infectious diseases. Our history of treating infections successfully is brief, however, and dates back only 50 or 60 years. Sustaining this ability in the long term

requires a willingness to invest in interventions both to extend the therapeutic life of existing drugs and to discover and develop new ones. Some of these interventions, such as better infection control, introduction of affordable vaccines, and proper dosing, would benefit patients immediately; others, such as using combination treatments for malaria and investing in new drugs, may not bear fruit in the near term. Without a sustainable, long-term vision of coexistence with harmful microbes and imaginative solutions to the problem of resistance, our ability to control infectious diseases stands in peril.

NOTE

1. The fitness cost of resistance is an evolutionary disadvantage placed on resistant pathogens. However, some argue that although most resistance-determining mutations engender some fitness cost, these costs are likely to be ameliorated by subsequent compensatory mutations.

Chapter 56

Community Health and Nutrition Programs

John B. Mason, David Sanders, Philip Musgrove, Soekirman,
and Rae Galloway

Rapid improvements in health and nutrition in developing countries may be ascribed to specific, deliberate, health- and nutrition-related interventions and to changes in the underlying social, economic, and health environments. This chapter is concerned with the contribution of specific interventions, while recognizing that improved living standards in the long run provide the essential basis for improved health. Consideration of the environment as the context for interventions is crucial in determining their initiation and in modifying their effect, and it must be taken into account when assessing this effect.

Undoubtedly much change has stemmed from scientific advances, immunization being a prominent case. However, the organizational aspects of health and nutrition protection are equally critical. In the past several decades, people's contact with trained workers has been instrumental in improving health in developing countries. This factor applies particularly to poor people in poor countries but is relevant everywhere; indeed, it is a reason that social services have essentially eliminated almost all occurrences of child malnutrition in Europe (where, when malnourished children are seen, it is caused by neglect).

Community-based programs under many circumstances provide this crucial contact. Their role is partly in improving access to technology and resources, but it is also important in fostering behavior change and, more generally, in supporting caring practices (Engle, Bentley, and Peltó 2000; UNICEF 1990). Such programs may also play a part in mobilizing social demand for services and in generating pressure for policy change.

In community-based programs, workers—often volunteers and part-time workers—interact with households to protect

their health and nutrition and to facilitate access to treatment of sickness. Mothers and children are the primary focus, but others in the household should participate. Commonly, people go regularly to a central point in their community—for example, for growth monitoring and promotion—or are visited at home by a health and nutrition worker. The existence, training, support, and supervision of the community worker—based in the community or operating from a nearby health facility—are indispensable features of these programs. Thus community organizations are a key aspect of community-based health and nutrition programs (CHNPs).

This chapter focuses on large-scale (national or state) programs. Although these programs are primarily initiated and run at the local level, links with the national level and levels in between are necessary. Both horizontal and vertical organizations are needed. Local organizations make action happen, but they need input and resources, such as training, supervision, and supplies, from more central levels.

The experience on which this chapter is based comes from a considerable number of national and large-scale programs. Most of these programs include both nutrition and health activities, aimed particularly at the health and survival of reproductive-age women and children. We draw on these experiences as we try to put forward principles on which future programs can be based—programs that may have broader health objectives for other population groups and diseases.

As of 2001, some 19 percent of global deaths were among children—and 99 percent of all child deaths took place in low- and middle-income countries. The disability-adjusted life years (DALYs) lost attributed to zero- to four-year-olds—plus maternal and perinatal conditions, nutrition deficiencies, and endocrine disorders—amount to 42 percent of the total disease

Table 56.1 Estimated Contributions to the Disease Burden in Developing Countries

Factor	DALYs lost (percentage)		
	Direct effect	As risk factor	Total
General malnutrition	1.0	14.0	15.0
Micronutrient deficiencies	9.0	8.5	17.5
Total	10.0	22.5	32.5

Source: Mason, Musgrove, and Habicht 2003, table 10.

burden (all ages, both sexes) from all causes for developing regions. CHNPs address about 40 percent of the disease burden. In terms of prevention, Mason, Musgrove, and Habicht (2003) estimated that eliminating malnutrition would remove one-third of the global disease burden. Comparative studies by Ezzati, Lopez, and others (2002) and Ezzati, Vander Hoorn, and others (2003) have reemphasized malnutrition as the predominant risk factor and improvement of nutrition as playing a potentially major role in reducing the burden. Clinical deficiencies contribute directly to malnutrition, but even more, malnutrition is a risk factor for infectious diseases (table 56.1). Furthermore, changes in child malnutrition levels in developing countries are closely related to the countries' mortality trends (Pelletier and Frongillo 2003).

Dealing with women and children's health and nutrition addresses a substantial part of global health problems. Moreover, the experience of community-based programs linked to nutrition constitutes a significant part of the body of knowledge on ways of improving it. A number of large-scale, sustained health interventions, such as those described by Sanders and Chopra (2004), use a mix of improved access to facilities and community health workers. These interventions include the Comprehensive Rural Health Project, Jamkhed, India; community health projects in Brazil (Ceará, Pelotas); and the work of the Bangladesh Rural Advancement Committee (BRAC). Table 56.2 describes the program experiences drawn on.

The evidence is clear that significant differences occur between countries in the rates of change in health and nutritional status. Figure 56.1 shows a comparison of Indonesia, the Philippines, and Thailand. As is common, the indicator used is underweight children, which is likely to reflect broader conditions of health and survival. For Thailand, the figure shows the now-well-known rapid improvement in the 1980s and 1990s. For Indonesia, it shows slower but consistent improvement. The Philippines had little progress until recently, and the start of an improving trend coincided with increases in the number of village health workers and implementation of high-coverage interventions such as iodized salt and vitamin A supplementation (FNRI 2004). A crucial issue is how much of the improvements was caused by interventions that could be replicated—and within that issue is subsumed how much was because of

context, how much was programmatic, and what were the interactions. The contrasts between these three countries are instructive in part because they have several similar contextual factors; for instance, the status of women is relatively good, and social exclusion¹ is not extensive (compare both of these in, for example, South Asia). Thus programs may account for a significant part of the differences seen in improvement.

The benefits from CHNPs extend well beyond child nutrition (which is used as a summary measure). These benefits have not been quantified but would include improved educability (see chapter 49) and probably increased earning capacity associated with it and with physical fitness.

WHAT IS KNOWN ABOUT EFFICACY AND EFFECTIVENESS

The efficacy of health and nutrition interventions in developing countries has been established for decades (for example, Gwatkin, Wilcox, and Wray 1980). Prospective studies in several settings showed that health interventions with or without supplementary foods caused children to thrive and survive better: studies in Narangwal, India (Kielmann and others 1978; Taylor, Kielmann, and Parker 1978); by the Institute for Nutrition for Central America and Panama (Delgado and others 1982); in Jamaica (Waterlow 1992); and in The Gambia (Whitehead, Rowland, and Cole 1976) are examples.² These studies showed the effect of interventions on growth and (usually) mortality but did not generally factor out the relative contributions of health and nutrition. In fact, results from Narangwal showed similar mortality effects from food *or* health care; results from The Gambia indicated interaction such that sick children did not grow even with adequate food intake (appetite also playing an important role), and well children did not grow with inadequate food intake (Gillespie and Mason 1991, annex 2).

By the early 1980s, the conclusion, based on data at the experimental level (not from routine large-scale programs), was that better health and better nutrition are both required for child survival and development. This conclusion remains generally agreed on today; furthermore, concern exists that health interventions may become less effective unless nutrition is concurrently addressed (Measham and Chatterjee 1999; Pelletier and Frongillo 2003). In their chapter on malnutrition in the first edition of this book, Pinstrip-Andersen and colleagues (1993) drew largely on efficacy findings, with an emphasis on food supplementation. Those studies are not revisited here, but we can continue to build on their conclusions.

The efficacy studies were followed by a number of national or other large-scale programs in several countries. Some of those were a direct follow-on; for example, the World Bank Tamil Nadu Integrated Nutrition Program (TINP) followed the

Table 56.2 Country Experiences in Community-Based Programs

Country and program	Program experience
<i>Africa</i>	
Tanzania: Iringa	Area program with UNICEF and WHO inputs, 1984–91. After rapid initial drop in child malnutrition, moderate steady improvement. Program not sustained.
Tanzania: Child Survival and Development Program	1985–95, World Bank support. Results similar to Iringa.
Zimbabwe: Supplementary Feeding Programme	Wide-scale program following independence, 1980–90; infant mortality rate (IMR) dropped from 110 to 53 (1988). Not sustained.
<i>Asia</i>	
Bangladesh: Bangladesh Integrated Nutrition Program and national	BINP: area targeted covering 7 percent of population. Rapid improvement at start (1997); final evaluation not seen. National: program coverage expanding from 2000 on. Substantial improvement in anemia and child underweight seen in Bangladesh starting 1995.
Bangladesh: Bangladesh Rural Advancement Committee	Community-based health services with village health workers. Wide coverage since 1980s; particular focus on diarrhea.
India: Integrated Child Development Services	Implemented since 1976. Village program with community health (<i>anganwadi</i>) worker. Accelerated improvement reported in some states.
India: Tamil Nadu Integrated Nutrition Program	Implemented 1980 to mid 1990s. Village program in Tamil Nadu with World Bank support; growth monitoring, supplementary feeding, and so on. Substantial improvement in underweight reported.
Indonesia	Massive expansion of village programs 1975–90, covering all villages by 1990. Steady decrease in underweight during this time. Program not sustained in 1990s; now planned to restart.
Philippines: national	No wide CHNPs despite national decree in 1974. No significant improvement in child nutrition.
Thailand	National program from late 1970s; 600,000 village health volunteers trained (1 percent of population). Rapid improvement 1980–90; for example, 36 percent to 13 percent underweight children.
<i>Americas</i>	
Costa Rica	Expanding rural health services from 1970s following malaria control. Rapid fall in IMR, 1965–80; in stunting, 1979–89.
Jamaica	Expanded health services with community health aides from mid 1970s. Rapid fall in underweight, 1985–89.
Nicaragua	Community health movement, 1979–90, reduced IMR, eliminated polio; about 1 percent of population as village health volunteers.

Narangwal study, which was supported by the U.S. Agency for International Development (USAID). A number of overviews and analyses of these programs have been conducted—for example, Allen and Gillespie (2001); Berg (1981, 1987); Gillespie, Mason, and Martorell (1996; includes a summary of overviews, 60); Gillespie, McLachlan, and Shrimpton (2003); Jennings and others (1991); Mason (2000); Sanders (1999); and Shrimpton (1989). These plus some newer examples provide case studies for this chapter, and the sources for the case studies are included in table 56.2.

Underweight prevalences are improving at about 0.5 percentage points (ppts) per year except in Sub-Saharan Africa, which is largely static (ACC/SCN 1989, 1992, 1996, 1998, 2004). Programs are needed to accelerate this trend. Cost data

from an earlier study (Gillespie and Mason 1991, 76), combined with the estimated improvements from large-scale programs, led to the assertion that “there seems to be some convergence on around \$5 to \$10 per head (beneficiary) per year being a workable, common level of expenditure in nutrition programmes, though not generally including supplementary food costs . . . effective programmes, with these levels of expenditure, seem to be associated with reducing underweight prevalences by around 1–2 percentage points per year” (Gillespie, Mason, and Martorell 1996, 69–70).

A further important consideration is that the effect is likely to be nonlinearly related to the expenditure, showing the familiar dose-response S-shaped curve. Thus, the first expenditures produce little effect on the outcome, and one needs a minimum

Sources: ACC/SCN 2004; FNRI 2004; Mason, Rivers, and Helwig 2005.
 Note: -2 standard deviations NCHS/WHO standards; ages 0-60 months.

Figure 56.1 Comparison of Trends in Underweight Children in Indonesia, the Philippines, and Thailand

input level of resource use before a worthwhile response is achieved (Habicht, Mason, and Tabatabai 1984). This factor generally applies to drawing inferences from cost-effectiveness ratios, which often assume linearity. If the relation is S-shaped, the implication is important: applying too few resources does not simply solve the problem more slowly but does not solve it at all and is a waste. Therefore, program intensity (resources per person) is a critical measure.

Effective interventions must include a range of activities relating to health and nutrition. They should be multifaceted, not just for effectiveness but also for organizational efficiency. The structure needed for community-based programs could never make sense or be sustainably set up for single interventions alone. One often-argued case (for example, by Save the Children U.K. 2003) concerns children's growth monitoring: evidently growth monitoring in isolation from activities that *improve* children's growth is not going to achieve anything (or worse, considering the opportunity cost); however, weighing children and charting their weight can be a useful part of broader programs (for example, as growth monitoring and promotion).

COMMUNITY- AND FACILITY-BASED PROGRAMS

Protecting and improving health, especially in poor communities, requires a combination of community- and facility-based activities, with support from central levels of organization, as well as some centrally run programs (for example, food fortification). The place of these activities in a strategy is likely to vary, depending on level of development (of infrastructure, health services, and socioeconomic status) and on many local factors. For the poorest societies, the first priorities are basic

preventive services, notably immunization, access to basic drugs, and management of the most serious threats to health, such as some access to emergency care. Moving up the development scale, starting community-based activities may soon become cost effective for prevention, referral, and management of some diseases (notably diarrhea) when coverage of health services is poor. Community-based programs continue to play a key role until health services, education, income, and communications have improved to the point that maternal and child mortality has fallen substantially and malnutrition is much reduced; at this intermediate development level, the needs are less felt, and health services again take on a more prominent role. In this scheme, the widely felt need for better access to emergency obstetric services is problematic, requiring a well-developed human and physical infrastructure, yet arguably being one of the highest priorities.

Facility-based programs can be seen either as linking with the community program (referrals, home visits from clinics, and so forth) or as actually being part of the same enterprise. A distinction is that community-based activities take place outside the health facility, in the home or at a community central point, even if they may be supported by health personnel based in health facilities. The local workers in community-based programs may be drawn from the community itself, may be home visitors from a health center or clinic, or may sometimes be volunteers supervised by these home visitors. Many community-based programs come under the health sector, whatever the exact arrangements with local health services. Regarding specific program components, we return to the relative role of community programs and facilities later.

The integrated management of infant and childhood illness (IMCI) program provides guidance mainly on the curative health aspects and contains a number of nutrition activities (for example, administration of vitamin A capsules). Links to local health facilities are essential for the maintenance of the community activities and for referral in cases of illness (see chapter 63). As the IMCI training and implementation progresses, it should integrate directly with CHNPs (in fact, become part of the same exercise), which will add treatment of additional diseases. IMCI addresses diarrhea, acute respiratory infection (ARI), malaria, nutrition, immunization, safe motherhood, and essential drugs (WHO 1997). The 16 key practices for child survival defined in the context of IMCI (Kelley and Black 2001, S115) are exactly those to be promoted within CHNPs, and most are already included (four are nutritional).

Decentralization should be considered in this context. Although decentralized systems might be thought to be more effective in supporting CHNPs, the evidence for this assumption is scarce. Decentralization can reduce resources available at the local level if it involves devolving responsibility without the concomitant budgetary resources (Mills 1994). For example, in Kenya, decentralization did not accompany devolving authority

for raising revenue locally. In other cases (for example, the Philippines), decentralization has involved a shifting of resources, but with priorities set in the local government units by locally elected officials (municipal and city mayors), these resources may be used for shorter-term priorities than under previous, centrally decided, policies.

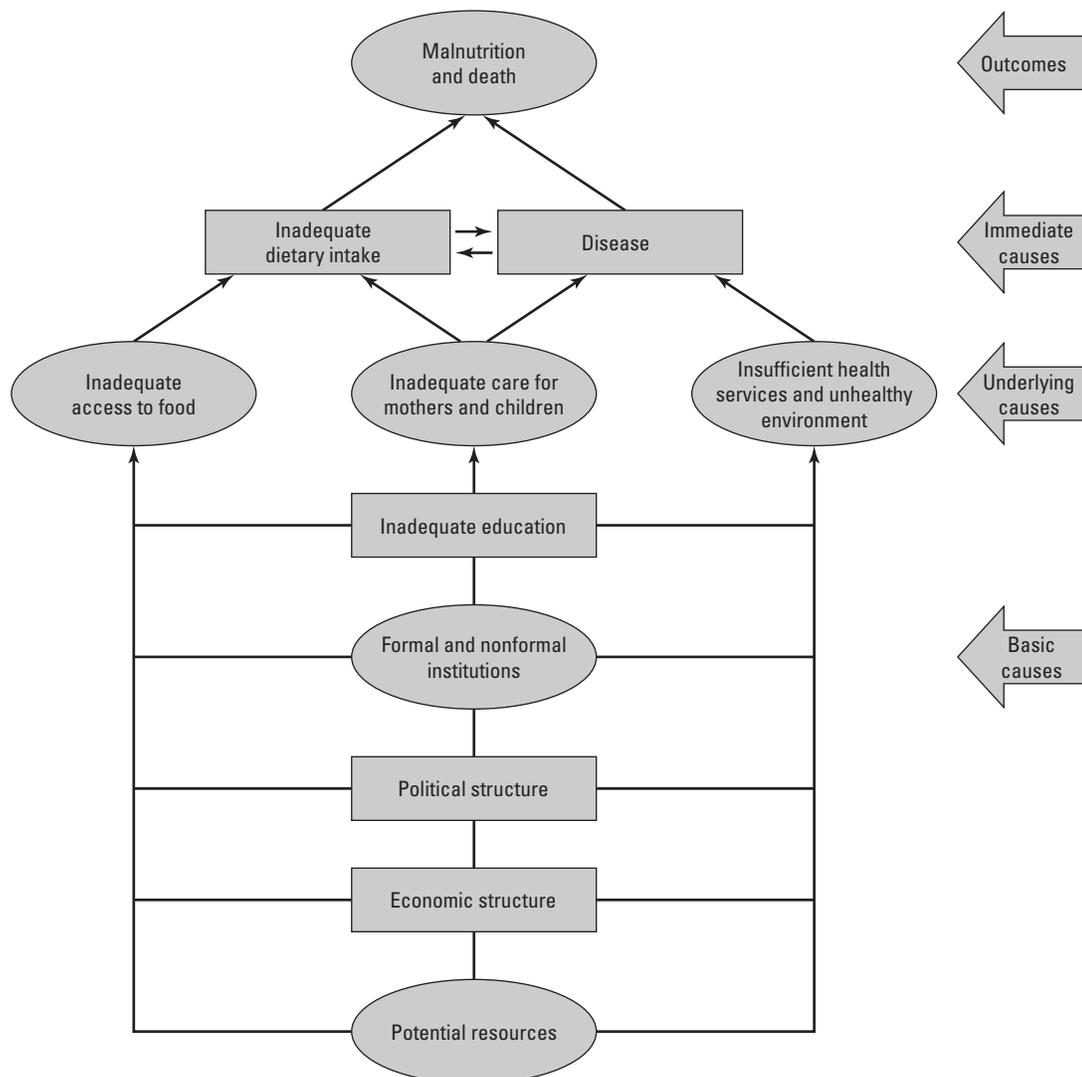

SUCCESS FACTORS

A number of useful concepts grew in the 1990s in relation to effective community-based programs. The concept of success factors helped sort out complex interactions: when numerous possibilities exist, understanding the successful pathway to effectiveness is more important than trying to disentangle what did not work. Focusing on successful programs helps simplify complexity and identify success factors, only some of which are

programmatic (directly under the influence of the intervention itself); others are contextual.

The importance of context, within which programs are initiated and run, thus emerged as crucial, and priority factors were proposed from studies of community-based programs in Asia (Gillespie, Mason, and Martorell 1996, 67; Jonsson 1997). Sanders (1999) described similar concepts under the headings of *community participation* and *political will*. This distinction and interplay between context and program factors is helpful in identifying required supporting policies to improve the context to make programs work. Details are in the later section titled “Contextual Factors.”

An overall framework (figure 56.2) for causal links to child survival and nutrition, put forward by the United Nations Children’s Fund (UNICEF 1990), gave a basis for a common language—even if the details might be questioned—revolving

Source: Redrawn from UNICEF 1990.

Figure 56.2 Conceptual Framework for the Causes of Malnutrition in Society

around food, health, and care as proximal causes to be addressed through programs. Improving these factors attacks hunger, disease, and neglect, which are the converse of food, health, and care. Basic causes are, like context, open to influence through policy decisions and acting through directly influencing food, health, and care and by modifying the effect of programs. Here malnutrition is seen as the outcome of processes in society, and direct interventions are seen as both shortcutting the needed basic improvements in living conditions and being dependent on these improvements in the long run for sustainability.

COMMUNITY-BASED PROGRAMS—WHAT ARE THEY?

Community health and nutrition programs are often initiated and run by the health sector, but sometimes a separate ministry (for example, in India and Indonesia) or service (for example, in Bangladesh) is set up. Attempts to use a national coordinating body appear to be less effective in leading to widespread community programs; an example existed in the Philippines until approximately 2000 (Heaver and Mason 2000). This ineffectiveness stems from the tendency of the coordinating body not to have direct authority over fieldworkers or the budget to create a national program with sufficient coverage and intensity to have a measurable effect. In some other cases, the services linked to poverty alleviation and social welfare programs can play this role (for example, the Samurdhi program in Sri Lanka). Involvement of the health services remains crucial, sometimes as the operational agency responsible for the programs and certainly always for referral.

CHNPs have so far been much more relevant to communicable diseases than to noncommunicable diseases in conditions of poverty and where undernutrition is common. (An exception occurs if CHNPs help prevent intrauterine growth retardation with later risks of noncommunicable diseases.) However, in areas where diet-related chronic diseases are developing in conditions of poverty (for example, much of Latin America and the Caribbean) and obesity is rising rapidly, the promotion of behavior change through counseling in CHNPs may become increasingly important. Promoting healthier diets requires access to outlets for fruit and vegetables, often displaced by fast foods, which should be a concern of community activities, as should lifestyle improvements such as use of exercise and recreational facilities.

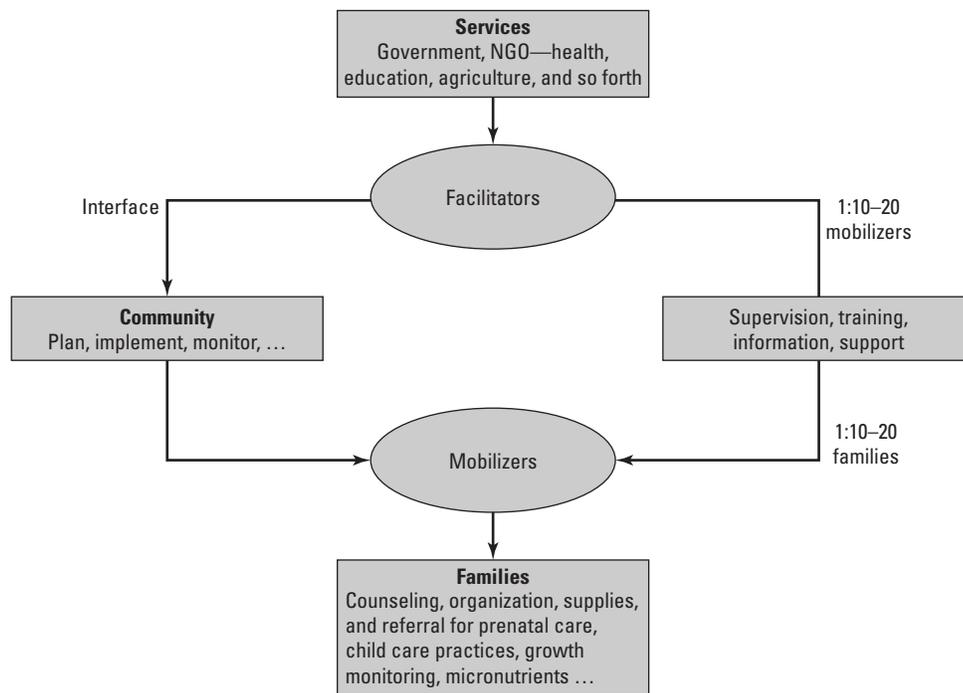

CHNPs often include activities well beyond direct prevention and behavior change. As envisaged with primary health care, water, sanitation, and other aspects of environmental health are frequently included, as well as agricultural interventions (for example, Zimbabwe in the 1980s). In Thailand, the village programs are part of the “Basic Minimum Needs” approach, which includes housing and environment, family

planning, community participation, and spiritual and ethical development.

A diagram of the structure, derived from Thailand’s program (figure 56.3), shows the relations between services that provide supervision and contacts with the community (“facilitators”) and with community workers, referred to as “mobilizers.”

The activities undertaken in CHNPs—the program content—are familiar and are described here only briefly. Program components, implemented by village workers or in facilities, come under the following headings, which form a menu, with the actual mix depending on local capabilities and conditions (UNICEF 1998, 84; see chapter 24):

- *Prenatal care* includes checking weight gain in pregnancy, prepregnancy weight, anemia, and blood pressure; providing multiple micronutrient supplementation and immunization (tetanus); counseling on diet, workload, breastfeeding; and predicting and arranging for delivery.
- *Women’s health and nutrition* entails counseling on health and nutrition and checkups, promoting improved status and resource allocation in home and outside, promoting improved access to health services, and often offering family-planning services (these services may even be an initiating factor for CHNPs, for example, in Indonesia).
- *Breastfeeding* includes providing knowledge on practices (initial, exclusive, continued); arranging mutual support; building confidence; preventing misinformation and undermining factors; facilitating time for breastfeeding; and providing information along the lines of the infant formula code.
- *Complementary feeding* includes providing knowledge and counseling (timing of introduction, type, energy density, frequency, and so on); sometimes promoting village or urban area production of weaning foods; sometimes marketing inexpensive food; facilitating mother’s time allocation; and promoting technology—storage, preservation, hygiene methods (fermentation, even refrigerators).
- *Growth monitoring and promotion* requires equipment (scales, charts, manuals); training and supervision; needs training of weigher to interpret charts and counsel mother; and a referral system for problems (for treatment, counseling, or other preventive intervention if growth is faltering). Weighing at birth and monthly weighing should be included, if possible, and adequate weight gain (rather than achieved weight or any gain) should be used for guidance on counseling or other intervention.
- *Micronutrient supplementation* should include vitamin A for nonpregnant and pregnant women (low dose weekly, preferably as part of multinutrients); for women within one month of delivery (massive dose to protect infant through breast milk); for infants and children (massive dose at nine months immunization contact and thereafter every six months and when medically indicated). It should also

Source: Adapted from Tontisirin (1996, personal communication).
NGO = nongovernmental organization

Figure 56.3 General Structure for Community-Based Programs, Based on Thailand's Program

include vitamin A—daily or weekly, with immunization campaigns, and so forth—and iron—daily or weekly for women (especially during pregnancy) as well as for children and adolescents. Iron is usually provided together with folic acid and may also be provided as part of multiple micronutrient supplementation. Iodine is usually provided by fortification and can be an infrequent (six-monthly) oral supplement, if necessary, but it should be part of multiple micronutrients for pregnancy.

- *Micronutrient fortification* is not usually included locally, although it is an important central program, but local monitoring is a coming opportunity, especially of iodized salt testing kits.
- *Supplementary feeding, using external supplies* may sometimes be appropriate in emergencies and in conditions of extreme poverty (for example, the Bangladesh Integrated Nutrition Program, or BINP), providing 200 to 500 kilocalories per person per day, but otherwise it is to be avoided as costly, with high opportunity cost, and not very effective; moreover, it can distort programs, which come to be seen largely as a source of free food.
- *Supplementary feeding, using local supplies* can be useful for complementary feeding (weaning) if carefully organized (which requires some resources). Village community production and processing are useful, if feasible (for example, in Zimbabwe), and the system can move to coupon method (for example, in Thailand).

- *Oral rehydration* includes highly effective local preparations for dehydration in acute diarrhea, as well as (or better than) oral rehydration salts. These preparations require counseling of mothers and take a lot of parents' time. Persistent diarrhea requires other intervention, especially nutritional. Care of children during sickness—especially continued breastfeeding and other foods—needs to be stressed (applies also to other illnesses).
- *Immunization* includes informing, referring, and facilitating.
- *Deworming* requires distribution and dosage supervision of mebendazole every few months, a highly effective nutrition intervention. Distribution methods are an issue.

The relative suitability of community- and facility-based operations for the different components again depends on local conditions, and these operations should be complementary. Community activities are essential for infant and child feeding, other caring practices, environmental sanitation, and the like. Facilities have a key role in immunization, prenatal care, and—of course—referral for treatment. Growth monitoring, micronutrient interventions, oral rehydration, and similar activities may be focused in either. Because it has more regular contact with clients, a community-based program may be more effective in actually reaching mothers and children with the component interventions than one that is facility based. Box 56.1 compares two programs in Honduras that offered the same content but differed in where the programs were based.

Box 56.1

Differential Effectiveness of Community- and Facility-Based Programs

Effectiveness is more likely to be possible through community-based programs because contact with caregivers is typically more frequent and consistent. For example, 83 percent of children enrolled in a community-based growth monitoring and promotion program in Honduras (Atención Integral a la Niñez Comunitaria, or AIN-C) were weighed two or more times in a given three-month period, whereas only 70 percent of children were weighed with the same frequency in a facility-based program. Workers visited 30 percent of mothers participating in the community program in their homes at least once for follow-up when their children were sick, were not growing, or had missed a weighing session. Controlling for a range of maternal and socioeconomic factors, researchers found that children 6 to 24 months of

age participating in the community-based program were 1.6 times more likely to be appropriately fed than were children not enrolled in growth monitoring and promotion. Children participating in the community program also were more likely to have received vitamin A and iron supplements than children participating in the facility-based program. Results show that consistent participation in the community-based program was associated with better weight for age. When a range of maternal and socioeconomic factors were taken into account, children participating fully in the community program were 435 grams heavier than children who were enrolled but participated infrequently. In the facility-based program, there was little difference in weight for children based on levels of participation.

PROGRAMMATIC FACTORS

Programmatic factors are considered first in terms of the characteristics of the activities—their population coverage and targeting, how much resources are applied per head (intensity), and the technologies used. Then the needs for initiating and sustaining these activities are discussed—the training needs, supervision methods, and (importantly) incentives and remuneration for field workers.

Coverage, Targeting, Resource Intensity, and Technology

Even effective programs improve the health and nutrition only of those they reach, so achieving as complete coverage as possible of those at risk is a major determinant of the effect. Although variations in the content of programs are seen in different circumstances, most activities are common to most programs. Variations in effect stem from factors such as coverage and adequacy of resources. How have CHNPs fared in reaching large sections of the population with adequate resources—and, indeed, what is the gap that would need to be filled? The achievements of the 14 programs drawn on here as case studies are summarized in table 56.3.

The programs expanded to include most of the communities within the areas targeted. The common evolution was to target select areas and specific biological groups within those areas—generally women and children—but not to give priority to any great extent to poorer or less healthy communities. Screening is sometimes done of individuals for admittance into

the programs (a form of targeting), based on nutritional status, as in growth monitoring and promotion, as well as on a one-time basis (for example, thin children in Zimbabwe). Recent thinking suggests that because mortality risk, growth failure, and morbidity are concentrated in children less than two or three years of age, in contrast to an earlier focus on children under five, these younger children should increasingly be a focus of CHNPs. A common policy observed in practice, therefore, is to aim for complete coverage within the areas participating, adding new sites until the entire region is covered. Relatively untargeted expansion to universal coverage may have been at the expense of establishing adequate resources and quality in the areas initially covered. In at least one case (Thailand), having achieved broad coverage and reduced malnutrition, the program became more targeted to areas in which progress was lagging. The coverage figures in table 56.3, although approximate, demonstrate considerable success in initiating and implementing CHNPs on a large scale—usually enough to have a substantial effect if the other factors needed for success were met.

How complete a coverage of the population should one recommend? This factor relates to targeting, to the additional resource requirements to reach the nonparticipants, and to their level of risk. Usually risk is spread throughout the population, although the extent varies considerably—at least a doubling of indicators of risk is usually seen between better- and worse-off areas or groups (for example, see Mason and others 2001, figures 1.4–1.7, 1.10–1.13). The remoter areas—or

Table 56.3 Characteristics of Selected Programs

Country	Coverage, targeting	Resources, intensity
<i>Africa</i>		
Tanzania: Iringa F: (+)	Population served = 250,000 in 6 districts, 610 villages, 46,000 children, of which 33,700 participated (73 percent). Targeting: children < 5 years and women; no socioeconomic selection of communities. Progressed from 168 to 610 villages 1984–88.	US\$8 to US\$17/child/year (approximately US\$30/child/year from total costs: approximately US\$6 million) 2 village health workers/village = 1,220 total; approximately 1:40 children [Volunteers]
Tanzania: Child Survival and Development Program F: 0	9 of 20 regions (population total approximately 12 million; 2 million children). Aimed for complete coverage.	US\$2 to US\$3/child/year [Volunteers]
Zimbabwe: Supplementary Feeding Programme F: ++	Population served: 56,000–96,000 with supplementary feeding; up to 60 percent of all children in community-based growth monitoring.	External: US\$3 million over 10 years For example, 1990, US\$0.5 million, approximately US\$0.50/child/year (Approximately 1:10–200, based on numbers per project) [Extension agents]
<i>Asia</i>		
Bangladesh: BINP F: +	BINP: in 6 <i>thanas</i> , or subdistricts (7 percent of population), children < 2 years, 8 million pregnant and lactating women.	US\$14 million/year; approximately US\$18/child/year 1 community worker per 1,000 population Approximately 1:200 children [Project supported]
Bangladesh: BRAC	Health coverage 25 percent. Nutrition with BINP, now expanding.	1 community health volunteer per 300 households; 1 community nutrition promoter per 200 households; community nutrition centers, 1:120 mothers and children; supervision of community nutrition promoters by community nutrition organizer, 1:10
India: ICDS F: ++/++	Children 0–6 years and pregnant and lactating women, in 3,900 of 5,300 blocks, or subdistricts; approximately 74 percent of population. Coverage expanded without targeting except by area.	Nonfood costs: approximately US\$2/child/year. 1 community worker (<i>anganwadi</i> worker, or ANW) per 200 children; 1 supervisor per 20 ANWs [ANW paid, at low rate]
India: TINP F: +	Children 6–36 months, pregnant and lactating women. Children with growth failure selected. 40 percent of blocks in Tamil Nadu; 20 percent of children in 1990.	US\$9/child/year, plus approximately US\$3 on food. 1 community nutrition worker per 300 children; 1 supervisor per 10 community nutrition workers [Project supported]
Indonesia F: (+)	By 1990, 60,000 villages (of 65,000: 92 percent) had <i>posyandus</i> (village health/nutrition center). Women and young children.	US\$2–11/child/year, depending on supplemental food; Rohde (1993) gives < US\$1 recurrent. Village workers (approximately 3 million total), 1 per 60 people, approximately 1 per 10 children; supervision 1 per 200. [Volunteer]
Philippines: national F: 0	Several programs, all targeted (for example, to poorer areas), none with national coverage.	US\$0.40/child/year in targeted areas. Village workers (<i>barangay</i> nutrition scholars) approximately 1:300 [Low allowance given]
Thailand: Primary Health Care + Poverty Alleviation Program + Basic Minimum Needs F: (+)	Expanded over about 5 years to cover 95 percent of villages. 600,000 village health communicators (1 percent of population) trained; 60,000 village health volunteers.	Ministry of Public Health; approximately US\$11/head/year (1990) 1 village health communicator or volunteer per approximately 20 children; 1 supervision extension worker per 24 village health communicators and volunteers [Volunteer]

(Continues on the following page.)

Table 56.3 Continued

Country	Coverage, targeting	Resources, intensity
<i>Americas</i>		
Costa Rica F: ++ to 0	Expanded rural health program coverage 19–67 percent (1974–89).	Rural health program: US\$1.70/child/year Food and Nutrition Program: US\$12.50/child/year 2 health workers (full time) per 5,000 population; approximately 1:350 children [Health worker]
Honduras F: 0	With community health volunteers, AIN-C covers > 50 percent of health areas (expanded 1991 on), > 90 percent of children < 2 years in these; growth monitoring and home follow-up, plus referral and treatment.	Cost estimated as US\$6/child/year Volunteer teams 3:25 children, about 3.5 hours/volunteer/week
Jamaica F: 0	Community health aides (CHAs), waged, cover most of country from health centers, with home visiting.	CHAs (full time) 1:500 households; approximately US\$7/household/year [Health worker]
Nicaragua F: 0	Community health workers (<i>brigadistas</i>) with “multiplier” approach, training others; 1980 approximately 1 percent trained; many more for malaria control.	Volunteers, approximately 1:20 households

Source: See sources for table 56.2.

F = role of supplementary feeding in the program; F: ++ = mainly a feeding program, or primary role; F: + = significant but not main role, often to selected children; F: (+) = existed but relatively minor; F: 0 = none.

Note: The status of community workers is given in brackets in the last column.

groups that are hard to include for other reasons—may be more expensive to reach. Clearly the calculations depend on conditions and have to be made on a case-by-case basis. The principle is obvious: only those areas and people included in CHNPs are going to benefit; so wherever need exists, programs are indicated. The implementation strategy, in theory, may need to begin with the most urgent needs, although in practice, programs may expand from the easier, more accessible areas; this practice seems reasonable, provided that the expansion really occurs and leads to equitable use of resources.

The program content is a mix of the components described earlier, varying with local priorities. The most crucial difference is whether extensive supplementary feeding is included. In middle-income countries, supplementary feeding was less prominent, often considered unnecessary, and because expensive, perhaps counterproductive (for example, in Costa Rica; Mata 1991). At the other extreme, such as for the Integrated Child Development Services (ICDS) in India, food distribution became the *raison d'être* of the program but, alone, was again probably not worthwhile. For some of the intermediate cases, supplementary food played a supporting role, with varying results. Except in the very poorest societies, supplementary feeding seems unlikely to be cost-effective.

The resources used for the programs found in table 56.3 can be expressed per participant (referred to as *intensity*), as total expenditures, and in terms of personnel; the latter figures may be more generalizable. (The outcomes associated with these resources are shown in table 56.5.) Data such as these have been

the basis for estimating that US\$5 to US\$10 per child per year may be needed for effective programs. The dollar figures vary from less than US\$1 to more than US\$20. Probably the low end of this range (say, less than US\$1 per child per year) does explain low or doubtful effect. Both low coverage and low intensity may explain the unchanged underweight prevalences in the Philippines until 2000. Fund levels in Indonesia are unsure; Rohde (1993) gave a figure of less than US\$1, but others gave higher estimates. Most would reckon the intensity in India too low (Measham and Chatterjee 1999) at about US\$2 per child per year. Looked at otherwise, the intensity planned for external funding (even if part of such funding is international costs) is in the US\$10 to US\$20 range (Bangladesh, India—Tamil Nadu, and Tanzania) and is the same as the estimate for Thailand. A level of US\$10 to US\$20 per participant per year is probably advisable for planning and sustaining effective programs.

The intensity measures of workers per mother-child and the supervision ratios are relevant in assessing needs. The suggested norms, originating from the Thai experience are 1:10–20 for both. Since then, it has emerged that the full-time equivalence of community workers must be taken into account; the Thai workers are local volunteers, probably devoting 10 to 20 percent of their time. In Honduras, Fiedler (2003) in a careful cost study estimated that each volunteer spent 3.5 hours per week (less than 10 percent of full-time equivalent, or FTE), with a ratio of 1 volunteer to 8 children. The ratio of community health and nutrition workers (CHNWs) to children may, therefore, be as low as 1:200 for FTEs and as high as 1:8 or 1:10

for part-time volunteers. In Jamaica, where the community health aides work full time, the ratio is 1:500 households; in the BRAC program in Bangladesh, it is 1:300, about half-time work (afternoons) (Chowdhury 2003). (An indication of the status of community workers is shown in brackets in the last column of table 56.3.) In any event, these ratios provide some basis for gauging the adequacy of personnel, and it seems that an effective ratio may be about 1:500 for community workers employed full time and 1:10 or 1:20 for local volunteers working part time.

In reality, the ratios of community workers to children are probably—not surprisingly—on the low side. Thailand, which trained 600,000 village workers (1 percent of the population), operated at about 1:20 for part-time volunteers, with similar supervision ratios. The Indonesian program was similar (or better) but had much less supervision. In contrast, the low resourcing of the ICDS in India shows up in a ratio of 1:200 (for part-time *anganwadi* workers, or ANWs), and in the Philippines, the ratio has until recently been 1:300 (for essentially voluntary workers).

Increased application of technology can contribute to the organization and running of community-based programs. Technology can be applied easily to methods of assessment and monitoring of children's progress; improved weighing scales (or in some circumstances, where rapid assessment in remote areas is important, using arm circumference) can simplify anthropometry. Modern computer technology for recordkeeping could be much more widely used, freeing staff time for home visits (for example, in Jamaica); e-mail, which is being rapidly adopted, has great potential for transferring information, troubleshooting, and consultation. Cell phone use is beginning to transform communications even in the poorest countries, where it is leapfrogging landline installation and use; as coverage expands, it will facilitate referral, for example, for emergency obstetric care, the need for which may first be identified by community workers. Coupled with improved transportation and procedures to allow the use of such transportation in cases of urgent need, modern communications can link communities to centers with advanced knowledge for information exchange and, by facilitating transportation when time is crucial, for referral. Modern communications may also provide more efficient ways of providing training, retraining, and supervision.

Application of current research and resulting technologies can improve many of the other interventions discussed earlier. In the micronutrient field, periodic supplementation (with vitamin A in high doses) can be extended through community programs, and fortified foods and micronutrient “sprinkles” can be promoted (see chapter 28). The prospect of enabling communities to test their salt for iodine content with simple and cheap test kits is intriguing and has often been recommended but has not yet been widely applied. Improved immunization technology should continue to protect health, for

which CHNPs' main role is to provide information and to ensure that children are taken for immunization (either to regular clinics or for National Immunization Days and the like). Periodic deworming can be conducted by community programs (and hookworm vaccines currently under development may soon contribute). Supporting the use of insecticide-treated bednets could be fostered through CHNPs. By far the most potentially important application of technology, certainly in Sub-Saharan Africa, will be the unprecedented effort to provide millions of people with antiretroviral therapy and associated care and support, as discussed later.

Training, Supervision, Incentives, and Remuneration

Community-based health and nutrition programs typically involve community workers, who may be entirely part-time volunteers (for example, in Honduras and Thailand) or may receive some remuneration financially or in kind (for example, in India). Community workers may be part of the health system, earning a wage and based in a local clinic (for example, in Jamaica) or in the community itself (for example, in Costa Rica); or they may be selected by and report to the community (for example, in Tanzania and Thailand). Table 56.3 indicates the status of community workers in the programs examined here. The training, supervision, and incentives for community workers are critical aspects of successful programs.

Inadequate training and supervisory support of community workers are common weaknesses. Considerable attention was given to training for the Iringa project (Tanzania), with village health workers trained for up to six months. In the Tamil Nadu Integrated Nutrition Program in India, community workers received three months of training and participated in annual refresher trainings. ICDS (India) initially trained the ANWs for three months, with two annual refresher courses, but this process declined. In Thailand, volunteers had two to five days of initial training, with annual refresher courses; Indonesian practice was similar. In Jamaica, where the community workers are employees of the health system, two months of initial training is provided to recruits with significant prior educational requirements. In Bangladesh, the BRAC community health volunteers have four weeks of training. The quality of the training has varied, poor training having been blamed for inadequate implementation in cases such as ICDS in India (Measham and Chatterjee 1999). Sanders (1985, 176–93) describes experiences in the 1980s of village health workers (and barefoot doctors) and their relation to the community.

Supervision of community workers is generally done by employees who are commonly in the sector. Training of supervisors (who often take on the role in addition to many other tasks) for these purposes is highly variable and not always adequate. Providing resources for visits to provide supervision to community workers is a further constraint. Supervision

ratios in effective programs are about 1:20 (table 56.3, last column, when reported). Supervision and training of community workers are closely linked; indeed, supervision (which must be supportive rather than disciplinary) should include a substantial element of on-the-job training.

Remuneration and incentives for sustaining motivation are key issues in replicating the successful features of these programs, and the options vary with the culture. In Thailand, it is argued that village volunteers consider the prestige associated with the role of health worker preferable to getting a low wage. In many cases, some right of access to health care is part of the incentive. For the ICDS in India, in contrast, the ANW receives a small financial remuneration, but the government (as elsewhere) will not grant formal employment status (and attempts to form unions have been strongly discouraged). Direct comparisons of the options of paid remuneration and voluntary work are rare. One opportunity to study options for remuneration is in the Philippines, where under a World Bank Early Child Development project, the child development worker receives a wage, which could be compared to near-volunteers at the *barangay* (village) level.

When CHNWs are primarily voluntary, they are selected by the community and report to community committees in some form. CHNWs on government payrolls may come from the communities and thus may be known to and identify with the communities, but they may report to supervisors higher up in the system. Both models can work, depending on the culture. What probably works least well is when the community worker is paid little and receives inadequate support and recognition from the community or even comes from elsewhere. Furthermore, as development progresses, reliance on volunteerism may become less useful.

For planning CHNPs in terms of community workers, the total numbers and resource implications can be estimated as follows. A full-time equivalent CHNW might visit 5 to 10 households per day, averaging a visit to each household roughly every two months; a ratio of 1 CHNW to 200 households, therefore, seems to be in the range within which an effect in terms of improving child health and nutrition is expected. Calculations from salaries of community health aides (CHAs) in Jamaica work out to US\$7 per household per year, within the usual range for expected effect. An important factor in regard to financial resources, however, concerns the substantial cadre of personnel who have training and job descriptions for community work, are based in health centers, and for administrative and financial reasons seldom leave the health facility. Moreover, funds may not be released to allow travel to nearby villages. An example is from Jamaica, where, because of clinic workloads, CHAs spend time helping in clinics rather than on home visits; in fact, technology could free staff time for community work by automating tasks, such as record keeping, that detain the CHAs. More effective deployment of existing personnel may

frequently be an option. Hiring additional personnel as community health workers would consume a significant proportion of typical health budgets (at 1:200 households for FTEs, this would amount to US\$1 to US\$2 per person per year, or about 20 percent of public health budgets in low-income countries). A mix of redeployment of existing staff and new hiring from budget reallocations should, nonetheless, be cost-effective.

Organization

Effective, respected, and socially inclusive organization at the community level seems to have been a key feature of the success in launching, expanding, and sustaining CHNPs. Most of the successful CHNPs drew and built on established community procedures; where they did not, effect and sustainability were in doubt. In Thailand, the health services and the religious organization at village level were important. The health services themselves play a key role in Costa Rica, Honduras, and Jamaica. In Indonesia, it was the community organizations (and women's groups) together with (initially) the family-planning services. In Iringa, Tanzania, it was the local political party structure, with substantial input from UNICEF. In Zimbabwe, immediately after independence, it was the village organizations that had fought the war, later helped by a consortium of national and international nongovernmental organizations (NGOs). The major part of the still-expanding program in Bangladesh is run by BRAC, an NGO, and has built on its links to the community for development, food security, and educational activities, as well as for health. In contrast, CHNPs that either failed to launch a wide program (for example, in the Philippines) or had limited effect (in India, ICDS) probably lacked some of these features. Inclusiveness is probably hard to achieve if not inherent.

Support from the central government is also crucial: CHNPs need this support for training, supervision, wages, supplies, facilities, and the like. Where such support becomes a regular government budget item, activities tend to become embedded and are sustained, in contrast to where the support is from donors.

A further issue concerns maintaining the community program's preventive orientation. In Indonesia, for example, according to Rohde (1993), the health services co-opted (and medicalized) the *posyandu* (weighing post, or community health and nutrition center) system by adding a diagnostic and treatment module (in fact, a table in the meeting place). This module attracted most of the attention, to the disadvantage of the preventive aspects of the program. Thus, if the extension of IMCI into the community means treatment (by trained but not medically qualified people) in the community rather than referral to facilities, treatment could become the main or even sole focus, shifting attention from prevention. Some parallels exist to the experience of ICDS in India, where, as noted earlier, food became the *raison d'être*.

CONTEXTUAL FACTORS

Community-based programs *can* work usefully, bringing steady progress; whether they do depends on myriad factors relating to the context. Three different concerns are (a) factors affecting widespread initiation of CHNPs of potentially adequate coverage, intensity, and content; (b) factors that lead to sustainability; and (c) factors that allow activities to be effective in improving health and nutrition—at best, when they, themselves, also contribute to a rapid transitional improvement, as in Thailand, Costa Rica, and Jamaica.

Contextual factors may bring about improvements in health and nutrition without any additional direct action—through improving living conditions, education, and so forth. Often, the changes caused by such nonprogrammatic factors are diffi-

cult to distinguish from program effects (current examples are in Bangladesh and Vietnam, both showing rapid improvement in nutrition). Moreover, the same factors (again, such as education) may both produce endogenous change and increase the effect of program activities.

Five contextual factors have been suggested as priorities (in Asia; Mason and others 2001):

- women's status and education
- lack of social exclusion
- community organization
- literacy
- political commitment.

Table 56.4 shows estimates of the positions of countries with case study programs in regard to these factors. The levels of

a. Women's status and education can be quantified by indicators such as adult literacy rates, females as percentage of males, and secondary school enrollment for girls.

b. Since 2000, the Philippines has begun a significantly improving trend, one factor being increased implementation of programs (CHNPs, as well as others, such as salt iodization); this increase is caused in part by increased political commitment, both as new legislation and resource allocations.

Note: 0: worst; 5: best.

health and administrative infrastructure have been added. The table also shows changes in these factors that may help explain why the CHNPs declined in three cases.

Political commitment can lead to initiating community programs and mobilizing resources. It may also respond to emerging community mobilization, as seems to be the case when programs start after political upheavals, as in Zimbabwe and Nicaragua. Declining political commitment accounts for loss of interest by the government in CHNPs; economic decline undermining resource availability may cause a shift away from financial support of CHNPs (for example, in Tanzania). In table 56.4, estimates of levels of contextual factors are totaled both without and including political commitment (last two columns). The total without commitment may indicate how favorable the context is if commitment is then made. Costa Rica, Jamaica, and Thailand had a favorable context and, with commitment, succeeded. The Philippines had comparable favorable conditions—the position of women is generally good, there is limited social division (exclusion), and so on. However, the necessary commitment (of resources, in particular) was made only recently, with new legislation, adherence to regulations (for example, iodized salt went from 25 to 65 percent coverage), and increased resource allocation and assignment of community workers. This new commitment may well explain the recently resumed decrease in child malnutrition (figure 56.2). In other examples—such as Indonesia and Tanzania—the conditions were moderately favorable, and while political support and finance existed, progress was made. In Tanzania, financial crisis denied the programs sustained support; in Indonesia and Zimbabwe, bureaucratization and centralization of the political process, followed by political turmoil, contributed to a similar outcome (Sanders 1993). The situations in India and Bangladesh have not been very favorable. The position of women and social rifts, amounting to exclusion, have probably inhibited effective programs, even with political commitment. This context may now be changing in Bangladesh, as seen in the activities of BRAC. Finally, this analysis demonstrates the relation of decline in programs to falling political commitment in Tanzania, Zimbabwe, and Indonesia.

If this analysis approximates the truth, the forward-looking policy implications may be important:

- First, investing initially in a favorable context makes sense (as does possibly committing resources preferentially to interventions in the more favorable contexts). Supporting policies can address social constraints—such as improving education for women—and (relatedly) seek to improve human rights. In many cases, human rights may be of overriding importance for health: Farmer (2003) has made a compelling case for rethinking health and human rights as a

prerequisite for progress and as a responsibility for those working for health, especially of the poor and of the destitute sick. This investment may be long term and difficult—as in Kerala, India, for instance—but must be seen as integral to the struggle for health (Sanders 1985). Operationally, this commitment to human rights puts greater responsibility on advocates and investors in health to broaden the dialogue and scope for allocating resources and to avoid committing resources regardless of the prospect of success as influenced by the social and human rights context. In health and nutrition, as in other areas, adjustment of policies to support the success of interventions would be pragmatic as well as the right thing to do.

- Second, even if the context is more favorable, genuine political commitment is still essential. Excessive donor input may inhibit this commitment. It is striking that Thailand had to reject donor influence and make its internal decisions before its programs became successful (Tontisirin and Winichagoon 1999), Costa Rica had to fight and overcome a medicalized approach (Muñoz and Scrimshaw 1995), and Indonesia's *posyandu* system was undermined when treatment displaced prevention (Rohde 1993).
- Third, it is clear that severe economic stress, political pressure, or both have caused unsustainability (Indonesia, Nicaragua, Tanzania, and TINP).
- Fourth, if the context is unfavorable, it might be better to work on improving the context than to commit resources to programs that may not succeed—but, of course, success in improving context itself depends on circumstances, notably political commitment.

Considerations like these should contribute to identifying supporting policies needed for programs to be effective and modifications to interventions in particular conditions. For example, it is often observed that a particular factor—say, access to health services—is more strongly related to improvement among the better off (for example, the educated) population. This interaction of program with context leads to identifying new needs—in this example, perhaps facilitating access for the illiterate. In the longer run, resources or legislation (for example, to combat social exclusion or discrimination against women) may be highlighted as prerequisites before a program can be expected to work. Often failure to take account of context when trying to transfer experiences from a pilot trial (“scaling up”) may explain why efficacious interventions prove ineffective in a larger population.

This analysis of contextual circumstances indicates that targeting the poor may not always be cost-effective, and some interventions may not be feasible in certain contexts. An example is when the health infrastructure and services are almost nonexistent; under those conditions, it can be argued that

emergency treatment (especially for the diseases addressed by IMCI) should be established and reliable resources put in place first. A similar difficulty, often seen in food security, is that most interventions may not work for the poorest of the poor. For instance, supporting food (or cash crop) production in low-potential areas may not be realistic; nonagricultural employment may be better.

Thus, community-based programs work in a specific time and place: programs may start, work for a time, and then evolve or fade away. Even if they fade away, some useful effect may be achieved: sustainability need not be forever. At the same time, short project cycles (three years for many donors) can act against sustained programs. Some compromise in donor policies to allow assurance of continuity for reasonable periods (such as 10 years) could do a lot to increase the effectiveness of donor support to CHNPs.

The essence of time and place is not fully understood. Werner and Sanders (1997) give examples of favorable times, as when the old order is changing (for example, after internal conflict, as in Nicaragua and Zimbabwe) and when there is renewed vigor and some new organization is in place. Another generalization of a favorable context is when energy and interconnectedness exist in society. Thailand illustrates both: the Thais needed to change the approach, moving away from donor influence, in order to initiate the successful community programs that helped transform health and nutrition throughout the country, and that worked in part because of cohesive features of Thai society (Tontisirin and Winichagoon 1999).

In these examples, programs that continued on a large scale—either until the problem was largely resolved, as in Costa Rica, Jamaica, and Thailand, or as it was expanding, as in BRAC in Bangladesh or AIN-C (Atención Integral a la Niñez Comunitaria) in Honduras—clearly had supportive context, but their specific common features (and hence how they could be replicated) are elusive. Perhaps one crucial condition for success is that circumstances are such that people and communities begin to have the sense that they can take responsibility for—and control of—their health and quality of life. Responsibility comes with the emancipation of societies from colonial or other repressive conditions and possibly when grassroots attention becomes widespread, as it did in Bangladesh through an NGO that identified with the people. Evidence is growing that, among the poor in the United States, this sense of control is directly related to better health and reduced exposure to HIV and AIDS; Sampson, Raudenbusch, and Earls (1997) call the concept *collective efficacy*. Cohen and others (2000) show that health conditions improve when communities themselves fix up their environment—the “broken windows” theory. Such ideas may equally apply to poor communities, especially urban ones, in developing countries too.

RESULTS

Indicators of progress in implementation—*process indicators*—referring to coverage, intensity, and so on, are shown in table 56.3. As discussed earlier, most programs expanded population coverage without much targeting. But usually the level of resource application (intensity) was on the low side. More research is needed on the contribution of CHNPs to health process indicators, such as immunization coverage rates, as well as to nonhealth activities, for instance, in agriculture and community development.

Impact evaluation, which refers to the net effects of interventions on changing health outcomes, is sorely lacking. The efficacy of most of the component parts of CHNPs, when resources are adequate and the problems are correctly identified, is established, but in routinely administered large-scale programs, the changes in outcome that can be ascribed to program actions are less known. Although controlled trials by definition are not applicable, plausible evidence can be obtained by careful attention to research design, measurement, and analysis (Habicht, Victora, and Vaughan 1999). Some form of “with and without” and “before and after” comparisons is needed; for instance, such methods as staggered implementation, natural experiments, and selection of comparison groups with some statistical control can yield valuable information now lacking and should be more widely attempted. In this context, it should be noted that because of the timing and level of effort necessary for the evaluation, the impact evaluation results (changes in outcome ascribed to the program) may be more important for policy decisions on *future* programs than for the program that has been evaluated. Moreover, not all programs require detailed evaluation. Thus, financial support for such policy-relevant evaluations may come from budgets other than that of the program to be evaluated. The evaluations should also be prospective as far as possible, so decisions on evaluation design and finance are needed earlier rather than later.

Impact

For the examples used here, inferences were drawn from piecing together results either from ad hoc surveys or from program and administrative data; occasionally such inferences were made from the comparison of baseline estimates with midterm or final assessments, but the comparison groups, if any, were imperfectly matched. Thus, the conclusions on impact now put forward are tentative and based on judgments from available information. Some of these conclusions were drawn from trend assessments, details for which are in Mason (2000, annex 5).

The most widely available indicators are mortality rates (infant, child, and to a lesser extent, maternal; reliable data on

age zero and cause-specific mortality rates are not usually available from most developing countries); prevalences of underweight in children from national surveys (often supported by demographic and health surveys or UNICEF Multi-Indicator Cluster Surveys); and indicators of health services (notably immunization coverage rates). Estimates of morbidity, even of the common diseases (such as diarrhea and ARI), are not available systematically enough to judge trends in relation to programs. Child underweight (or stunting) has a particular value, because it measures an attribute of all children (age and weight or height), rather than assessing a relatively rare event, as in mortality estimates. Moreover, experience is well established of how underweight prevalences behave as a robust indicator, having a useful degree of responsiveness but not being subject to wide fluctuations with transient events.

Under controlled conditions, improving health and nutrition allows rapid catch-up in bodyweight and fast rates of reduction in underweight prevalence (for example, Pinstrup-Andersen and others 1993, 405). But in the real-world conditions of CHNPs, the expected rate is slower. As examples, Thailand maintained a reduction in underweight of about 2.9 ppts per year in the 1980s (see figure 56.1); the 22 projects reviewed as reported by Jonsson (1997) ranged between about 1 and 3 ppts per year. A reduction rate of -2 ppts per year, suggested earlier as an expectation from successful programs, would lead to very significant improvement if achieved at national levels: for South Asia, it would mean going from a prevalence of underweight of about 60 percent in 1980 to 20 percent in 2000; for Africa, from 30 percent in 1990 to 10 percent in 2000.

Detecting this rate can be difficult with the noise of sampling and nonsampling errors and with the common seasonal changes, which can amount to 5 ppts fluctuations or more, certainly in Africa. The potential program-ascribed trend needs to be separated from the underlying secular trend for the country, roughly 0.5 ppts per year (from 1985 to 1995; ACC/SCN 1996). Clearly the longer the program and the observing periods, the easier it is to assess trends.

Where the data are detailed enough, an initial rapid fall is seen in severe malnutrition—and probably in mortality,—followed by a slower fall in mild to moderate malnutrition. The reasons for the initial rapid fall are presumed to be immediate effects of improved health care, immunization, and the use of oral rehydration therapy. The outcomes estimated for the programs considered here concentrate on the sustained trend—after a year or two of implementation—as summarized in table 56.5.

In Zimbabwe, from 1980 to 1988, the infant mortality rate (IMR) fell from 110 to 53 per 1,000 live births, and severe malnutrition fell from 17.7 to 1.3 percent. However, stunting fell only in 1982–88, from 35.6 to 29 percent (1.1 ppts per year). Tanzania shows a similar effect in Iringa, with severe and moderate malnutrition falling much faster for the first two years.

Interestingly, the Child Survival and Development Projects (supported by the World Bank, among others), which covered a much larger population (but with less intensity than in Iringa), appeared to show almost the same pattern as in Iringa: a rapid initial fall (as much as 8 ppts per year, for one to two years), continuing at 1 to 2 ppts per year.

In Costa Rica, the child mortality rate plummeted in the late 1960s, well before stunting fell in the 1970s (Saenz 1995, 129; Vargas 1995, 111). A lag was seen in Thailand, where the child mortality rate started to fall rapidly in 1977, and both severe and moderate malnutrition appeared to start their fall in 1983–84. Both these improvements preceded the major growth in gross national product, which began in 1987 (Kachondam, Winichagoon, and Tontisirin 1992, tables 8 and 33). In analyzing Indian experience, where the IMR has fallen faster than child malnutrition, Measham and Chatterjee (1999) suggest that further improvements in child survival may be constrained by the high rates of child malnutrition.

The sustained effects are generally of about an additional 1 ppt per year improvement (table 56.5). For Bangladesh (the BINP), Tanzania, and Thailand, it is possible to distinguish the sustained rate from the initial rapid fall. In Bangladesh, the BINP started during a period of rapid improvement overall, so extracting the underlying trend is especially important to give a plausible view of the “with-project” rate: about 1.6 ppts per year again seems a reasonable estimate. A similar extraction of likely with-project changes allowing for underlying trends was reported previously (Mason 2000, annex 5) for Tamil Nadu, Andhra Pradesh (ICDS), and Orissa, indicating plausible improvements for the first two states.

In sum, these results support the contention that after an initial rapid fall, the sustained rates of improvement in child underweight prevalence settle down to about an additional reduction of 1 or 2 ppts per year. This conclusion is the same as previously reached (Gillespie and Mason 1991), now supported by some new results.

Cost-Effectiveness

Therefore, if we use prevalences of underweight children as the basis for calculation, US\$10 per child per year gives a reduction of 2 ppts per year. If we are to translate this cost into an implied effect on health and survival, underweight must be related to the measure of disease burden, DALYs lost. Then the resources needed per DALY saved—dollars per DALY—can be estimated. A 32.5 percent reduction in the loss of DALYs is associated with eliminating general plus micronutrient malnutrition as both direct effects and risk factors (see table 56.1, discussed earlier); as a first approximation, the average prevalence for developing countries of 30 percent underweight can be applied. We can calculate the associated DALYs gained from reducing malnutrition at this rate (and assume that loss of DALYs from *all*

Table 56.5 Outcomes and Resources in Selected Programs

Country	Outcomes	Resources
<i>Africa</i>		
Tanzania: Iringa	Underweight: 50 to 35 percent (1984–88) Immunization: 50 to 90 percent Rates in underweight: initial 2 years, –8 ppts/year; first 4 years, –4.5 ppts/year; sustained (years 2–7), –0.8 ppts/year	US\$8 to US\$17/person/year (US\$34/child/year from total costs); 2 village health workers/village = 1,220 total; Approximately 1:40 children
Tanzania: Child Survival and Development Program	Underweight reduction rates similar to Iringa	US\$2 to US\$3/child/year
Zimbabwe: Supplementary Feeding Programme	Stunting: 35.6 to 29 percent (1982–88) –1.1 ppts/year IMR: 1980–88: 110 to 53	External funds, approximately US\$0.50/child/year
<i>Asia</i>		
Bangladesh: BINP	BINP, first 6 <i>thanas</i> , initial effect (1997): approximately –11 ppts/year; then (to February 1999) approximately –1.6 ppts/year additional Underlying (nonprogram) trend: national approximately –1.7 ppts/year, program area approximately –2.4 ppts/year	1 community worker per 1,000 population; Approximately 1:200 children; US\$14 million/year, approximately US\$18/child/year
Bangladesh: BRAC	No program-specific data, but child underweight and anemia in women have substantial falling trend in recent years.	Over all programs, US\$196 million in 2003 (approximately US\$8/household over all households); health program covered 31 million people, over 20 percent
India: ICDS	Overall underweight prevalence declining only slowly; some states reported faster, but link to ICDS not shown.	1 supervisor to 20 ANWs
India: TINP	1979–90: –1.4 ppts/year in TINP districts; –0.7 in non-TINP districts: increased improvement of approximately –0.7 ppts/year (Reddy and others 1992, 45). From other data, increased improvement of –1.0 ppts/year.	US\$7–12/child/year
Indonesia	Probably about –1 ppt/year; underlying trend unknown IMR: 1970, 1980, 1990: 118, 93, 61, respectively	US\$2 to US\$11/child/year, depending on supplementary food. Rohde (1993) gives < US\$1 recurrent. Village workers (about 3 million total) 1:60 people; approximately 1:10 children; supervision 1:200
Philippines: national	No change found in underweight. IMR: 1960, 1996: 77, 32, respectively	Low coverage and intensity
Thailand	Approximately –2.9 ppts/year improvement in child underweight. Breaks down to 1982–84: –7.8 ppts/year; 1985–90, –1.9 ppts/year. IMR: 1970, 1980, 1990: 73, 55, 27, respectively	Ministry of Public Health, approximately US\$11/head/year (1990) Village health communicator or volunteer approximately 1:20 children; supervision by extension workers: village health communicators and volunteers approximately 1:24
<i>Americas</i>		
Costa Rica	Stunting improved by approximately 1–1.5 ppts/year (estimated from Muñoz and Scrimshaw 1995, 111), 1979–89. Source: See sources for table 56.2.

malnutrition comes down at this rate; CHNPs include some attention to micronutrients). This reduction is then cumulated through time (five years here) and assumes a linear relation between cost, underweight reduction, and disease burden avoided. The calculation also assumes a persistent effect of reducing malnutrition.

Using these assumptions gives an estimate of US\$200 to US\$250 per DALY saved in sustained programs. This estimate does not include gains in DALYs from diseases that do not show up as underweight, which must be substantial. Moreover, if this calculation is applied just to the first rapid fall, typically (in the three cases examined) about 8 ppts per year, the ratio might fall by a factor of four, to US\$50 to US\$60 per DALY saved (but start-up costs are higher too). The sustained figure should be the more generalizable.

Many further provisos exist. Much of the effect here is on a risk factor—malnutrition—reducing which, in turn, makes other interventions more effective; hence, the comparison of CHNPs with more direct interventions may not be valid. But conversely (or perversely) improving nutrition could actually reduce the cost-effectiveness of other interventions—such as measles immunization—by reducing the mortality risk of children who are not immunized.

FUTURE APPLICATIONS

The experience so far in CHNPs can be applied more broadly, especially where community organizations can sustain support for CHNWs. CHNPs have worked best so far in Asia and Latin America. However, with the HIV/AIDS epidemic in Sub-Saharan Africa needing high-priority attention, application of CHNP experience to the HIV/AIDS crisis should be explored.

Extending CHNPs' Coverage and Intensity

In a project sponsored by the Asian Development Bank (ADB) and UNICEF that was aimed at identifying ways of investing in improved child nutrition, Mason and others (1999, 2001) have reviewed the extent of CHNPs in Asian countries. Resources were estimated in terms of annual expenditures per child and of ratios of population to community workers (“mobilizers”). The project addressed the needs of eight countries (Bangladesh, Cambodia, China, India, Pakistan, the Philippines, Sri Lanka, and Vietnam), and previous experience in Indonesia and Thailand provided additional guidance.

The population coverage of CHNPs was estimated as about 5 to 20 percent, except for India with the ICDS, which reports about 70 percent coverage. The next indicators refer to estimates *within* programs. The calculated intensity was commonly 200 children to 1 community worker (for example, Bangladesh, India, Sri Lanka); ratios of up to 100:1 were reported in Pakistan

and Vietnam and up to 60:1 in the Philippines. Further research has stressed the variation in time commitment of CHNWs in different places—hence the need to convert to FTEs. The ratio used as the norm, derived from experience in Thailand and Indonesia, of about 1:20 is probably equivalent to 1:200 in FTEs. In India, opinion has been that about a doubling of the ANW numbers in the ratios is needed to get more effect (Measham and Chatterjee 1999). From this perspective, these estimates indicate that both coverage and intensity are low, although intensity may be half that needed, whereas coverage (except in India) is far too small. Supervision ratios are estimated as about 1:20 and higher. Expanding the numbers of CHNWs also means increasing the number of supervisors (usually from the health system), with associated costs.

Calculations from scarce financial resource data show that most government programs cost about US\$1 per participant child per year or less, whereas Bangladesh (BINP, with donor support and in line with other donor-supported programs) reached costs of US\$15 to US\$20 per child per year. By this calculation, too, the resources per head, as well as the coverage, were in most cases too low for widespread effect.

The estimates of coverage and intensity can be combined to calculate the extent of current programs in relation to that needed for full coverage at adequate intensity. The results based on a 1:20 ratio of CHNW to children suggest that less than 1 percent of the need was currently available; at 1:200 (which would cost more, because the CHNW would work full time) perhaps 10 percent of the need would be covered. Either way, a massive expansion would be called for if CHNPs were to be used as a means for widely improving health (but still calling for only about 20 percent of the public budget for health).

Expansion requires major resources, and not only financial ones. Thailand trained 1 percent of the population as community health workers (part time) and established an extensive supervision and support structure, including retraining. The estimates for the ADB-UNICEF project in financial terms were, for Bangladesh, Cambodia, Pakistan, Sri Lanka, and Vietnam, some US\$190 million to US\$280 million per year for improvement of underweight by an additional 1.5 ppts per year (Mason and others 2001, 64–68).

The Potential Role of CHNPs in Combating HIV and AIDS in Sub-Saharan Africa

Controlling the epidemic of HIV and AIDS in Sub-Saharan Africa will take an unprecedented effort. As antiretroviral therapy becomes available there will be new opportunities to turn the tide. Supply of antiretroviral therapy drugs, although essential and the cutting edge of new programs, is only part of the need. Food and income support, care for children (orphans and others affected), counseling, support to promote and sustain behavior change, and rehabilitation of people and

communities are needed (see chapter 18). Many of these activities have precedents in the types of CHNPs run by community health workers that are discussed here. What lessons are transferable?

One concern is that CHNPs have a greater history of success in developing countries *outside* Africa. Those within Africa seem to have been sustained for limited periods, often linked to donor interests. Reasons may have to do with lower levels of administrative infrastructure, different existing community organization, and varying political commitment (see table 56.4). These factors may now be weakened as the AIDS epidemic reduces the numbers of qualified people and undermines community organizations. It will be urgent to work on such contextual factors to create conditions in which community organizations can be refurbished and built on.

Community organizations can work in Africa, as elsewhere, when they have a real function with activities perceived as useful to pursue and some resources (including mobilizing their own) to use. Some transferable lessons are that such local organizations are crucial; that in regard to supervision and access to certain resources, they need to work with the government structure—often through health system employees; and that they need sustained resource support, much of which must come from donors.

Treatment and rehabilitation of people with AIDS will be home based in most cases and will depend substantially on community support. Nutrition is an important component; improved food intake is likely to enhance the effect of antiretroviral therapy, and when treatment progresses, nutrition will help get sick people back on their feet and returned to a productive life. A village health worker could play a key role in this process. In much of Africa, HIV and AIDS affect many communities, and in southern Africa, where HIV prevalences reach 30 to 40 percent, almost all communities have chronically sick adults. This fact means that most communities need programs: the problem is not highly concentrated. On the positive side, the more developed and accessible communities are those most affected by AIDS (Mason and others forthcoming; UNICEF 2004), where establishing programs may be easier. HIV and AIDS are affecting children both directly, as pediatric AIDS, and indirectly, through the impoverishment and destitution of affected households. This effect is seen in worsening child malnutrition. Here, too, support through CHNPs could play a useful role.

The characteristics of CHNPs elsewhere—in terms of intensity, training, supervision, and so forth—may provide some guidance for establishing or extending them in Africa. Mechanisms for identifying, supporting, and training village or community health workers in this context can draw on experience with CHNPs; such issues as their identification in the community and links with community and facility programs will arise. A key issue will be the remuneration and incentives

for community workers, and this issue may need some research and testing of different approaches. The activities of community workers in dealing with treatment (and prevention) of HIV and AIDS have parallels to malnutrition and would probably include the following items:

- social support and facilitating access to resources (possibly including food aid)
- counseling
- treatment and referral for opportunistic infections
- promoting rehabilitation to productive life (which may benefit from improved nutrition) as antiretroviral therapy progresses.

Schools too have an extremely important role in the fight against HIV and AIDS and should be linked to, or part of, CHNPs. Schools provide a refuge and a means of providing help for orphans and vulnerable children, and they also provide a crucial opportunity for preempting and combating high-risk behavior.

RESEARCH NEEDS

The question of incentives, training, and support for community workers urgently needs research, both from current experience and with prospective designs. The issues include the following:

- What is the CHNW's status, relative to the community or to the government (or NGO) hierarchy?
- How are CHNWs selected and to whom do they report (for example, community health committees, supervisors employed in the health or other system)?
- What educational background and how much training and retraining—and by what methods—are needed for CHNWs?
- What ratios of CHNWs to households are effective (or most cost-effective), both as part-time workers (volunteer or otherwise) and as full-time employees?
- What supervision ratios work?
- What remuneration and incentives are effective?
- How can these efforts be financed?

Enough programs have been in operation for long enough that researchers could base on them much of the needed research on processes of implementation, launching new trials only for processes for which sufficient information does not exist. In contrast, impact evaluation requires new and preferably prospective studies.

A major gap in research is the application of community-based programs to urban areas. Urban communities are

conceived differently from the rural areas of most CHNPs, organizations run along different lines, and so forth. Yet population growth is in urban areas, and some problems, notably HIV and AIDS, are worse there.

Finally, the cost-effectiveness analysis results given in an earlier section are based on rather few and approximate results. CHNPs may well provide a viable and cost-effective approach under many circumstances in poor countries, and it may be necessary to demonstrate this viability better and more quantitatively for support to CHNPs to compete with more traditional service delivery interventions. That, too, would constitute worthwhile research.

NOTES

1. Social exclusion refers to the exclusion of groups from the mainstream of public actions: lower castes in India, poorer groups in Pakistan, many indigenous ethnic groups throughout Asia and the Americas, and migrant workers in China and elsewhere; the result for public health is that excluded people do not participate in programs even if they are available.

2. Pinstруп-Andersen and others (1993) provide a more complete list.

Chapter 57

Contraception

Ruth Levine, Ana Langer, Nancy Birdsall, Gaverick Matheny, Merrick Wright, and Angela Bayer

The use of modern contraception to prevent pregnancies is a unique health intervention because, in many ways, it is not a health intervention at all. In general, couples in sexual relationships use contraception because, at the time the decision is made, one or both members do not wish to conceive a child, rather than because they wish to become healthier or to prevent a risk to health. Governments also may have an interest in promoting particular patterns of childbearing to meet social and economic objectives. This is most often the case when rapid population growth is seen as a drag on economic growth; in contrast, however, governments in low-fertility countries may promote pro-natalist policies to increase the labor supply. Thus, the effectiveness of contraception has to be seen, first and foremost, in terms of the effectiveness in permitting couples to achieve their desired family size.

Although contraception is rarely used to improve health, it does have health consequences. On the negative side, consequences may include the potential health risks of hormonal contraception or surgery. On the positive side, health may benefit from fewer pregnancies, lower exposure to sexually transmitted infections (STIs), and protection against ovarian cancer through the use of some types of contraception. Some of the consequences affect the users, some affect their sexual partners, and some affect their children. Contraceptives affect a user's sexuality by changing menstrual patterns and, therefore, particularly in some cultures, sexual activity. Also, by eliminating fear of unwanted pregnancy, contraceptives may enhance the quality of sexual experience. Finally, condoms may decrease sexual pleasure for men; true or not, this explanation is one of the most commonly cited to account for why some men (or couples) do not use condoms.

NATURE, CAUSES, AND BURDEN OF THE CONDITIONS THAT CAN BE ADDRESSED

Three rationales—each one involving controversy and touching on deeply held political and cultural perspectives—have underlain policy and programmatic interest in contraception, since the 1960s.

- The *demographic rationale*, typically framed around lowering the rate of population growth to achieve broad economic, social, and environmental aims, was most prominently applied in the 1960s and 1970s.
- The *fertility rationale*, which emerged in the 1980s, promoted lower fertility under the assumption that smaller families are better off in terms of economic and health conditions.
- The *human rights rationale*, which surfaced in 1994 at the International Conference on Population and Development in Cairo, served as a major force in the 1990s to focus attention on women's rights to autonomy and empowerment in childbearing and on female and male reproductive health. The Cairo Programme of Action stressed the political and cultural dimensions of contraception, including gender issues.

Population Growth and Fertility

In part because of the demand for and availability of modern contraception, the worldwide rate of annual population growth has declined from just over 2 percent in the late 1960s to 1.5 percent during 1980–2001. It is projected to decrease to 1 percent during 2001–15. Although the growth rate has

slowed, population growth in absolute terms is unprecedented. World population increased from 2.5 billion people in 1950 to 6.3 billion in 2003 and is expected to rise to 7.1 billion by 2015 (UN 2003; World Bank 2003).

Fertility rates in developing countries have declined rapidly in the past 50 years, from more than 6.0 children per woman in the 1950s to about 2.8 children per woman today. Fertility rates remain high, however, in the 49 least developed countries, which had an average total fertility rate of 5.46 children per woman during 1995–2000 (UN 2003).

Fertility levels and trends vary greatly between regions. Fertility rates are lowest in low- and middle-income countries in East Asia and the Pacific, at 2.1 children per woman. Countries in Central Asia and Latin America and the Caribbean also have relatively low total fertility rates, at 2.5 and 2.6 children per woman, respectively. The Middle East and North Africa and South Asia follow, with average total fertility rates of 3.4 and 3.3 children per woman in 2001, respectively. Fertility rates are highest in Sub-Saharan Africa, at 5.2 children per woman (World Bank 2003).¹ Regional averages conceal substantial variation among and within countries.

Because of a legacy of high fertility and corresponding young population structures, population momentum ensures that many developing countries will continue to grow at a relatively high rate for many decades, even as fertility rates continue to decline. Population momentum alone will account for almost three-fourths of the population growth in developing countries in the next quarter-century. The largest growth at present is in Asia and Sub-Saharan Africa. Total population increase in these regions is now twice what it was in 1950. By 2015, population growth is expected to be substantially lower in all regions except Sub-Saharan Africa.

Demand for Contraception

If a woman wishes to postpone or avoid childbearing and is not using contraception (including use by her partners), she is said to have an unmet need for contraception. The most commonly reported reasons for unmet need are lack of knowledge, health concerns, and social disapproval (Casterline and Sinding 2000).

In 2003, an estimated 122.7 million women in developing countries had an unmet need for contraception, including 105.2 million married women, 8.4 million unmarried women, and 9.1 million women of all marital status in the states of the former Soviet Union. This figure represents 17 percent of all married women, a 2 percent decline from the late 1990s that is due to increasing contraceptive use.

Overall, the highest unmet need is in Sub-Saharan Africa, where 19.4 percent of all women have unmet need. About 13 percent of women in Asia, 10.6 percent of women in North Africa and the Middle East, and 8.5 percent of women in Latin

America and the Caribbean and Central Asia have unmet need for contraception. Whereas women in the other regions of the world have an equally distributed unmet need for spacing and limiting births, the majority of unmet need in Sub-Saharan Africa is for spacing (Ross and Winfrey 2002). Unmet need is highest in countries where growing numbers of women want to avoid pregnancy but contraceptive prevalence is low. So, for example, among developing countries for which data are available from USAID's Demographic and Health Surveys, unmet need is currently highest in Haiti, where it nears 40 percent of all married women; it is more than 30 percent in Cambodia, Nepal, Pakistan, Rwanda, Senegal, Togo, Uganda, and the Republic of Yemen; and it is lowest, at less than 7 percent, in Brazil, Colombia, and Vietnam.

Total Potential Demand for Contraception. A rough measure of the total potential use of modern contraception in a country can be estimated by combining the measure of unmet need with the current proportion of women using contraception. Brazil, Colombia, and Vietnam all have demand for contraception greater than 80 percent of currently married women. They have satisfied most of this demand, with contraceptive prevalence rates above 75 percent, resulting in both low fertility rates and low unmet need (Westoff 2001). In contrast, in most Sub-Saharan African countries, the unmet need percentage exceeds the percentage of women currently using contraception (see table 57.1).

Health Consequences

Excess fertility is responsible for between 12 and 30 percent of the maternal burden of disease (see table 57.2)², although this is clearly an underestimate of the present and future burden of disease that can be prevented through investments in family planning. These estimates include only the direct health benefits of family planning for women by preventing unwanted births, decreasing the number of abortions, and increasing the length of birth intervals. Because of data limitations, these estimates exclude the potential effect of family-planning programs on children's long-term nutritional status and education; women's status and the household economy; and public savings from reduced fertility, AIDS, and other STIs through condom promotion and prevention of mother-to-child transmission (PMTCT). They also exclude the effect of such programs on environmentally related disease owing to population growth. Last, the estimates do not consider the disabling effects of unwanted pregnancies, despite the effect those pregnancies or their termination under unsafe conditions can have on women's welfare and productivity.

Each year, 585,000 women die and more than 54 million women suffer from diseases or complications caused by pregnancy and childbirth (WHO 1997).

Table 57.1 Total Potential Demand for Family Planning
(percentage of currently married women)

Country	Unmet need	Current contraceptive use	Total potential demand	Country	Unmet need	Current contraceptive use	Total potential demand

Risks Associated with Unwanted Pregnancies. Unwanted pregnancies expose women to additional health risks by increasing the number of lifetime pregnancies and deliveries. Because the lifetime risk of maternal mortality is a function of the number of pregnancies and the quality and utilization of health care, reducing the number of pregnancies can lower maternal mortality rates (Koenig and others 1988).

Ambivalence toward pregnancy also is associated with less early and continuous prenatal care and lower use of professional delivery care (Gage 1998; Joyce and Grossman 1990; Weller, Eberstein, and Bailey 1987).

Many women who have unintended pregnancies turn to induced abortion, both in countries where abortion is legal and safe and in those where it is illegal and too often unsafe.

Table 57.2 Maternal Burden of Disease Associated with Unwanted Fertility and Unsafe Abortions

Region	Deaths	Years of life lost	Years lived with disability	Disability-adjusted life years (DALYs)	Percentage of all maternal DALYs
East Asia and the Pacific	3,637	107,795	380,255	420,030	17
Latin America and the Caribbean	6,323	190,544	298,390	429,399	30
Middle East and North Africa	8,428	244,461	256,742	395,368	12
South Asia	30,074	878,028	1,079,661	1,669,727	20
Sub-Saharan Africa	43,077	1,270,598	764,012	1,821,721	18

Sources: Adapted from WHO 2002a. Maternal mortality related to unsafe abortions from WHO 1998. Percentage of infant disease preventable by family planning from Rutstein 2003.

Notes: Because of data limitations, estimates are not available for Eastern Europe and Central Asia. Burden-of-disease estimates include a 3 percent discount rate without age weighting. WHO regions are not identical to the World Bank Regions used here; however, a very close approximation was made by excluding WHO regions AMRO A, WPRO A, and EURO A. These estimates assume that 90 percent of abortion-related disease burden is preventable by family planning and that the percentage of other preventable maternal disease is equal to the percentage of all births that are unwanted.

Accurate measures of abortion are difficult to obtain in most parts of the world. In countries where abortion is illegal, data are lacking or incomplete, and even where it is legal, abortions may be underreported because of societal attitudes (Bongaarts 1997; Henshaw, Singh, and Haas 1999). It is estimated that about one-fourth of the 210 million pregnancies each year end in abortion.

In 1995, approximately 35.5 million abortions were performed in developing countries. The large majority of legal abortions, 10.6 million, occurred in China. Most of the remaining legal abortions took place in other parts of Asia (5.7 million) and in the Caribbean (0.2 million). Developing countries, which experienced an estimated 19 million illegal abortions in 1995, account for 95 percent of illegal abortions worldwide. Nearly 10 million illegal abortions occurred in Asia, followed by an estimated 5 million in Africa and 4 million in Latin America. These figures mark a particularly large increase for Africa, which was estimated to have only 1.5 million illegal abortions in 1987 (Henshaw, Singh, and Haas 1999).

Unsafe abortion, typically associated with illegality, has large impacts on both maternal mortality and maternal morbidity. Each year, unsafe abortion is believed to account for 80,000 maternal deaths, or 13 percent of the burden of disease in women of reproductive age (WHO 2002a). Deaths related to unsafe abortions are estimated at 100 to 600 death per 100,000 abortions, compared with the mortality rate from legal abortions of 0.6 deaths per 100,000 abortions (Salter, Johnston, and Hengen 1997). Survivors of unsafe abortions also experience consequences; unsafe abortion causes disability in an additional 5 million women (WHO 2002a). Treatment of complications from unsafe abortions constitutes a large proportion of emergency gynecological hospital admissions (Konje, Obisesan, and Ladipo 1992) and requires substantial resources (Kinoti and others 1995; Salter, Johnston, and Hengen 1997).

Legalizing abortion, improving the quality of abortion care, and increasing access to safe abortion can have profound impacts on the health consequences of abortion. When abortion was illegal in Romania in 1988, complications from unsafe abortion caused 86 percent of maternal deaths. After abortion was legalized in 1989, the frequency of abortion persisted because of contraceptive supply shortages, but the number of maternal deaths fell by 50 percent (Hord and others 1991).

Risks Associated with Pregnancy and Birth. All pregnancies and births involve some health risks to women, so preventing any pregnancy reduces women's health risks. Higher mortality and morbidity of women, infants, and children are positively associated with the risk factors of giving birth when a woman is too young or too old, the births are too close together, there are too many births, or a woman has a preexisting health condition. Births in most of these groups—women who are older (over age 35), births that are spaced too closely (24 months or less after the preceding birth), and births that are higher order (fifth or higher)—are also more likely to be reported as unintended, making their prevention doubly important (Tsui, Wasserheit, and Haaga 1997).

An estimated 15 million women under age 20 give birth each year. Women age 15 to 19 are twice as likely to die from childbearing as women in their 20s, and women under age 17 are at even greater risk (Starrs 1997). Adolescent mothers are more likely to suffer from obstetric complications if they lack physical maturity or are malnourished (Aitken and Walls 1986). They are also less likely to receive adequate prenatal or obstetric care, which may cause negative outcomes for them and for their infants (McDevitt and others 1996). In many contexts, negative social consequences are profound, including loss of school and employment opportunities.

Children born to adolescent mothers face a number of risks. Research has demonstrated that infants of teenage mothers are

more likely than those born to mothers in their 20s to die before they reach their first birthday (Hobcraft 1992; McDevitt and others 1996; Ross and Frankenberg 1993; Starrs 1997; Sullivan, Rutstein, and Bicego 1994). Children of mothers under age 20 may have a 20 to 30 percent higher risk of death than children of older mothers (Hobcraft 1992; Sullivan, Rutstein, and Bicego 1994). Infants of teenage mothers are also at higher risk of being of low birthweight, small for gestational age, or premature. Finally, adolescent women are less likely to provide adequate care for their infants and children, because they often lack the maturity, education, and resources to do so (Geronimus 1987; Govindasamy and others 1993).

Women over age 35 face an increased risk of maternal mortality. Mothers age 40 to 44, for example, are five times more likely to die during pregnancy or childbirth than mothers in their 20s (Royston and Lopez 1987). Mothers in their late 30s and 40s may also face additional negative consequences, because they may have preexisting health problems owing to age or previous births.

As with children of adolescent mothers, children of women over age 35 also suffer negative consequences. Children born to mothers over age 40 are more likely than those born to younger mothers to die before age 5 (Bicego and Ahad 1996; Sullivan, Rutstein, and Bicego 1994). Older women are also more likely to have stillbirths or to bear children with congenital abnormalities who may not survive childhood (Cnattingius and others 1992; Fretts and Usher 1997).

Longer birth intervals reduce women's risks of death and ill health during pregnancy and childbirth. One study assessed the effects of birth spacing in 450,000 women on the basis of hospital records from 1985 to 1997 in 19 Latin American and Caribbean countries. The study found that women who have their babies 27 to 32 months after a preceding birth are more than two times more likely to survive pregnancy and childbirth than women who have short intervals of 9 to 14 months. Birth intervals of 27 to 32 months are also associated with lower incidence of third trimester bleeding, premature rupture of membranes, anemia, and other negative outcomes (Conde-Agudelo and Belizan 2000).

Recent research suggests that birth intervals of three to five years provide even greater benefits than the two-year intervals that were previously promoted. One study assessed the effect of this longer birth interval in more than 430,000 pregnancies in 18 countries and found that children who are born three to five years after the preceding birth are more likely to survive from the perinatal period through age five. Children born at intervals of three to five years are also 1.2 to 1.4 times less likely to be malnourished or underweight or to experience stunting than those born at intervals shorter than two years (Rutstein 2003).

Putting together a range of patchy data on the effect of family planning on child mortality can yield estimates of the total global impact, but those estimates are highly dependent on

assumptions and have varied widely. The World Bank (1993) estimated that family-planning programs could prevent between 20 and 40 percent of all infant deaths by preventing mistimed and underspaced births. In a study of 25 countries, Hobcraft (1994) estimated that if all birth intervals of less than two years were prevented, child mortality levels would be reduced by an average of 17 percent and up to one-third in several countries. Rutstein (2003) found that birth spacing of three to five years alone could prevent up to 46 percent of infant mortality. Muhuri and Menken (1997) found that in rural Bangladesh poor spacing and timing accounted for 25 percent of child mortality. Trussell and Pebley (1984) estimated that spacing could decrease infant mortality by 10 percent and child (age 1 to 5) mortality by 21 percent. Another study found that, even in Latin America, which has lower child mortality rates, spacing could reduce perinatal mortality by 14 percent (Conde-Agudelo and Belizan 2000).

In a study of 19 African countries, Rafalimanana and Westoff (2001) found that median actual birth intervals in every country were shorter than the preferred birth intervals reported by women, reflecting the substantial unmet need for birth spacing. Achieving preferred intervals would decrease neonatal mortality by only 6 percent on average, and infant mortality by a comparable amount, whereas removing all short intervals would decrease both by 13 percent.

Women giving birth for the fourth or higher time are at much higher risk of maternal complications and death. Independent of a woman's age, her risk of dying when giving birth for the fourth or higher time is 1.5 to 3 times greater than during a second or third birth (Winikoff and Sullivan 1987). Women who have had at least three births are also more likely to experience hemorrhage, uterine rupture or prolapse, or kidney disease (Maymon and others 1998).

Children born to mothers who have had many births face risks similar to those of children born to older mothers; they are often the same women. Children born to mothers who have had three or more births are more likely than those born to younger mothers (those under age 20) to die before age 5 (Bicego and Ahad 1996; Sullivan, Rutstein, and Bicego 1994). Women who have had many births are also more likely to have stillbirths or to bear children with congenital abnormalities who may not survive childhood (Cnattingius and others 1992; Fretts and Usher 1997). Children from larger families often receive lower levels of education and health care than children from smaller families because of competition for finite family resources (Blake 1981).

Women with preexisting health conditions often face greater risks in pregnancy and childbirth. Pregnancy can aggravate conditions such as high blood pressure, heart disease, malaria, anemia, tuberculosis, hepatitis, and STIs, including HIV. Indirect causes, including these preexisting conditions, account for an estimated 20 percent of maternal deaths each year (WHO 1997).

INTERVENTIONS

The “intervention” of contraception can be considered as the method itself and as the means by which family-planning clients obtain services (including counseling) and contraceptive commodities. Both the methods and the types of services are diverse.

Contraceptive Methods

Contraceptive methods can be classified as permanent and long term—primarily for those women and couples who have completed childbearing—or temporary—primarily for those women and couples who wish to delay pregnancy.

Permanent and Long-Term Methods. Female sterilization, or tubal ligation, used by about 187 million women worldwide (WHO 2002a), is the most popular and effective contraceptive available. The most effective types of female sterilization have a 10-year cumulative pregnancy rate of 7.5 per 1,000 procedures (Peterson and others 1996).

Sterilization accounts for one-third of all contraceptive practice. Because sterilization is considered a permanent form of contraception, some women may regret their decision during ensuing years. Some dissatisfaction with sterilization is expected and is always observed among sterilized populations; in most cases, the proportion of women regretting sterilization falls below 10 percent. Regret is higher when sterilization was a woman’s first and only contraceptive method, when a woman was sterilized at or under age 30, or when a woman has fewer than four living children (Loaiza 1995).

Between 40 million and 50 million men worldwide have undergone a vasectomy, a figure representing 8 percent of the world’s couples of reproductive age. This method comes in fourth in contraceptive popularity, after female sterilization (19 percent), the intrauterine device (IUD; 13 percent), and oral contraceptives (“the pill”; 8 percent), and right ahead of the male condom (4 percent; WHO 2002a). The method is as effective as female sterilization (failure rate of less than 1 percent) and much simpler and safer than tubal ligation.

The IUD is now used by 150 million women worldwide, or about 13 percent of the world’s women of reproductive age, because of its efficacy, safety, and convenience. After female sterilization, it is the most popular method of contraception. The 5-year life span of the IUD means fewer visits to health providers and less expenditure of money, time, and effort.

IUDs prevent pregnancy through several mechanisms: they alter sperm migrations, inhibit fertilization, and generate a foreign-body reaction in the endometrium. Progestogen-releasing IUDs cause changes in the amount and viscosity of cervical fluid, altering sperm penetration. In a small percentage of women, ovulation is inhibited in the first two years of use.

Failure rates for all copper-bearing IUDs are usually less than 1 per 100 women in the first year of use.

Temporary Methods. By far the most popular temporary contraceptive method is the oral contraceptive, commonly known as “the pill,” which has a failure rate typical use of less than 10 percent over a year. Among 67 developing countries for which survey data are available (not including China or India), about 50 percent of married women who have ever used contraception have used the pill at some point. The pill has been most popular in Latin America; there, about 55 percent of all married women have used the pill. In the Near East and North Africa, about one-third of married women have used the pill, and in Sub-Saharan Africa, about 15 percent have used it at some time (Johns Hopkins Population Information Program 2000).

More than 20 million women use systemic contraceptives containing only progestins. These contraceptives include subdermal implants such as Norplant, injectable products, IUDs, and vaginal rings. These products have high rates of contraceptive efficacy (0.3 to 1.0 percent failure rate over 12 months). Their long duration of action allows for a relatively infrequent dose. Their main drawbacks are their tendencies to cause highly irregular endometrial bleeding and amenorrhea. Although altered bleeding does not have any ill health effects, it does pose a problem for women in societies that bar or restrict women from certain social and religious activities during menstruation. The World Health Organization estimates that between 10 and 30 percent of women abandon their progestin-only methods for this reason (WHO 2002a).

Barrier methods, although less effective than hormonal methods, IUDs, or sterilization, can offer effective contraception when used consistently and correctly. Barrier methods, and particularly condoms, are the only type of contraception that offers additional protection against STIs.

When used correctly during every act of sexual intercourse, the male latex condom is effective against both unwanted pregnancy and HIV infection and other STIs. Typical use results in pregnancy rates of 3 to 14 percent per year. If a condom breaks or tears during intercourse, emergency contraception can be used to reduce the risk of pregnancy.

The female condom, made of soft, pliable polyurethane and prelubricated with a silicone-based substance, is inserted into the vagina before sexual intercourse. The female condom is slightly less effective than the male condom, with a failure rate of 5 to 21 percent. Unlike the male condom, the female condom can be inserted up to eight hours before intercourse. The female condom adds to the arsenal of weapons in the fight against STIs; offers women more control in sexual negotiations; can be used in conjunction with the IUD, hormonal methods, and sterilization; and has no special storage requirements.

The diaphragm, although not a popular method in developing countries, is being studied as a means of preventing not

only pregnancy but also bacterial STIs. Results from those randomized trials are pending.

Emergency Contraception. Since the mid 1960s, the use of certain oral contraceptives has been shown to be effective in preventing pregnancy. Two hormonal regimens have proved to be both safe and effective for emergency contraception: combined oral contraceptives and progestogen-only pills. Both can be taken for up to 120 hours after unprotected intercourse. Emergency contraception represents a second chance to prevent an unwanted pregnancy after unprotected sex, and it is particularly responsive to the needs of youths and of women who have been coerced into intercourse.

Despite the demonstrated safety and efficacy of emergency contraception, its acceptance by providers and the public, and its inclusion on the WHO's essential drug list, emergency contraception is not widely available in many developing countries (Langer and others 1999).

ORGANIZATION OF FAMILY-PLANNING PROGRAMS

Because of the variety of users and methods of contraception, a range of quite distinct ways to deliver needed goods and services has been developed and tried over the past several decades. Some programs are dedicated to providing only family-planning services, often referred to as *vertical programs*; some provide a range of reproductive and other health services, loosely termed *integrated programs*; and some try to reach current and potential clients through social marketing and community-based distribution methods.

Vertical versus Integrated Service Delivery

The original large-scale family-planning programs in developing countries, many of which were launched on the basis of the demographic rationale, tended to be organized around a vertical structure with central management and logistics. Family-planning workers based at fixed sites—whether run by government agencies or by nongovernmental organizations (NGOs)—were dedicated exclusively to providing information, services, and contraceptive commodities related to family planning. Funding, often from external donor agencies, was earmarked for family-planning activities. In many instances, the supervisory, budgeting, training, and logistics systems were all separate from those of other health services. Some of the largest vertical programs, such as the India program, promoted sterilization on a large scale, sometimes provided through rudimentary health facilities. Others, such as the Bangladesh program, relied on the provision of information and commodities through female outreach workers going house to house.

In the past two decades, increasing emphasis has been placed on integrating family-planning programs into other

health services, particularly other types of reproductive health services. Under this arrangement, family-planning services are delivered in conjunction with routine primary care—a recognition that women's health needs are in no way confined to contraception and that a broad range of reproductive and other health services must be provided.

Social Marketing

Social marketing refers to a variety of strategies using traditional commercial-marketing techniques to promote socially beneficial behaviors, products, and services. In family planning, social marketing has focused on making supplies of methods of contraception widely available in existing commercial retail outlets and on promoting these contraceptives to consumers through mass media. In recent years, social-marketing programs have expanded their focus to behavior change and the delivery of clinical services through social franchises.

In countries with low contraceptive prevalence, social-marketing programs for contraceptives typically import donated contraceptives and then repackage and promote them with their own sales force. In higher-prevalence countries, programs may partner with commercial manufacturers to market existing brands, often subsidizing promotion in exchange for price guarantees. In the Dominican Republic, for instance, the oral contraceptive manufacturer Schering agreed to cut the price of its pills in half in exchange for advertising by a social-marketing organization.

Most social-marketing programs for contraceptives distribute commodities through existing commercial outlets, such as shops, pharmacies, and tobacco shops. Retailers make a small profit, which increases their incentive to stock and promote the products. Because such programs do not spend money building their own distribution network, they typically enjoy low costs per output.

Social-marketing programs have achieved dramatic contraceptive sales throughout the developing world, providing contraception to about 10 million couples in 60 countries, in addition to promoting a variety of other health products. However, evidence from cross-national studies suggests that social marketing's effect on contraceptive use is driven less by its brand sales—because users often switch brands—and more by its promotional activity (Bulatao 2002).

INTERVENTION COST AND COST-EFFECTIVENESS

Synthesizing data on family-planning costs, outputs, and outcomes to inform resource allocation has distinct challenges. First, nearly all existing studies have estimated average—not marginal—costs. The dearth of marginal cost data, general to most of the cost-effectiveness studies presented in this volume, severely weakens the ability to recommend interventions.

Second, cost data based on units of output that cannot be linked to health outcomes have limited use. Most studies on effectiveness have not included costs, and most studies on costs have not included effectiveness. In the family-planning literature, cost per output (such as the cost per couple-year of protection, or CYP) has often been called cost-effectiveness. Here, we reserve the term *cost-effectiveness* for measures of cost per unit of health impact (Gift, Haddix, and Corso 2003). Those studies that have measured cost-effectiveness typically come from mature programs, where both marginal costs and marginal effects are likely to be low.

Third, costs vary considerably according to the accounting method used, the program setting and scale, the level of latent demand among couples targeted, the method mix, the quality, and the existing supply and service infrastructure (Dayaratna and others 2000; Janowitz and Bratt 1992). Clinical costs are particularly sensitive to setting, given the broad differences in local salaries.

Finally, most evaluations of family planning estimate effects within a single generation. However, averting a birth also averts grandchildren, great-grandchildren, and so on. For economic cost-benefit analyses, the multigenerational effects of a single birth averted can be significant. However, this consideration can be addressed through the use of an appropriate discount rate.

Cost per Output

The most common measure of output in family-planning programs is the CYP. Stover and others (1996) estimated the number of contraceptives of various methods needed to provide 1 CYP, given typical use: 15 cycles of pills, 120 condoms, 120 foaming tablets, or 4 three-month or 12 one-month injectables. An IUD provides 3.5 CYPs; male and female sterilization, 11 CYPs; and an individual trained in natural methods, 2 CYPs.

IUDs and voluntary sterilization have the lowest cost per CYP, although they have a high up-front cost. Oral contraceptives are usually the least costly methods. Condoms and injectables are more expensive than the pill, and implants are often the most expensive method per CYP. Mauldin and Miller (1994) estimated that, based on the method mix in developing countries, the weighted average commodity cost of contraception was US\$1.55 per CYP.³

Commodity costs are relatively constant across programs, although there is some variation owing to bulk procurement. When program costs are added, costs vary considerably by the program setting and mode of delivery. A review of programs in Africa, for instance, found method costs per CYP could vary by an order of magnitude, with the greatest variation in the cost of condoms.

Barberis and Harvey (1997) found considerable variation in costs per CYP by region and mode of service delivery in 14

developing countries. Across regions, costs per CYP were comparable in Asia, Latin America, and the Middle East, at US\$4.00 to US\$5.00. Costs were considerably greater in Africa, where the average cost per CYP was US\$14.00.

The least expensive mode of service delivery was clinical provision of sterilization, with a weighted average cost of US\$2.34 per CYP. The second most economical mode was social marketing of contraceptives, although those costs are highly dependent on setting. In African countries, where such programs were less developed, the costs were high—up to US\$19.00 per CYP. The weighted average cost of social marketing of contraceptives was US\$3.00.

Costs of community-based distribution programs ranged from US\$4.85 to US\$35.37 per CYP, with a weighted average of US\$12.55. Costs of clinic-based services, excluding sterilization, ranged from US\$4.44 to US\$16.65 per CYP, with a weighted average of US\$7.93. Clinic-based services supplemented with community-based distribution were the most expensive mode of service delivery, ranging from US\$4.44 to US\$19.38, with a weighted average of US\$18.21. As noted above, these estimates have typically not included costs to users (see table 57.3).

Marginal Costs

Knowles and Wagman (1991) found that unit costs decline as the number of contraceptive users increases. Larger programs enjoy an economy of scale in procurement; average costs

Table 57.3 Weighted Average Program Costs per CYP, by Region and Mode of Delivery (2001 U.S. dollars)

Region	Mode of service delivery	Cost per CYP
Africa	Social marketing	15.95
	Community-based distribution	20.32
	Clinics	16.65
	Clinics with community-based distribution	8.02
Asia	Social marketing	2.59
	Community-based distribution	6.50
	Clinics	5.07
	Clinics with community-based distribution	19.38
Latin America	Social marketing	−1.64
	Community-based distribution	35.37
	Clinics	6.40
	Clinics with community-based distribution	6.47
Middle East	Social marketing	3.82
	Community-based distribution	4.85
	Clinics	4.44
	Clinics with community-based distribution	9.03

Source: Adapted from Barberis and Harvey 1997.

decrease as fixed costs from training and from information, education, and communication (IEC) programs are distributed over more units; labor may be more efficiently used at higher volumes; and larger programs may be further ahead on the learning curve. However, as marginal costs diminish with size, so may marginal returns in mature programs (Haaga and Tsui 1995).

High rates of underutilization suggest marginal costs may be close to zero for many clinics. Knowles and Wagman (1991) and Janowitz and others (1996) found underutilization of clinical capacity in Morocco and Bangladesh. In Morocco, more than a third of all labor costs were spent waiting for patients. Foreit and others (1992) found that administrative costs accounted for 16 to 65 percent of fixed costs for a sample of clinics, whereas capacity utilization ranged from only 32 to 76 percent.

One study of a community-based distribution project in Bangladesh found that marginal costs represented 20 to 40 percent of average costs and decreased with scale (Attanayake, Fauveau, and Chakraborty 1993). In social-marketing programs, marginal costs are close to commodity costs less revenue (Bulatao 1993). A weighted average of current commodity costs based on the existing method mix in developing countries suggests a marginal cost of about US\$1.55 per CYP (Mauldin and Miller 1994).

Cost-Effectiveness Outside of Programs

The estimates of cost-effectiveness included here show only the direct health benefits of family planning for women and children from increasing birth intervals and reducing teenage pregnancies. As noted earlier, these estimates ignore important benefits of family planning for the health of families. Because of data limitations, most of these omissions cannot be corrected here. Some are a general consequence of using the global burden-of-disease framework, which takes disease, rather than health interventions, as the starting point. This orientation makes results less useful for the purpose of setting priorities in health care, particularly for interventions, such as family planning, that affect a number of sequelae (Williams 1999).

Despite the abundance of cost-per-output data in family planning, these data cannot be used to set priorities in health funding because the protection offered by a unit of contraception is related to the behavior of a particular user. Several studies have sought to estimate a program's impact on fertility as a simple division of CYPs distributed in a population by the mean birth interval in the population (Cakir, Fabricant, and Kircalioglu 1996). However, such adjustments are not substitutes for actual measures of impact.

A considerable literature has developed around the problems of using CYP as a measure of protection (for reviews, see Fort 1996 and Shelton 1991). The typical calculation of CYPs does not account for use-failure rates, wastage, and client char-

acteristics such as fecundity, coital frequency, use effectiveness, or frequency of contraceptive use—one couple using condoms all the time has a greater effect on fertility than two couples using condoms half the time.

Most critically, even if CYP were an appropriate measure of protection, CYPs do not account for method substitution. Many clients who obtain contraceptives from a family-planning program, at some program expense, were buying or would otherwise have bought contraceptives from commercial providers or would have relied on natural methods. Community-based distribution programs, for instance, may be more expensive per CYP than social-marketing programs, but if such programs reach more nonusers than social-marketing programs, they may be more cost effective in preventing unwanted pregnancies. Similarly, sterilization is the cheapest method per CYP, but in many countries, it has a limited impact on fertility.

Three examples demonstrate the hazard of confusing output, or even intermediate outcomes, with impact. Jensen (1996) found that public providers in Indonesia, while more expensive per CYP than private providers, had a greater effect on fertility per unit output. Public programs may have reached more nonusers. Janowitz and others (1992) found that a Honduran social-marketing program distributed more than 40,000 CYPs but had no net effect on contraceptive prevalence. Users substituted one contraceptive brand or method for another. Bertrand and others (1986) found that a community-based distribution program in then Zaire increased modern contraceptive prevalence without affecting total contraceptive prevalence. Modern methods were substituted for traditional ones, such as prolonged lactation, periodic abstinence, or withdrawal. (Such substitution can be an improvement when the traditional method replaced is rhythm or withdrawal, but there is no more protective contraception than postpartum abstinence.)

Cost-effectiveness analysis thus requires true estimates of project effect—the difference between what happens in a project's presence and what happens in that project's absence. A number of studies have estimated effect, measuring births averted, total or unwanted pregnancies averted, unsafe abortions averted, maternal and child deaths averted, and measures of health utility, such as the disability-adjusted life year (DALY).

As table 57.4 shows, costs vary significantly within regions. In some regions, maximum and minimum costs differ by two orders of magnitude. Our sensitivity analysis found that the cost-effectiveness of programs was most sensitive (as a percentage of swing) to the existing level of unmet need for birth spacing and limiting.

Costs per Births Averted. In a review, Pritchett (1994) found that costs per birth averted ranged from US\$37 in Jamaica, the Philippines, and Thailand to US\$415 in Nepal, with the median value of 12 studies being US\$82. Cochrane (1988) estimated US\$78 per averted birth in a cross-national analysis.

Table 57.4 Average Costs per Benefit of Family Planning
(2001 U.S. dollars)

Region	Births averted	Infant deaths averted	Maternal deaths averted	Disability-adjusted life years saved	Years of life lost averted	Years lived with disability
East Asia and the Pacific	163	4,907	12,880	60	110	103
Latin America and the Caribbean	87	2,316	34,564	53	66	187
Middle East and North Africa	97	1,989	18,917	49	55	209
South Asia	113	1,577	5,172	30	37	98
Sub-Saharan Africa	131	1,367	10,231	34	37	194

Source: Authors, based on a model by AGI and others (2000).

Note: The model used country-level data for 68 developing countries. Output costs were based on Population Action International estimates in 1994 of the public sector cost per user. Estimates are not available for Eastern Europe and Central Asia.

Experimental studies in Bangladesh estimated the cost per averted birth at US\$95 (Attanayake, Fauveau, and Chakraborty 1993), US\$281 (Pritchett 1994), US\$293 (Balk and others 1988), and US\$296 (Simmons, Balk, and Faiz 1991), varying by the accounting method used. The Bangladesh experiment was likely more expensive than other programs, as it involved a frequent schedule of visitation for community-based distribution. The model we developed for the Disease Control Priorities Project produced costs between US\$87 and US\$163 per birth averted, with costs lowest in Latin America and the Caribbean and in the Middle East and North Africa.

Costs per Death Averted. Walsh and others (1993) estimated that in a typical high-mortality country with a 20 percent contraceptive prevalence rate, family-planning programs cost US\$8,261 per maternal death averted and US\$1,276 per perinatal infant death averted. In a setting with high mortality and low contraceptive prevalence rates, offering family planning alone was considerably more cost-effective in averting both maternal and infant deaths than offering an integrated program including prenatal care and birth attendant training. The model developed for the Disease Control Priorities Project produced regional average costs between US\$5,172 and US\$34,564 per maternal death averted and between US\$1,367 and US\$4,907 per infant death averted. Costs were lowest in South Asia and Sub-Saharan Africa. Costs within regions varied by as much as two orders of magnitude.

Stover (2003) estimated that by offering family-planning services at PMTCT and voluntary counseling and testing sites in countries with high HIV prevalence, child HIV infections could be averted at a cost of US\$489, and child deaths could be averted at a cost of US\$278 per event—well below the costs of averting these events using traditional PMTCT services. In addition, these family programs would avert orphans at a cost of US\$278, and maternal deaths at a cost of US\$1,824 per event.

Costs per DALY. The 1993 report on world development (World Bank 1993) estimated that family-planning programs in low-income countries cost from US\$40 to US\$60 per DALY. In the first edition of *Disease Control Priorities in Developing Countries*, Jamison (1993) estimated the costs of IEC or behavior-change communication (BCC) programs promoting condom use for family planning at between US\$20 and US\$100 per DALY, depending on child and maternal mortality rates.

Average costs for regions per YLL ranged from US\$37 to US\$110. Costs per DALY and year of life lost (YLL) were lowest in South Asia and Sub-Saharan Africa, whereas costs per year lived with disability (YLD) were lowest in South Asia and in East Asia and the Pacific. As with costs per death averted, costs per DALY varied within regions by as much as two orders of magnitude.

Family-planning programs that target HIV-positive women to prevent mother-to-child transmission may be even more cost-effective. According to an analysis of Stover's (2003) estimates, such programs cost about US\$5 per DALY. In comparison, traditional PMTCT services, including antiretrovirals and replacement feeding, cost US\$37 per DALY, and nevirapine regimens cost US\$5 to US\$12 per DALY (Marseille and others 1999; UNAIDS 1999). Kumar (2000) found that adding family-planning and abortion services to PMTCT programs increased their cost-effectiveness from US\$124 per DALY for a short-course antiretroviral drug regimen to US\$93 per DALY for an integrated strategy. Despite its cost-effectiveness, family planning is not currently included in most policies addressing mother-to-child transmission of HIV.

Cost-Effectiveness within Programs

Few studies compare the cost-effectiveness of program designs and elements—for instance, between social marketing and

community-based distribution, or between price subsidies and promotional spending. Thus, although donors or government ministers may have enough information to justify funding family-planning programs, managers of such programs have much less information to use in deciding how best to spend money within their programs.

Program Inputs. Roughly half of program funds are spent subsidizing price (Sanderson and Tan 1996), but there is little evidence that price subsidies significantly affect contraceptive use, even among the poor (Matheny 2004). In every demographic and health survey over the past decade, price has been reported as a barrier to contraceptive use by fewer than 2 percent of women with unmet need. Several studies suggest that even the poorest urban users are typically willing to pay commercial contraceptive prices—once they intend to contracept. This finding is not entirely surprising, because the economic costs of childbearing dwarf those of contraception (Pritchett 1994). Particularly if profits are reinvested in a program's quality of services, higher prices may permit the provision of amenities that attract more clients (Foreit and Levine 1993; Litvack and Bodart 1993).

The most commonly reported barriers to contraceptive use are lack of knowledge, health concerns, and social disapproval (Casterline and Sinding 2000). It is likely, then, that the most cost-effective inputs are those that address these barriers—by increasing accurate knowledge about and social acceptance of contraception, as well as by improving the quality of and access to a variety of contraceptive methods.

Evidence suggests that quality has improved contraceptive use for birth spacing in Tunisia (Cochrane and Guilkey 1995). However, results are mixed in Peru (Mensch, Arends-Kuenning, and Jain 1996) and the Philippines (DeGraff, Bilsborrow, and Herrin 1993). Schultz (1994) found that, on average, improved quality does not affect the contraceptive prevalence rate at the national level.

Some improvements in quality require additional resources—expanding facilities, adding equipment and staff, and diversifying services. Quality improvements are necessary to respond to ethical imperatives. Beyond the ethical rationale, quality improvements can reduce the cost per unit of output—improving the flow of clients and shifting service delivery from physicians to paramedics. Improvements in quality can also increase utilization and allow higher prices to be charged.

Unfortunately, the relative cost-effectiveness of investments in these inputs has not been established. However, there is reason to believe that, among all inputs, investments in IEC and BCC activities are the most cost-effective—especially those that encourage users to purchase contraceptives or services from the private sector. Studies in many countries show that exposure to IEC and BCC messages through television, radio, and print

increases the likelihood of contraceptive use (Dayaratna and others 2000; Westoff and Bankole 1997). Social-marketing programs appear to succeed in increasing contraceptive use principally through their promotional activities (Bulatao 2002). IEC and BCC activities can also increase the efficiency of clinic programs by increasing caseloads. Last, among all family-planning activities, IEC and BCC activities may be the most prone to market failure, providing a strong rationale for public investment.

Integration. Integrating family planning with other reproductive health services was a major goal of the 1994 International Conference on Population and Development. Although the logic of integration is compelling, little research has been done on the costs of integrated programs. In theory, integrated programs should be more efficient because they distribute joint costs across more services. In clinics, integration should increase cost-effectiveness if services such as Papanicolaou smears, ultrasounds, pregnancy testing, abortions, and post-abortion care are used to cross-subsidize less profitable contraceptive services. Mitchell, Littlefield, and Gutter (1999) found relatively low family-planning costs in two integrated clinics and concluded that adding clients has a larger effect on costs in a clinical setting than adding services does. Mancini, Stecklov, and Stewart (2003), however, found that vertical programs that focused exclusively on family planning offered contraceptive supplies and services at a significantly lower cost per CYP than integrated programs.

Delivering contraception services alongside abortion or postabortion care can be cost-effective. Few clinics and hospitals that treat women suffering from abortion complications offer contraceptive counseling and services as part of their postabortion care, yet these services are effective in increasing contraceptive use. The key obstacle is finding support from abortion providers—especially private providers, who may not see profit potential in providing family planning. The same is true of prenatal care. One study in Kenya showed that exposing women to information about family planning during prenatal care doubled the likelihood that they would use contraception (Ndhlovu 1997). A study of 27 countries found that two-thirds of women had an unmet need for contraception within one year of their last childbirth (Ross and Winfrey 2001). In fact, about one-third of all unmet need was among women postpartum. This need could be satisfied with greater integration of maternal and child health services and family planning, particularly during prenatal visits, delivery care, and six-week postpartum visits.

Finally, integrating STI services with family planning can help identify women with STIs who wish to avoid risky pregnancies and prevent fetal and neonatal complications. Integrating STI services may also draw more men to family-planning clinics.

EQUITY: DISTRIBUTING THE BENEFITS OF SUBSIDIES

It is the poorest whose health and prosperity are most threatened by unwanted pregnancies, and who are least able to pay for family-planning services. Yet a significant portion of public subsidies for family planning benefit the wealthy. This outcome is in part a natural consequence of the demand for family planning. Wealthier couples typically want smaller families than poorer couples. If subsidies follow demand rather than need, they will concentrate among the wealthy. However, because there is substantial unmet need for family planning among poor couples, an efficient segmentation of the market would have subsidized providers target poorer clients and unsubsidized providers target wealthier clients.

In a study of 10 countries, Sine (2002) found that nonpoor users obtained 45 percent of subsidized oral contraceptives and 56 percent of subsidized condoms supplied by governments and nonprofit organizations. An analysis in Indonesia found that only 16 percent of public subsidies for family planning accrued to the poorest quartile. In the Philippines, 64 percent of subsidies accrued to the richest half of households, whereas 17 percent accrued to the poorest quarter. In the Philippines, the distribution of subsidies varied widely by contraceptive method, with vasectomy subsidies concentrated among the poor and condom subsidies concentrated among the middle class (Haaga and Tsui 1995).

Behrman and Knowles (1998) found that the family-planning program in Vietnam was only weakly pro-poor. The main source of inefficiency stemmed from the greater use of more heavily subsidized government providers, particularly hospitals, by wealthier clients. One study in Bangladesh found that, although family-planning workers had the largest effect on the contraceptive behavior of uneducated women, the workers—who typically come from the educated class—were more likely to visit educated women (Arends-Kuenning 1997). For similar reasons, clinics are often located in wealthier areas.

Whereas a significant share of wealthier users obtain subsidized goods, a large share of poor users obtain goods from the commercial sector. In a study of 12 countries, more than half of even the poorest condom users purchased condoms from the commercial sector in all countries but the Philippines (Foreit 1999). Sine (2002), in turn, found that 20 percent of poor and near-poor users obtained their oral contraceptives from the commercial sector, even in countries where free or subsidized brands were available.

ECONOMIC BENEFITS OF INTERVENTION

Contraception or family planning can yield long-term economic benefits through three main routes. One is reasonably direct and easy to quantify; the others are more complex. First,

contraception can produce economic benefits by reducing maternal mortality and morbidity and improving child health—benefits that can be captured through estimates of savings to the health system.

Second, contraception can have economic payoffs if it occurs in a setting where high fertility is constraining economic growth. Longstanding arguments in development economics have centered on whether rapid population growth acts as a drag on economic growth. Some camps argued that high fertility, in particular, would condemn a country to slow (or even negative) per capita income growth. Others argued that the negative effects would be mild and short lived, as households adapt to existing resource constraints by reducing childbearing and as technological changes, such as those that result in higher agricultural yields, alter the productivity equation. By the late 1990s, however, a consensus emerged from examination of more than 40 years of experience and data: rapid population growth, in general, and high fertility, in particular, typically lead to slower economic growth and higher levels of poverty than would otherwise be realized (Birdsall and Sinding 2003).

Third, when contraception reduces the rate of population growth, it can have multiple effects (economic and other) on the environment. High fertility, coupled with rural-to-urban migration, has led to rapid urban growth, often outpacing the provision of clean water and sanitation. In an analysis of 42 cities in Latin America, Asia, and Africa, Bockerhoff and Brennan (1998) found that urban growth rates were positively correlated with infant mortality rates, likely owing to crowding, a weakening of the public infrastructure, and increased air pollution. Ambient air pollution is now emerging as a serious threat to human health in virtually all the large cities in the world, responsible for 1 percent of global deaths and DALYs (WHO 2002b).⁴

Population growth is also responsible for much of the increase in carbon emissions that contribute to global climate change. Although developing countries account for only 20 percent of carbon emissions today, some researchers have estimated that these countries will account for 50 percent by 2050, given current rates of development (Bongaarts 1992). Bongaarts estimated that population growth would account for 48 percent of the growth in carbon emissions in developing countries between 1985 and 2100. Birdsall (1994) estimated that realistic reductions in fertility could reduce emissions in 2050 by as much as 15 percent in developing countries; more important, however, she estimated that by reducing fertility, family-planning programs could reduce emissions more cost-effectively than taxes on carbon emissions could. Similarly, Brinkley, Potts, and Walsh (2003) found that family-planning programs are likely more cost-effective than any emissions policy. (At the same time, it is important to note that the largest per capita consumption of nonrenewable natural resources occurs in the low-fertility settings of wealthy countries, where policies promoting conservation are overdue.)

RESEARCH AND DEVELOPMENT AGENDA

The agenda for research and development in the field of contraceptives and family planning is ample. It benefits from a strong tradition of data- and research-driven policy and programmatic decisions. Priorities suggested below fall into the realms of science, operations (or program), and policy.

On the scientific agenda, the top priority must be the development of contraceptive products that protect women and men against both pregnancy and HIV infection in ways that are more acceptable from a user perspective than male or female condoms. Two other high-priority topics are the development of male contraceptives and of microbicides, a female-controlled method that protects against both STIs (especially, HIV) and unwanted pregnancy.

With respect to operations research, high-priority questions include how to reach adolescents effectively and cost-effectively; what to do in settings where progress has stalled (for example, Bangladesh); and how to stimulate demand for family planning in Sub-Saharan African countries, where the demand is relatively low.

Another important and neglected topic is how to introduce the sexual health dimension into contraceptive services. In general, providers do not take into account sexuality and sexual health during counseling or service delivery, in spite of the mutual influence between sexual behavior and preferences and contraception. On the one hand, women and couples' sexual activities strongly influence the adoption of contraception, and the preference of these women and couples for a certain method, in turn, influences its effective use and continuity. On the other hand, particular characteristics of the different methods affect women's and couples' perceptions of their own sexuality (Bruce 1987). In spite of these obvious links, neither the family-planning literature nor family-planning services have yet paid enough attention to the matter (Dixon-Mueller 1993).

On the policy research agenda, further research is required to understand the relationship between fertility and other reproductive health outcomes and economic outcomes at microeconomic and macroeconomic levels. Such research includes, for example, a careful analysis of how access to contraception may affect women's productivity, as well as human capital investments in the next generation. In addition, better understanding of the distributional effect of family planning and other reproductive health services would inform policies about how best to target public resources.

NOTES

1. These are 2001 averages; country-by-country figures are 2000 and earlier.

2. One problem in applying the burden-of-disease framework to family planning is unique to interventions that affect the size of a population. In most effectiveness analyses, one compares the state of the world with a

particular program to the state of the world without that program. However, effectiveness analyses using disability-adjusted life years (DALYs) are typically not conducted this way. The number of DALYs averted by family planning is not the number of DALYs without a family-planning program minus the total number of DALYs with a family-planning program. Given the negative nature of DALYs as a measure, such an exercise would lead to an absurd result. Nearly all lives have some number of DALYs attached to them. These DALYs may be averted most cost-effectively by preventing all births, reducing the burden of disease to zero. To avoid this result, we cannot measure the effect of family planning by comparison with a pure counterfactual. Rather, it is measured by ignoring the DALYs that would have been attributed to contingent persons. By the definition of DALYs, no individual can have any expectation of healthy life until the moment of live birth. This, however, is not an ideal solution. Both parents and health practitioners typically want to avoid perinatal deaths, even if doing so means preventing the birth of an infant. This fact suggests that one aim of health care is to prevent the ill health of contingent persons—in which case we ought, at least in some circumstances, to measure the potential DALYs averted by preventing a birth.

3. All dollar amounts are expressed in 2001 U.S. dollars. In a few cases, the year was not specified in the original source, and currency was converted from the year of publication.

4. Because of data limitations, these DALYs include no morbidity.

Chapter 58

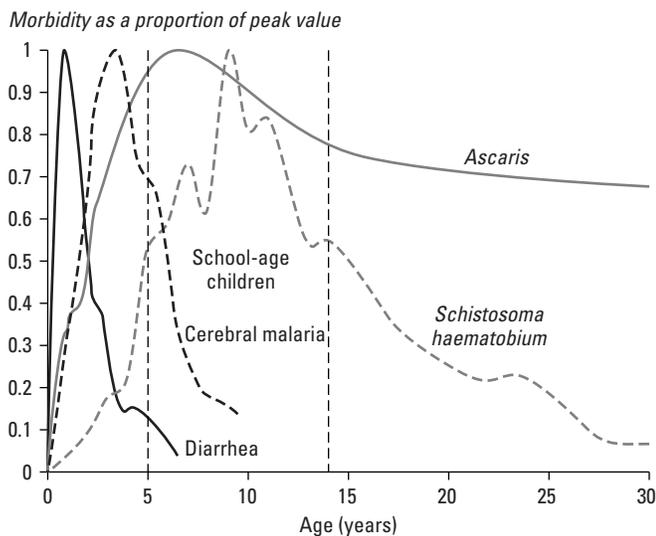

School-Based Health and Nutrition Programs

Donald A. P. Bundy, Sheldon Shaeffer, Matthew Jukes, Kathleen Beegle, Amaya Gillespie, Lesley Drake, Seung-hee Frances Lee, Anna-Maria Hoffman, Jack Jones, Arlene Mitchell, Delia Barcelona, Balla Camara, Chuck Golmar, Lorenzo Savioli, Malick Sembene, Tsutomu Takeuchi, and Cream Wright

The paradigmatic shift in the past decade in our understanding of the role of health and nutrition in school-age children has fundamental implications for the design of effective programs. Improving the health and nutrition of schoolchildren through school-based programs is not a new concept. School health programs are ubiquitous in high-income countries and most middle-income countries. In low-income countries, these programs were a common feature of early, particularly colonial, education systems, where they could be characterized as heavily focused on clinical diagnosis and treatment and on elite schools in urban centers. This situation is changing as new policies and partnerships are being formulated to help ensure that programs focus on promoting health and improving the educational outcomes of children, as well as being socially progressive and specifically targeting the poor, girls, and other disadvantaged children. This evolution reflects five key changes in our understanding of the role of these programs in child development.

- First, ensuring good health at school age requires a life cycle approach to intervention, starting in utero and continuing throughout child development. In programmatic terms this requirement implies a sequence of programs to promote maternal and reproductive health, management of childhood illness, and early childhood care and development. Promoting good health and nutrition before and during school age is essential to effective growth and development.
- Second, operations research shows that the preexisting infrastructure of the educational system can often offer a more cost-effective route for delivery of simple health interventions and health promotion than can the health system. Low-income countries typically have more teachers than nurses and more schools than clinics, often by an order of magnitude.
- Third, empirical evidence shows that good health and nutrition are prerequisites for effective learning. This finding is not simply the utopian aspiration for children to have healthy bodies and healthy minds, but also the demonstration of a systemic link between specific physical insults and specific cognitive and learning deficits, grounded in a new multisectoral approach to research involving public health and epidemiology, as well as cognitive and educational psychology.
- Fourth, the provision of quality schools, textbooks, and teachers can result in effective education only if the child is present, ready, and able to learn. This perception has additional political momentum as countries and agencies seek to achieve Education for All (EFA) by 2015 and address the Millennium Development Goals of universal basic education and gender equality in education access. If every girl and boy is to be able to complete a basic education of good quality, then ensuring that the poorest children, who suffer the most malnutrition and ill health, are able to attend and stay in school and to learn while there is essential.

Source: Bundy and Guyatt 1996.

Figure 58.1 Age Distribution of Infection-Specific Morbidity

- Finally, education, including education that promotes positive health behaviors, contributes to the prevention of HIV/AIDS—the greatest challenge for generations to come. School health and nutrition programs that help children complete their education and develop knowledge, practices, and behaviors that protect them from HIV infection as they mature have been described as a “social vaccine” against the disease.

Because of the success of child survival programs, the number of children reaching school age (defined as 5 to 14 years of age) is increasing and is estimated to be 1.2 billion children, with 88 percent living in less developed countries (U.S. Census Bureau 2002). As figure 58.1 illustrates, the pattern of disease is age specific. A large body of evidence shows that these conditions affect cognition, learning, and educational achievement (see Jukes, Drake, and Bundy forthcoming; Pollitt 1990 for reviews of this extensive literature).

This chapter focuses on the health, nutrition, and education of the school-age child and on the programs that can be implemented at school age to promote positive outcomes.

INFECTIOUS DISEASE AND SCHOOL-AGE CHILDREN

A range of infectious diseases affect school-age children.

Helminth Infections

Between 25 and 35 percent of school-age children are estimated to be infected with one or more of the major species of worms (Bundy 1997; see also chapter 24). The most common

and important infections are caused by geohelminths (the roundworm *Ascaris*, the whipworm *Trichuris*, and the two species of hookworms *Ancylostoma* and *Necator*) and by the schistosomes (*Schistosoma* spp.), which give rise to a wide range of chronic but largely nonspecific symptoms. The most intense worm infections and related illnesses occur at school age (Partnership for Child Development 1998b, 1999) and account for some 12 percent of the total disease burden and 20 percent of the loss of disability-adjusted life years (DALYs) from communicable disease among schoolchildren (World Bank 1993).

Infected schoolchildren perform poorly in tests of cognitive function; when they are treated, immediate educational and cognitive benefits are apparent only for children with heavy worm burdens or with concurrent nutritional deficits. Treatment alone cannot reverse the cumulative effects of life-long infection or compensate for years of missed learning, but studies suggest that children are more ready to learn after treatment for worm infections and may be able to catch up if this learning potential is exploited effectively in the classroom (Grigorenko and others forthcoming). In Kenya, treatment reduced absenteeism by one-fourth, with the largest gains for the youngest children who suffered the most ill health (Miguel and Kremer 2004).

Malaria

Up to 5 percent of children infected with malaria early in life have residual neurological sequelae (Snow 1999). In areas of unstable transmission, malaria accounts for 10 to 20 percent of all-cause mortality among school-age children (Bundy and others 2000), and those who have suffered repeated attacks have poorer cognitive abilities. In Kenya, primary school students miss 11 percent of school days because of malaria, equivalent to 4 million to 10 million days per year (Brooker and others 2000).

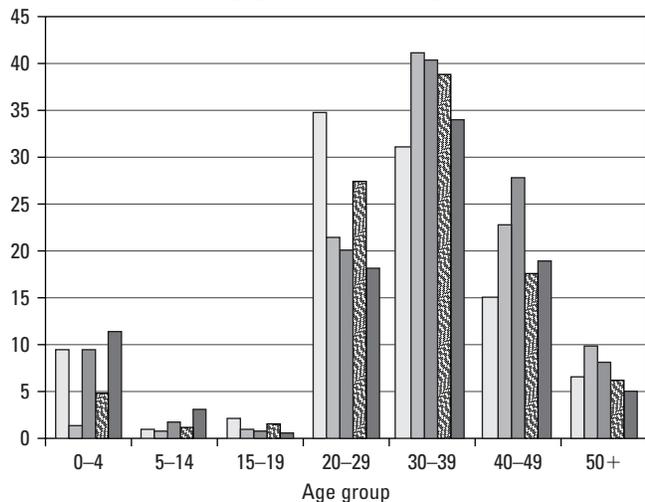

Oral antimalarial treatment reduced school absenteeism by 50 percent in Ghana (Colbourne 1955); the use of insecticide-treated bednets in Tanzania reduced malaria and increased attendance (Shiff and others 1996). Girls in The Gambia were more than twice as likely to enroll in primary school if they had received malaria prophylaxis in early childhood (Jukes and others submitted).

HIV/AIDS

Although school-age children have the lowest infection prevalence of any age group (figure 58.2), an estimated 3.8 million children under 15 years of age have been infected with HIV and more than two-thirds have died (UNAIDS 2002). Even uninfected children suffer physically, socially, and psychologically through death or illness in their family (World Bank 2002). The proportion of orphans, most of whom are of school age, has risen from 2 to 15 percent in some African countries, with

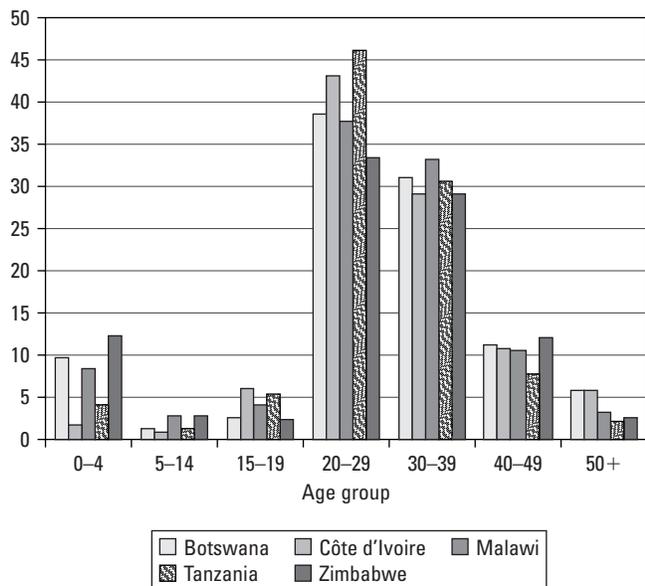

a. Male Cases

Percent infected in each age group, as a percentage of cases

b. Female Cases

Percent infected in each age group, as a percentage of cases

Source: UNAIDS epidemiological fact sheets 2000.

Note: Figure shows percentage of males (top) and females (bottom) infected with HIV in each age group (as a percentage of all HIV-infected males and females, respectively), for five countries in Africa. Infection peaks at a younger age in women than in men, and the lowest prevalence of infection occurs in school-age children.

Figure 58.2 Age Prevalence of HIV/AIDS

AIDS accounting for 50 percent of this increase. The number of orphans is expected to reach more than 25 million by 2010.

School-age children with HIV infections have lower IQ levels and poorer academic achievement, language, and visual motor functioning. These deficits can be reduced or reversed with antiretroviral therapy. The improvement is greater for children of school age than for younger children.

Acute Respiratory Infection

Acute respiratory infection, the most common acute infection in school-age children globally, is a significant cause of absenteeism. Research in industrial countries (Cohen and Smith 1996) finds that flu infection affects attention and reaction time; colds primarily affect hand-eye coordination, as well as reduce the ability to tolerate high levels of noise and other distractions common to the classroom.

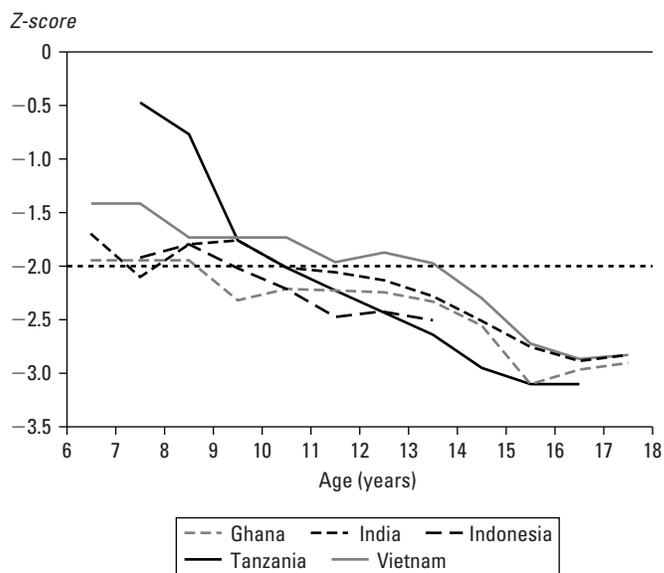

MALNUTRITION, NONINFECTIOUS DISEASE, AND HEALTH AND EDUCATION

Malnutrition and noninfectious disease also affect school-age children.

Malnutrition

Stunting (low height for age) is a physical indicator of chronic or long-term malnutrition, whereas underweight (low weight for age) is an indicator of both chronic and acute malnutrition. Both are common in school-age children (figure 58.3).

Girls who are better nourished are more attentive and more involved during class, and boys have improved classroom behavior and increased activity levels. One Z-score increase in height for age is associated with an increase of 0.1 standard deviation (SD) in tests of arithmetic and language. Stunted children enroll in school later than other children. School food-service programs have been successful in improving school attendance.

Source: Data from Partnership for Child Development 1998a.

Note: Z-scores of less than -2 indicate stunting.

Figure 58.3 Mean Z-scores of Height-for-Age of Boys in Five Countries

Short-Term Hunger

Hunger, which reduces ability to perform school tasks, is readily reversed by feeding. Children age 11 to 13 years in Jamaica improved their scores on arithmetic tests after one semester of receiving breakfast at school because they attended more regularly and studied more effectively (Simeon 1998). Missing breakfast impairs performance to a greater extent for children of poor nutritional status, who also benefit most from food intervention (Pollitt, Cueto, and Jacoby 1998; Simeon and Grantham McGregor 1989).

Micronutrient Deficiency

Micronutrient deficiencies may take several different forms, each with negative impacts on children's ability to perform well in school.

Iron Deficiency. Iron deficiency, the most common form of micronutrient deficiency in school-age children, is caused by inadequate diet and infection, particularly by hookworm and malaria (Hall, Drake, and Bundy 2001). More than half the school-age children in low-income countries are estimated to suffer from iron deficiency anemia (Partnership for Child Development 2001). Children with iron deficiency score 1 to 3 SD worse on educational tests and are less likely to attend school. Iron supplementation reduces these deficits.

Iodine Deficiency. Iodine deficiency affects an estimated 60 million school-age children; studies indicate prevalence rates between 35 and 70 percent. Iodine deficiency is related to lowered general cognitive abilities and tests scores. No conclusive evidence shows that iodine supplementation improves cognitive abilities in this age group (Huda, Grantham-McGregor, and Tomkins 2001).

Vitamin A Deficiency. Vitamin A deficiency affects an estimated 85 million school-age children. The deficiency, which causes impaired immune function and increases risk of mortality from infectious disease, is an important cause of blindness. Recent studies suggest that this deficiency is also a major public health problem in school-age children. Multiple-micronutrient supplements have improved cognitive function and short-term memory in schoolchildren and have reduced absenteeism caused by diarrhea and respiratory infections.

Obesity

An estimated 17.6 million children worldwide are overweight. Obesity is associated with underperformance in education. In low-income countries obesity is still rare, but the prevalence in

the children of many middle-income countries is similar to that in the United States.

ESTIMATING THE BURDEN OF DISEASE

The cost per DALY of school health programs has been estimated at US\$20 to US\$34, implying that the programs are at least as cost-effective as many other public health "best buys" (Bobadilla and others 1994). However, current methods of estimating the burden for school-age children result in a significant underestimation of both the developmental consequences of disease and malnutrition at school age and the overall benefits for health and development of school health and nutrition programs.

There are two key reasons for this underestimation. The first issue relates to time scales. Many serious diseases in adulthood, including heart disease and carcinomas, are a consequence of unhealthy practices established in early life. This later burden can be substantially and cost-effectively averted by early intervention, particularly by school-based life-skills programs. For example, in the United States (Del Rosso and Marek 1996), US\$1 invested can avert US\$18.80 spent on the later problems caused by tobacco and US\$5.70 on problems of drug and alcohol abuse. DALY estimates cannot capture these downstream consequences of upstream intervention and instead attribute the disease burden to the adult age group in which it appears. This kind of estimate is particularly misleading in the case of HIV/AIDS, for which prevention education at school age is effective in averting later infection and disease (World Bank 2002), and in the case of estimates of intergenerational effects, in which ensuring the health of an adolescent girl may help secure the health of her baby born a few years later.

The second issue is illustrated by experience with helminth infections. In 1990, the burden was first estimated at 18 million DALYs, close to the value for tuberculosis, measles, and malaria. This estimate reflected the ubiquity of infection and the long-term consequences of cognitive impacts. In 2001, the estimate was only 4.7 million DALYs (WHO 2003), and during the intervening years one estimate put the value as low as 2.6 million.

This extraordinary variability is caused in part by different emphases on the cognitive and health impacts and illustrates how, for very common conditions, even minor changes in disability weight can affect the overall values. This variability also reflects the importance of a sectoral perspective, because the low estimates reflect a focus on health, whereas the higher estimates include impact on educational achievement and child development.

The scale of the burden of disease in terms of cognition is illustrated by estimating the impact of stunting, anemia, and helminths on the cognition of the estimated 562 million school-age children in developing countries. According to typical

deficits in test scores attributable to these diseases, the total global loss of points ranges from 600 million to 1.8 billion IQ points, an additional 15 million to 45 million cases of mental retardation (defined here as IQ less than 70), and a loss of between 200 million and 524 million years of primary schooling (Jukes, Drake, and Bundy forthcoming). Although the precision of these striking figures may be open to debate, they clearly show that even minor cognitive deficits resulting from ubiquitous conditions can result in an extraordinarily large scale of effect.

INTERVENTIONS

In light of the significant effects of ill health and malnutrition on educational outcomes, the role of effective health promotion and simple school-based programs to deliver low-cost interventions becomes increasingly important (Bundy and others 1992). Other chapters provide information on the integrated management of childhood illness, early child development, and adolescent health (see chapters 63, 27, and 59, respectively). The focus here is on ill health and malnutrition at school age and the role of the formal and nonformal education sector in delivering interventions.

Developing a Programmatic Approach

The focus of school health and nutrition programs in low-income countries has shifted significantly over the past two decades away from a medical approach that favored elite schools in urban centers and toward an approach that improves health and nutrition for all children, particularly the poor and disadvantaged. This change began in the 1980s, when research showed not only that school health and nutrition programs were important contributors to health outcomes but also that they were essential elements of efforts to improve education access and completion, particularly for the poor.

In an effort to reconceptualize the relationship between health and education, the United Nations Education, Scientific, and Cultural Organization (UNESCO) hosted a series of workshops on this topic in the 1980s (Bundy 1989; Halloran, Bundy, and Pollitt 1989) and supported one of the first authoritative reviews of the area (Pollitt 1990). Similarly, the United Nations Development Programme, in conjunction with the Rockefeller, Edna McConnell Clark, and J. S. McDonnell Foundations supported the creation of the Partnership for Child Development to strengthen the evidence base across the education and health sectors and to support the dissemination of information (Berkley and Jamison 1990; Bundy and Guyatt 1996). This paradigm shift coincided with the World Conference on Education for All in Jomtien, Thailand, in 1990 and led to renewed efforts by countries and agencies to develop more effective programmatic approaches to school health and nutrition.

The United Nations Population Fund (UNFPA) has pioneered population and family life education (PopEd) as an intrinsic part of school curricula. In 1994, the International Conference on Population and Development placed specific emphasis on school health, including reproductive and sexual health. Efforts at country level have addressed PopEd both within the school system and outside, and the concept has evolved to include references to family life education, sex education, HIV/AIDS awareness and prevention, and life-skills programs. Today, approximately 84 countries have UNFPA-supported school health programs.

In 1995, the World Health Organization (WHO) launched its Global School Health Initiative to foster the development of health-promoting schools (HPSs) (WHO 1996). The concept started in Europe in the early 1990s, based on the Ottawa Charter of Health Promotion (WHO 1986; European Commission 1996), which recognized that health is created by caring for oneself and others, by being able to make decisions and have control over one's life and circumstances, and by creating conditions that support health for all. WHO's European Regional Office, the Council of Europe, and the Commission of the European Communities widely promoted the concept of HPSs to foster healthy lifestyles and develop environments conducive to health (European Commission, WHO Europe, and Council of Europe 1996). Although definitions vary among regions, countries, and schools, an HPS may be characterized as one that is constantly strengthening its capacity as a healthy setting for living, learning, and working. The initiative fosters the development of HPSs by the following:

- consolidating research and expert opinion to describe the nature and effectiveness of school health programs
- building capacity to advocate for the creation of HPSs and to apply the components to priority health issues
- strengthening collaboration and national capacities to assess the prevalence of important health-related behaviors and conditions and to plan and implement policies and programs that improve health through schools
- creating networks and alliances, including regional networks.

The key elements of how this approach is interpreted today are listed in table 58.1.

In the mid 1990s, the United Nations Children's Fund (UNICEF) began promoting the Child-Friendly Schools framework as a holistic way to promote children's rights as expressed in the Convention on the Rights of the Child (UNICEF 1990) and children's access to education as stated in the World Declaration of Education for All (UNESCO 1990). This approach included a gender-sensitive component, which was further strengthened when girls' education became the first priority in UNICEF's Medium Term Strategic Plan, 2002–5. Another key element is skills-based health education,

Table 58.1 Characteristics of Agency-Specific School Health and Nutrition Programs, within the FRESH framework

FRESH framework	Health-promoting schools (WHO)	Child-friendly schools (UNICEF)	PopEd (UNFPA)	Global school feeding campaign (World Food Program)
Policy	Respects an individual's well-being and dignity Provides multiple opportunities for success Acknowledges good efforts and intentions as well as personal achievements	Respects and realizes the rights of every child Acts to ensure inclusion, respect, and equality of opportunity for all children Is gender sensitive and girl friendly Is flexible and responds to diversity Sees and understands the whole child in a broad context Enhances teacher capacity, morale, commitment, and status	Creates a supportive and enabling policy environment for reproductive health and HIV prevention for young people	Focuses on the poorest and most food-insecure communities. Gives priority to girls and AIDS-affected children
School environment	Is healthy Provides opportunities for physical education and recreation	Is healthy, safe, and secure Is protective emotionally and psychologically	Protects young people from early and unwanted pregnancy, sexually transmitted diseases, sexual abuse, and violence	Serves as platform for essential package approach that includes water, sanitation, and environmental measures
Education	Provides skills-based health education Fosters health and learning	Promotes quality learning outcomes Provides education that is affordable and accessible Provides skills-based health education, including life skills relevant to children's lives	Strengthens HIV/AIDS and sexual and reproductive health education programs	Supports learning through good nutrition Promotes access to education
Services	Provides school health services Provides nutrition and food-safety programs Provides programs for counseling, social support, and mental health promotion Provides health promotion programs for staff Includes school and community projects and outreach	Promotes physical health Promotes mental health	Ensures access to youth-friendly sexual and reproductive health services	Provides food Promotes and supports deworming
Supportive partnerships	Engages health and education officials, teachers, teachers' unions, students, parents, health providers, and community leaders in efforts to make the school a healthy place	Is child centered Is family focused Is community based	Targets young people in school and out of school Ensures active participation of parents, youths, community leaders, and organizations	Promotes community and school partnerships

Source: Summarized from World Bank Fresh Toolkit (2000), WHO (1996), and personal communications from Arlene Mitchell and Sheldon Shaeffer (May 2005).

including life skills, which has been promoted through UNICEF with partner organizations as part of HPSs, child-friendly schools, and the framework for Focusing Resources on Effective School Health (FRESH). Research shows that this approach is more effective than traditional strategies, which tend to be didactic and to focus on scientific information alone. In contrast, skills-based health education uses the experiences of students as the starting point and explores the links between knowledge, attitudes, and the interpersonal skills

required to promote health and learning (UNICEF, WHO, World Bank, UNFPA, UNESCO 2003). The approach is interactive, activity based, and flexible so that it can be used to address a range of health and social issues, including HIV/AIDS, sanitation, drug use, violence and bullying, nutrition, and cross-cutting issues such as gender and culture. Some key elements of how the child-friendly schools approach is interpreted currently, including its focus on healthy and protective learning environments, are listed in table 58.1.

Also during the 1990s, the World Bank Human Development Network sought to support countries in implementing school health and nutrition programs (Del Rosso and Marek 1996; World Bank 1993) and launched an International School Health Initiative with the aim of raising awareness among decision makers in the education sector.

Thus, the 1990s were characterized by the creation of a number of apparently separate programs to promote and support school health. However, analysis at the country level revealed that although the various agency initiatives used different “prisms” to view school health—public health for WHO, quality education for UNESCO, and child rights for UNICEF—the core activities for all the programmatic approaches were essentially the same.

FRESH Framework

A major step forward in international coordination and cohesion was achieved when the FRESH framework was launched at the World Education Forum in Dakar in April 2000 (World Bank FRESH Toolkit 2000). Among the early partners in this effort were the Education Development Centre, Education International, the Partnership for Child Development, UNESCO, UNICEF, the World Food Programme (WFP), WHO, and the World Bank. This partnership recognizes that the goal of universal education cannot be achieved while the health needs of children and adolescents remain unmet and that a core group of cost-effective activities can and must be implemented across the board to meet those needs and to deliver on the promise of EFA.

The expanded commentary on the Dakar Framework for Action reflects the recommendations of this partnership and describes three ways in which health relates to EFA: as an input and condition necessary for learning, as an outcome of effective quality education, and as a sector that must collaborate with education to achieve the goal of EFA. In the follow-up to the Dakar Forum, UNESCO designated FRESH as an interagency flagship program that will receive international support as a strategy to achieve EFA.

The FRESH framework, which is based on good practice recognized by all the partners, provides a consensus approach for the effective implementation of health and nutrition services within school health programs. The framework proposes four core components that should be considered in designing an effective school health and nutrition program and suggests that the program will be most equitable and cost-effective if all of these components are made available, together, in all schools:

- *Policy:* health- and nutrition-related school policies that are nondiscriminatory, protective, inclusive, and gender sensitive and that promote the nutrition and physical and psychosocial health of staff, teachers, and children

- *School environment:* access to safe water and provision of separate sanitation facilities for girls, boys, and teachers
- *Education:* skills-based education, including life skills, that addresses health, nutrition, HIV/AIDS prevention, and hygiene issues and that promotes positive behaviors
- *Services:* simple, safe, and familiar health and nutrition services that can be delivered cost-effectively in schools (such as deworming services, micronutrient supplements, and nutritious snacks that counter hunger) and increased access to youth-friendly clinics.

The FRESH framework further proposes that these four core components can be implemented effectively only if they are supported by strategic partnerships between the following groups:

- health and education sectors, especially teachers and health workers
- schools and the community
- children and others responsible for implementation.

Adopting this framework does not imply that these core components and strategies are the only important elements; rather, implementing all of these in all schools would provide a sound initial basis for any pro-poor school health program.

The common focus has encouraged concerted action by the participating agencies. It has also provided a common platform on which countries, agencies, donors, and civil society can support all programs, including agency-specific programs (table 58.1). Another important consequence of the FRESH consensus framework has been to offer a common point of entry for new efforts to improve health in schools, as illustrated by the three examples in box 58.1.

This consensus approach has increased significantly the number of countries implementing school health reforms. The simplicity of the approach, combined with the enhanced resources available from donor coordination, has helped ensure that these programs can go to scale. Annual external support from the World Bank for these actions approaches US\$90 million, targeting some 100 million schoolchildren.

Common Interventions

Table 58.2 lists some specific interventions commonly combined within the school health intervention package, but it should be recognized that not all of these interventions will be needed or be appropriate for all locations. Some interventions are synergistic: for example, worm infection will be addressed by the provision of latrines, the promotion of hand washing, relevant health and hygiene education, and deworming services. Similarly, HIV/AIDS infection among youths will be addressed by ensuring girls’ participation in school, offering

Box 58.1

Three Efforts to Improve Health in Schools

The Multiagency Effort to Accelerate the Education Sector Response to HIV/AIDS in Africa

This effort, coordinated by a Working Group of the UNAIDS Inter-Agency Task Team on HIV/AIDS and Education, promotes the FRESH framework specifically and helps education systems do the following:

- adopt policies that avoid HIV/AIDS discrimination and stigmatization
- provide a safe and secure school environment
- provide skills-based health education, including life skills, in schools to promote positive behaviors and healthy lifestyles
- improve access to youth-friendly health services.

More than 36 countries and a similar number of agencies, bilateral donors, and nongovernmental organizations have collaborated in this effort since November 2002.

The Global School Feeding Campaign of the WFP

This campaign has gone beyond providing food aid to develop a programmatic link between nutrition and education. Working with partners, including national governments, parent-teacher and other community organizations,

Source: Authors.

UNICEF, WHO, the World Bank, UNESCO, and the Food and Agriculture Organization, the campaign promotes the following:

- policies that make food aid conditional on girls' participation in education
- an essential package that includes school sanitation and water and environmental improvement
- nutrition education that improves the quality of students' diets and HIV prevention education
- nutrition services that include food, deworming, and alleviation of short-term hunger.

Some 70 countries have begun to implement these principles and activities since 2002.

The Partnership for Parasite Control

Led by WHO and involving a broad range of development partners, this initiative promotes public and private efforts to include deworming in school health services, following a resolution of the 54th World Health Assembly to provide by 2010 regular deworming treatment to 75 percent of school-age children at risk (an estimated target population of 398 million). Of 41 target countries in Africa, 19 have begun school-based deworming programs since 2001.

skills-based health education (including life skills), offering peer education, providing access to health clubs, and providing access to treatment for sexually transmitted infections (STIs) at clinics. It is also apparent that whereas some interventions promote multiple outcomes—for example, skills-based health education and life-skills development can help promote positive behaviors that prevent STIs and substance abuse—other interventions may have a single focus, such as iron supplementation to avoid anemia.

Out-of-School Children

More than 100 million school-age children are out of school; 60 percent are girls (UNESCO 1993). School health programs in Guinea and Madagascar have demonstrated that many of these children will take advantage of simple services, such as deworming, provided in schools (Del Rosso and Marek 1996); the school acts essentially as a community center. It also has been demonstrated that deworming programs in schools benefit out-of-school children by reducing disease transmission in the community as a whole (Bundy and others 1990).

Nevertheless, it is apparent that out-of-school children cannot benefit from many of the important components of school-based programs, such as skills-based health education and life-skills development programs to prevent HIV/AIDS. Reaching these children requires more flexible approaches that combine the best of nonformal, informal, and community-based approaches (see chapter 59).

COST-EFFECTIVENESS OF INTERVENTION

A key issue in addressing the costs of the new approach to school health and nutrition programs is the significant savings offered by using the school system infrastructure rather than that of the health system as the key delivery mechanism. The school system provides not only a preexisting mechanism, so costs are at the margins, but also a system that aims at being pervasive and socially progressive. Some important interventions, especially in terms of health education, may be virtually cost free; they require only policy changes that result in doing things differently.

Table 58.2 Common Interventions within a School Health Program

FRESH category	Intervention	Expected outcome
Policy	<ol style="list-style-type: none"> 1. Child rights, avoidance of discrimination and stigmatization, gender sensitive, child centered 2. Inclusion of pregnant girls and mothers in education 3. Enforcement of code of practice for teacher behavior zero tolerance policy 4. Collaboration between health and education sectors 	<ol style="list-style-type: none"> 1. Inclusion of all children 2. Specific inclusion of girls 3. Avoidance of harassment and abuse 4. Effective implementation
Environment	<ol style="list-style-type: none"> 1. Access to safe water 2. Hand washing 3. Provision of sanitation 4. Gender-separate sanitation 5. Garbage disposal 	<ol style="list-style-type: none"> 1,2,3,5. Reduced infection 4. Reduced drop out of adolescent girls
Education	<ol style="list-style-type: none"> 1. Curriculum addressing health, hygiene, and nutrition 2. Life-skills program 3. Peer education program 4. Health-promoting clubs 	<ol style="list-style-type: none"> 1. Improved knowledge and skills to promote good health, hygiene, and nutrition 2. a. For South America and Africa, costs are standardized for 1,000 kilocalories for 180 days.

Annual costs of providing some common school-based interventions to students are given in table 58.3. This table illustrates two important points. First, some of the most widely needed interventions can be provided at remarkably low cost. Second, significant diversity exists in the cost of interventions,

which is affected by factors such as local capacity, location and remoteness of communities, and community values and opinions; hence, these factors must be borne in mind when identifying a school health package. (See chapter 41 for details of the costs of sanitation provision.)

Not illustrated in the table is the cost advantage of using the existing school infrastructure for delivery. Estimates for delivery of simple interventions (such as anthelmintic pills or micronutrient supplements) suggest that the teacher-delivery approaches listed here may be one-tenth of the cost of the more traditional mobile health teams and yet equally effective (Guyatt 2003). As with all education innovations, however, the additional cost of teacher orientation and training (in-service as well as preservice) needs to be factored into the costs of using the education system for delivery of health services.

ECONOMIC BENEFITS OF INTERVENTION

The most obvious benefit of school health interventions is arguably through the economic returns of improved adult health outcomes. Studies have increasingly documented a causal effect of adult health (broadly defined) on labor force participation,

wages, and productivity in developing countries; Strauss and Thomas (1995) present an overview of economic studies in this area. For example, height has been shown to affect wage-earning capacity as well as participation in the labor force for both women and men (Haddad and Bouis 1991). The effect of health on productivity and earnings may be strongest where low-cost health interventions produce large effects on health, such as low-income settings where physical endurance yields high returns in the labor market. For a 1 percent increase in height, Thomas and Strauss (1997) find a 7 percent increase in wages in Brazil compared with a 1 percent increase in the United States.

However, the apparent benefits of school health and nutrition programs will be underestimated when measured using only mortality or health-related disability metrics because these measures do not capture the impact of ill health on cognitive development or educational outcomes. Evidence over the past decade suggests these impacts have effect sizes in the range 0.25 to 0.4 SD and have implications for the child's education and for life beyond school, including future earning potential. We investigate those implications by considering the economic benefits in terms of IQ and school attendance and by comparing school health programs with traditional education interventions.

Economic Benefits of Long-Term Improvements in IQ

School health interventions can yield considerable economic benefits through returns to wages and productivity if they translate into improved cognitive functioning and IQ in adulthood.

For the United States, Zax and Rees (2002) estimate conservatively that an increase in IQ of 1 SD is associated with an increase in wages of more than 11 percent, falling to 6 percent when controlling for other covariates. Similar estimates for the relationship between IQ and earnings have been made for Indonesia (Behrman and Deolalikar 1995) and Pakistan (Alderman and others 1997) and in a review of developing countries (Glewwe 2002). In South Africa, an increase of 1 SD in literacy and numeracy scores was associated with a 35 percent increase in wages (Moll 1998). Extrapolating these results, a 0.25 SD increase in IQ, which is a conservative estimate of the benefit resulting from a school health intervention, would lead to an increase in wages of from 5 to 10 percent.

Economic Benefit of Improved School Attendance

School health interventions can raise adult productivity not only through higher levels of cognitive ability, but also through their effect on school participation and years of schooling attained. Healthier children are more likely to attend, and modest improvements in examination scores can be associated with continuation in schooling.

Malaria chemoprophylaxis given in early childhood in The Gambia led to an increase of more than one year in primary

schooling. In preschool children in Delhi, iron supplementation was associated with an increase of 5.8 percent in rates of participation at the preschool level (Bobonis, Miguel, and Sharma 2004). In western Kenya, deworming treatment improved primary school participation by 9.3 percent, with an estimated 0.14 additional years of education per pupil treated (Miguel and Kremer 2004). On the basis of crude estimates of returns to schooling, an increase of 9.3 percent in participation rates results in a return of US\$44. Miguel and Kremer (2004) conclude that these benefits still outweigh the costs even if increased school participation leads to greater costs in teacher compensation through the need for additional teachers. They note that the benefit-cost ratio remains over 10 even if the rate of return to an additional year of schooling is as low as 1.5 percent. These results suggest that for realistic estimates of returns to schooling, the net present discounted value of lifetime earnings is likely to be high compared to the costs of treatment even for small gains in school participation.¹

In the absence of studies estimating the direct link between school health interventions and school participation, the relationship can be estimated indirectly by considering the effect of interventions on test scores and the implications that improved test scores have for school participation. Improvements in cognitive function can be converted into an equivalent number of years of schooling. For example, Jukes and others (2002) found that heavy schistosomiasis was (nonsignificantly) associated with a decrease in arithmetic scores of 1.35 marks (0.25 SD). An extra year of schooling was associated with an increase in arithmetic scores of 2.24 marks (0.42 SD). Thus, the negative effect of heavy schistosomiasis was equivalent to missing just over half a year of schooling. The cognitive gains from an extra year of schooling can also be estimated retrospectively: in a study of adults in South Africa, each additional year of primary schooling was associated with a 0.1 SD increase in cognitive test scores (Moll 1998). According to these estimates, a typical increase of 0.25 SD associated with school health and nutrition programs is equivalent to an additional 2.5 years of schooling.

Liddell and Rae (2001) assessed the direct effect of test scores on grade progression in Africa. Each additional SD scored in first-grade exams resulted in children being 4.8 times as likely to reach seventh grade without repeating a year of schooling.² According to these estimates, an increase of 0.25 SD in examination scores, which is typically achieved by school health and nutrition programs, will make children 1.48 times³ as likely to complete seventh grade, which implies that the extra cumulative years of schooling attributable to the school health intervention average 1.19 years per pupil. The previous estimates for added years of schooling owing to school health interventions range from seven months to two years. Increased years of schooling are associated with, among other outcomes, higher worker productivity and generally higher productivity in nonmarket production activities, including greater farmer

efficiency and productivity (Jamison and Lau 1982; Psacharopoulos and Woodhall 1985; Strauss and Thomas 1995). Psacharopoulos and Patrinos (2002) summarize a wide range of studies that focus on individual wage earnings. For Sub-Saharan Africa, they find a 12 percent rate of return to one additional year in school, compared with 10 percent for Asian countries. These returns are very high, even allowing for a portion of the return to years of schooling to be capturing ability and factors other than schooling itself (Card 2001).

Education brings benefits beyond improved earnings. One year of extra education for girls can lead to a reduction of from 5 to 10 percent in infant mortality (Schultz 1993). Five extra years of education for women in Africa could reduce infant mortality by up to 40 percent (Summers 1994).

Economic Benefits of Programs

The educational gains from school health and nutrition programs should be considered in the context of alternative educational inputs, such as improving teacher salaries and qualifications, reducing class size, improving school facility infrastructure, and providing instructional materials. Many studies relate student outcomes to school characteristics, but few of these studies provide information on the relative or actual costs of the educational inputs. The costs, however, are substantially greater than for the school health interventions considered here. Despite the higher costs, the evidence from the few randomized evaluations that have been conducted suggests that the scale of effect of additional education inputs is typically low (see discussion in Miguel and Kremer 2004). A review of studies showed that instructional materials (such as additional textbooks) had the highest productivity, raising student test scores significantly more than other inputs for each dollar spent. However, even these interventions have only a weak effect. In a randomized experiment in Kenya, for example, providing textbooks had no effect on the bottom three quintiles of students and raised test scores by only 0.2 SD for the upper two quintiles. Relating these results to the findings in the previous section and to the annual per pupil costs, school health interventions appear very cost-effective compared to the highest-productivity, more traditional education inputs.

Recently, conditional cash-transfer programs have been viewed as potentially very cost-effective methods to increase school enrollment. These programs are generally large in scope, representing a commitment of between 0.1 and 0.2 percent of gross national income. The ProgresA program in Mexico is estimated to have increased enrollment by 3.4 percent and to have increased schooling by 0.66 years, with an average cash transfer (for grades 3 to 8) of about US\$136 per child per school year (assumed to be 180 days). Gains from a similar program in Nicaragua were estimated at 0.45 years of school at a cost of US\$77 per year. If we compare these results with those presented for school health and nutrition programs, the condi-

tional cash-transfer approach is, in both cases, apparently at the lower end of effectiveness and the higher end of cost.

IMPLEMENTATION OF PROGRAMS AND LESSONS FROM EXPERIENCE

The FRESH framework provides strategic guidance, but the practical design of actual programs reflects differences in local needs and capacity. Successful and equitable programs in low- and middle-income countries are characterized by a focus on school-based delivery, on a public health paradigm that minimizes the need for clinical intervention and reliance on health service facilities, and on participation of the public sector and civil society locally.

Policy and Economic Issues in Defining Sectoral Roles in Intervention

A negative correlation between income level and both ill health and malnutrition is clearly demonstrated both in cross-country comparisons and within countries (see de Silva and others 2003), partly because poverty promotes both disease and an inadequate diet. Similarly, children who are not enrolled in school come from households with lower income levels (Filmer and Pritchett 2001). This fact suggests that school health services that are pro-poor and specifically linked to efforts to achieve universal participation in education will have a greater return.

Early school health programs, particularly in colonial Africa, were intended to serve the minority of children who had access to school in urban centers or elite boarding facilities. They relied on specific infrastructures and services—such as mobile health teams, school visits, school nurses, and in-school clinics—that were additional to the normal range of health service provision. This approach has proven difficult to make universally available, even in middle-income countries. A school nurse program in KwaZulu-Natal, for example, achieved inadequate coverage (18 percent of the target population) and little referral or follow-up treatment of cases of ill health detected, despite a relatively high investment of US\$11.50 per student targeted per year (World Bank FRESH Toolkit 2000). As shown in the following examples, using the FRESH framework approach reduces costs significantly and enhances both coverage and outcomes.

An important element of the new approach to school health is a focus on minimizing the need for clinical diagnosis. Mass delivery of services, such as deworming and micronutrient supplementation, is preferable on efficacy, economic, and equity grounds to approaches that require diagnostic screening (Warren and others 1993).

Sectoral Roles in Implementation

Table 58.4 gives examples from low- and middle-income countries of how the four core components of FRESH are being supported by different approaches. In about 85 percent

Table 58.4 Nine Low- and Middle-Income Countries and How They Use FRESH

Program approach	Country examples	Policy	Environment	Health education	Health services	Outcomes (Costs per child per year)
Public sector: public sector—supported and —implemented	Guinea, Ghana, and Tanzania	In all three countries, the Ministry of Education (or in Ghana, its executive body, the Ghana Education Service) implements the program under the guidance of the Ministry of Health, on the basis of a formal policy agreement. In Tanzania, the Ministries of Community Development and of Local Government are also parties to the agreement. The existing in-service teacher training and supply-line infrastructures are used to prepare teachers and supply the necessary materials.	Separate sanitation facilities for girls and boys in all new schools; access to potable water in all schools.	Health, hygiene, and nutrition education as part of the formal curriculum.	Deworming (for both schistosomiasis and intestinal worms) provided by teachers twice a year; in Guinea, this service is followed by iron folate supplementation.	In three years, in Guinea—1.1 million students, in Ghana—577 schools and 83,000 students (US\$0.54), in Tanzania—353 schools and 113,000 students (US\$0.89).
Parastatal support for public sector intervention	Madagascar	The Community Nutrition Programme provides training and support to the Ministry of Education on the basis of a formally agreed-on health policy for the education sector. In all schools in the 43 poorest districts (44 percent of all districts), the program prepares teachers and provides materials. In addition, the program also provides Parent-Teacher Associations (PTAs) with access to a social fund to support construction of facilities. Each PTA can request up to US\$500, with a 20 percent community contribution based on an annual parental contribution of US\$0.16.	Access to potable water and hand-washing facilities, in all schools; where requested by PTAs, construction of latrines, wells, fences, and sports facilities.	A formal health education curriculum, supported by community information, education, and communication (IEC).	Twice-yearly deworming and iron folate (for three months) delivered by teachers; test kits to confirm iodization of local sources of salt; where requested by PTAs, provision of food preparation facilities.	In three years, 14,000 teachers trained in 4,565 schools, 430,000 students (US\$0.78 to US\$1.08 per capita per year).
Social fund: public sector support for community intervention	Tajikistan	The Ministry of Labor and Social Protection, with the Ministries of Education and of Health, have developed a memorandum of understanding that sets out health policies for the education sector. The program channels resources through PTAs, which identify and assist needy children. A training program, delivered by NGOs, prepares PTA members to develop proposals of up to US\$5,000 for their school to support activities selected from a menu of items.	Provision of sanitation facilities, potable water, and sports facilities.	Training of teachers in health promotion.	Training of teachers to provide first aid, micronutrients, and deworming; provision of food preparation facilities.	The program targets the 100,000 neediest children in all 200 schools in the six poorest districts of Tajikistan (US\$1 per capita per year).

Private sector: community payment for NGO-implemented intervention	Indonesia	The NGO Yayasan Kusuma Buana has a formal agreement with the education department in Jakarta and three other major cities to train teachers, perform diagnostic tests, and provide medicines and materials. The NGO offers Papanicolaou smear tests and referral services to teachers. Unit costs are low because parasite diagnosis involves mass screening in a central laboratory (approximately 2,500 diagnoses per day) and medicines are obtained at preferential rates from two commercial partners.	Not included in program.	Nutrition and hygiene education as part of the curriculum.	Stool examination by the laboratory and deworming by teachers as necessary twice a year; iron folate provided by teachers twice a year (for three months).	The program has been in existence for 17 years and currently reaches 627 schools and 161,000 students, at a cost to parents of US\$0.10 annually.
NGO implementation with financial support from public sector	Burkina Faso, Malawi, and the Philippines	The international NGO Save the Children U.S.A. implements school health and nutrition activities in nonformal schools created with support from government, local communities, and private donations.	Separate sanitation facilities for girls and boys and access to potable water.	Health, hygiene, and nutrition education as part of the curriculum supported by extracurricular IEC activities	Deworming and micronutrient supplementation (vitamin A and iron) provided by teachers annually.	In three years, in Burkina Faso, 42,000 students plus nonenrolled children in 171 schools (US\$2). In four years, in Malawi, 122,000 children in 181 schools (US\$3). In four years in the Philippines, 23,000 children in 53 schools (US\$6).

Source: Authors.

of programs reviewed, school health and nutrition programs are delivered and funded by the public education sector, with a formal role for the health sector in design and supervision.

Although this public sector “mainstream” model has proven the most popular approach, it is not the only successful one. In some cases, the public sector has identified appropriate options and developed operational manuals but then has used a social fund to provide direct support to communities and has used schools to select and implement the most relevant actions locally, often with the assistance of nongovernmental organizations (NGOs). In other cases, services have been contracted out by the public sector, and in some middle-income countries, the move toward a demand-led approach has resulted in a private sector service.

The private sector approach has proven sustainable over nearly two decades in urban Indonesia but may require a technical infrastructure and local market base that are inappropriate for predominantly rural low-income countries. The approach is modeled on a program initiated in Japan in 1948, which relied on private sector technicians, working independently at first but later formalized within the Japan Association of Parasite Control, who conducted stool examinations and then treated infected individuals for a per capita fee equivalent to approximately US\$0.74 in 2004. At its peak, the private sector program conducted some 12 million examinations annually, implying a turnover of nearly US\$9 million at today’s prices. The prevalence of roundworm infection fell from a high of 73 percent in 1949 to less than 0.01 percent by 1985.

Although a private sector response is effective in some circumstances, overall the characteristics of school health and nutrition programs make a compelling case for public sector intervention. First, treatment externalities may create external benefits to others in addition to the benefit for the treated individual. This situation is clearly the case for communicable disease interventions, especially against worm infection. Second, some forms of intervention (such as vector control, health education campaigns, epidemiological surveillance, and interventions that have strong externalities) are almost pure public goods; that is, no one can be excluded from using the goods or service they deliver, and thus the private sector is unlikely to compete to deliver these goods. Finally, there is typically little private demand for general preventive measures, such as information on the value of washing hands. None of these factors is an argument against a private sector role in service delivery, but they do suggest that private sector demand is likely to be greater in middle-income populations and where public sector actions have created a demand.

Roles of Key Stakeholders in Implementation

There are many ways to approach the delivery of school health, but these diverse experiences suggest common features—in

particular, the consistency in the roles played by government and nongovernmental agencies as well as other partners and stakeholders (table 58.5). In nearly every case, the Ministry of Education is the lead implementing agency, reflecting both the goal of school health programs in improving educational achievement and the fact that the education system provides the most complete existing infrastructure for reaching school-age children. However, the education sector must share this responsibility with the Ministry of Health, particularly because the latter has the ultimate responsibility for health of children. It is also apparent that the program’s success depends on the effective participation of numerous other stakeholders, including civil society, and especially the beneficiaries and their parents or guardians. The children and their families are the clients of these programs, and their support for program implementation is critical to the program’s success.

Key Issues in Designing Effective Programs

The diverse experiences of school health programming suggest some key elements that are common contributors to success in many programs.

- *Focus on education outcomes.* Making explicit links among school health programs and learning and education sector priorities (especially EFA and gender equity) helps ensure the commitment of the sector to program support and implementation.
- *Develop a formal, multisectoral policy.* Education sector actions in health require the explicit agreement of the health sector. This potential tension can be resolved by defining sectoral responsibilities at the outset; failure to enter into dialogue has led, in Africa and Central Asia, to some health sectors resisting teacher delivery of deworming drugs, despite WHO recommendations.
- *Initiate a process of wide dissemination and consultation.* Because there are multiple stakeholders, implementers, enablers, and gatekeepers, a process of consultation is necessary to establish ownership and to identify obstacles before they constrain progress. The process should involve at least community-based organizations, NGOs, faith-based organizations, pupils, and teacher associations. In one country in East Africa, lack of prior agreement on the content of sexuality education delayed implementation for more than three years.
- *Use the existing infrastructure as much as possible.* Building on existing curriculum opportunities and the network of formal and nonformal teachers will accelerate implementation and reduce costs. Programs that rely on the development of new delivery systems—mobile school health teams, a cadre of school nurses—take longer to establish and are expensive and complicated to sustain and take to scale.

Table 58.5 Roles of Agencies, Partners, and Stakeholders in School Health and Nutrition Programs

Partner	Roles	Comments
Ministry of Education	Lead implementing agency Lead financial resource Education sector policy	Health and nutrition of schoolchildren is a priority for EFA. Education policy defines school environment, curriculum, duties of teachers. Education system has a pervasive infrastructure for reaching teachers and school-age children.
Ministry of Health	Lead technical agency Health sector policy	Health of school-age children has lower priority than clinical services, infant health. Health policy defines role of teachers in service delivery, procurement of health materials.
Other public sector agencies (for example, Welfare, Social Affairs, local government)	Support for education and health systems Fund holder	Ministries of local government are often fund holders for teachers and schools and for clinics and health agents. Ministries of Welfare and Social Affairs provide mechanisms for providing social funds.
Private sector (for example, health service, pharmaceuticals, publications)	Specialist service delivery Material provision	Sector has major role in drug procurement and training materials production. Sector has specialist roles in health diagnostics.
Civil society (for example, NGOs, faith-based organizations, PTAs)	Training and supervision Local resource provision	At the local level, organizations serve as gatekeepers and fund holders and may target implementation. Organizations provide additional resource streams, particularly international NGOs.
Teacher associations	Definition of teachers' roles	School health programs demand an expanded role for teachers.
Community (children, teachers, parents)	Partners in implementation Definition of acceptability of curriculum and teachers' roles Supplementation of resources	Communities are gatekeepers for the content of health education (especially moral and sexual content) and for the role of nonhealth agents (especially teachers) in health service delivery; pupils are active participants in all aspects of the process at the school level. Communities supplement program finance at the margins.

- *Use simple, safe, and familiar health and nutrition interventions.* Success in rapidly reaching all schools depends on stakeholder acceptance, which is more likely if the interventions are already sanctioned by local and international agencies and are already in common use by the community.
- *Provide primary support from public resources.* Compelling arguments exist for public investment in school health programs: the contribution to economic growth, the high rate of return, the large externalities, and the fact that the majority of interventions are public goods.
- *Be inclusive and innovative in identifying implementation partners.* Although public resources are crucial for school health programs, contributions from outside the public sector can be vital. NGOs have proven effective in supporting public sector programs through training and supervision, particularly at local levels. Although market failure appears to have largely precluded the private sector from effectively implementing national programs in low-income countries, examples of successful contributions do occur, particularly in dense urban populations and in middle-income countries.

RESEARCH AND DEVELOPMENT AGENDA

Reliable evidence suggests that ill health and malnutrition affect education access, participation, completion, and achievement, and that school-based health and nutrition programs can provide a cost-effective and low-cost solution. This evidence does not imply, however, that no uncertainties exist.

Cost-Effectiveness of School-Based HIV/AIDS Prevention

Substantial evidence suggests that skills-based health education, including life-skills development programs, can promote positive behaviors and reduce the risks of exposure to HIV infection, and that girls' education programs have similar effects (Kirby 2002). Evidence also exists for a positive effect of completing education on HIV prevalence (de Walque 2004; World Bank 2002). What is lacking is direct evidence about the contribution that school-based prevention programs can make in reducing the incidence of HIV infection, as well as evidence for the relative cost-effectiveness of such programs compared with existing efforts to promote education completion and girls' education.

Cost-Effectiveness of Malaria Programs

Malaria occurs commonly in schoolchildren, particularly in areas of unstable transmission in Africa and Asia. It is a leading source of mortality in this age group and adversely affects education by reducing school attendance, cognition, learning, and school performance. Current school-based approaches focus on knowledge of the disease and the use of impregnated bed-nets but do not address the need for treatment of affected children. Yet presumptive treatment by teachers has been shown to significantly reduce mortality (Pasha and others 2003), and intermittent preventive treatment also shows considerable promise (Brooker and others 2000). There is a need to confirm the success of school-based treatment in different epidemiological settings and to address questions about the cost and sustainability of this approach.

Cost-Effectiveness of Targeting Food Aid

The high prevalence of malnutrition in children continues to be a major challenge for low-income countries. Providing food to children at school is often seen as an important part of the solution and is a major focus for food aid. However, the nutrition literature suggests that ensuring good nutrition earlier in life—certainly before 3 years of age, but perhaps earlier—is essential to ensuring an appropriate development trajectory throughout life (see chapter 27). Where food is limiting, it raises the question whether the first target should be preschool rather than school-age children. This debate has been blurred by admixing the nutrition outcomes with broader social and education issues. Clearly, providing a meal at school is socially desirable and can offer education benefits for children who otherwise would have to walk often long distances home to eat or remain hungry. It is also clear that schools represent an extensive and established network for providing nutrition interventions to very large numbers of children at a low cost per child. No comparable network exists to reach preschool children. However, from a nutritional perspective, it remains unclear whether ensuring good nutrition early in life has more effect on subsequent development—including educational achievement—than providing food at school age.

CONCLUSIONS

The rationale for school-based health and nutrition programs and the approach to their implementation have undergone a paradigm shift over the past two decades.

The traditional perception of these programs as seeking to improve the health of schoolchildren cannot be justified on the basis of mortality or public health statistics alone. Instead, it is increasingly recognized that a major—perhaps the major—impact of ill health and malnutrition on this age group is that on cognitive development, learning, and educational achievement.

In consequence, the clearest benefit of school health and nutrition programs is measurable in terms of education outcomes and their economic returns. The scale of benefit is significant: school health and nutrition interventions can add four to six points to IQ levels, 10 percent to participation in schooling, and one to two years of education. This scale of benefit can add 8 to 12 percent to labor returns and provide a rate of return that offers a strong argument for public sector investment.

Compelling evidence suggests that education qua education can help protect individuals from HIV infection. Achieving EFA goals and combining this outcome with school health programs that help establish lifelong positive behaviors are now recognized as essential to the multisectoral prevention response to HIV/AIDS.

The scale of the education benefit and the role of education in the fight against HIV/AIDS mean that school health and nutrition programs are today seen as a priority for both the education and the health sectors. This focus, in turn, has resulted in a shift toward public health rather than clinical intervention and toward school-based delivery rather than health system approaches. These policy changes enhance cost-effectiveness and social progressiveness, because delivery through the school system is an order of magnitude less costly than using health systems and in low-income countries is better targeted to the poor.

These changes in emphases have coincided with significant technical and political policy reform. Technical consensus around the FRESH framework has encouraged countries and agencies to develop programs around a common coordinating principle, while the political imperative has been strengthened by the recognition that school health and nutrition programs are essential to achieving EFA and the Millennium Development Goals and are at the center of the preventative response to the HIV/AIDS pandemic.

Although much of this change has evolved over the past two decades, significant acceleration has occurred since the World Education Forum in 2000. Today, a majority of low-income countries have recognized the need for school health and nutrition programs and are seeking to implement them.

NOTES

1. These calculations assume the following: a return to an additional year of school is 7 percent; wage gains are earned over 40 years in the workforce, discounted at 5 percent per year with no wage growth; annual wage earnings are US\$400 per year, which is below the estimated agricultural and nonagricultural annual wages for low-income countries (World Bank 2003). The opportunity costs of the additional schooling (child labor) have not been considered but are likely to be negligible.

2. These calculations assume that a pupil's falling behind the equivalent of one year in test scores has the same effect on earnings as losing one year of schooling; that the advantage that third graders have over second graders, for example, is the same as the advantage someone who has studied for a total of three years has over someone who has studied for two years; and that the impact of first-grade examination scores on

the probability of transition from one class to the next is the same at each grade level.

3. If an increase of 1 SD in exam scores leads to children being 4.8 times as likely to reach seventh grade, the increased likelihood of reaching seventh grade because of a 0.25 SD increase can be calculated as EXP (0.25 × LN(4.8)).

Chapter 59

Adolescent Health Programs

Elizabeth Lule, James E. Rosen, Susheela Singh, James C. Knowles, and Jere R. Behrman

This chapter reviews the main direct causes of loss of productive life years among adolescents and the range of interventions to address these causes. It pays special attention to sexual and reproductive health because adolescence is when important transitions occur that can have a direct effect on young people's health as well as potential long-term consequences. In addition, a number of interventions have focused on this aspect of young people's behavior. The discussion centers on defined interventions that have some relatively rigorous evaluation component. There are some limitations to this chapter, however. First, it reviews existing research and does not carry out new research; however, it points to gaps in research and areas needing more work. Second, the chapter uses a focused definition of *health* that includes the most basic health outcomes (death, illness, timing of transitions, or specific risky or protective behaviors that research has attempted to measure). It does not attempt to cover aspects that would be included in a broad definition of health and well-being (for example, potential for growth, creativity, or participation) that are important but are poorly researched to date. Finally, although the broader environment in which adolescents live influences their behavior and responses to programs, this chapter does not attempt to review that important group of factors or the broader set of programs that have a more indirect effect on the health of young people (for example, school quality or public health promotion activities at the societal level).

NATURE AND CAUSES OF THE BURDEN OF DISEASE IN YOUNG PEOPLE

At first glance, adolescence appears to be a relatively healthy—although not hazard-free—period of life, given the relatively low mortality rates of young people.¹ Nevertheless, adolescents

and young adults engage in a range of behaviors that can affect the quality of their health and the probability of their survival in the short term as well as affect their lifetime health and survival.

Health Challenges of Adolescents

If we look only at disability-adjusted life years (DALYs) for the adolescent age group, adolescents appear to be relatively healthy. Nonetheless, more than 33 percent of the disease burden and almost 60 percent of premature deaths among adults can be associated with behaviors or conditions that began or occurred during adolescence—for example, tobacco and alcohol use, poor eating habits, sexual abuse, and risky sex (WHO 2002). Adolescence-related risk factors are a greater problem in wealthier countries, largely because of the relatively greater impact of smoking and diet-related risks in those countries, though the prevalence of these risks is expanding rapidly in many low- and middle-income countries (LMICs). Thus, although adolescents are apparently healthy, they are practicing unhealthy behaviors that will ultimately result in much death and disability. This is an immense public health issue. Therefore, focusing attention both on diseases experienced during adolescence and on risk factors with their roots in adolescence makes sense. Adolescent health efforts should emphasize prevention because so much of the disease burden is preventable and because prevention is a particularly cost-effective strategy in relation to adolescents, given the long duration over which benefits will be reaped and adolescents' greater openness to change than adults.

Burden of Disease in Adolescence

The global burden-of-disease approach used to calculate DALYs is an imperfect representation of the prevalence, morbidity, and

Table 59.1 Worldwide Distribution of DALYs for Major Categories of Diseases and Conditions by Age Group and Sex, 2002 (percent)

Category	Women		Men	
	Age 5–14	Age 15–29	Age 5–14	Age 15–29
Sexual and reproductive causes	4.6	33.4	3.9	9.5
HIV/AIDS	3.8	11.9	3.7	8.6
Maternal conditions	0.4	16.3	0.0	0.0
Other sexual and reproductive conditions	0.4	5.2	0.2	0.9
Respiratory conditions	11.9	3.7	9.9	3.7
Cardiovascular conditions	2.2	2.9	2.0	3.3
Neuropsychiatric conditions	15.5	33.8	14.9	32.0
Unipolar depressive disorders	5.4	10.1	5.6	7.1
Bipolar disorders	0.6	4.1	0.7	4.2
Schizophrenia	0.7	4.4	2.3	4.2
Other mental health conditions	1.0	4.4	0.6	2.6
Alcohol use disorders	0.1	1.1	0.3	5.7
Drug use disorders	0.1	0.6	0.2	2.3
Other	7.6	9.1	5.2	5.9
Injuries	25.0	14.0	32.4	33.1
Unintentional, road traffic accidents	5.7	2.2	7.7	7.5
Unintentional, other	16.8	7.7	21.8	12.9
Intentional, self-inflicted	1.0	2.9	0.9	3.8
Intentional, not self-inflicted (war, violence)	1.5	1.2	2.0	8.9
Other communicable diseases	31.1	7.1	27.7	11.1
Tuberculosis	1.5	3.0	1.4	3.9
Other noncommunicable diseases	9.9	9.6	9.2	10.0
Total	100.2	104.5	100.0	102.7

Source: WHO 2004a.

mortality of conditions that adolescents face. DALYs fail to capture fully the complexity of adolescent health concerns. Nonetheless, no better comprehensive and comparative measure currently exists; thus, the discussion in this section will rely primarily on available DALY data.

The World Health Organization (WHO), in 1999, commissioned a special analysis of the burden of disease in adolescence, which examined the 10 to 14 and the 15 to 19 age groups. The study found that young people age 10 to 19, who constitute 19 percent of the world's population, account for 15 percent of the disease and injury burden worldwide. It also found that more than 1 million people in that age group die each year (WHO 1999). The top three causes of DALYs were found to be unipolar major depression, transportation accidents, and falls. The profile of disease burden was significantly different for younger and older adolescents. In the 10 to 14 age group, injuries and communicable diseases were prominent causes of DALYs. For the 15 to 19 age group, the disease burden shifted to outcomes of sexual behaviors and mental health.

Using 2002 data, WHO has made more detailed calculations of DALYs by sex for the 5 to 14 and 15 to 29 age groups (table 59.1). These age ranges overlap adolescence and are, thus, broadly indicative of the 10 to 19 age group. Notably, table 59.1 shows large differences by sex in the pattern and level of DALYs. These differences are important, because they relate to the different needs of young women and young men for interventions and services. Particular interventions also potentially have different costs and benefits because of the different proportions of females and males.

Worldwide, among young men age 15 to 29, injuries and neuropsychiatric illnesses account for a high proportion of DALYs (33 percent and 32 percent, respectively). By comparison, among young women age 15 to 29, injuries account for 14 percent of DALYs, and neuropsychiatric illnesses account for about the same percentage of DALYs as among young men. However, sexual and reproductive health conditions account for 33 percent of young women's DALYs, much higher than the 10 percent for young men. For both young men and young women, all other communicable and noncommunicable

diseases account for moderate proportions of DALYs (7 to 11 percent, depending on sex and disease group).

The disease burden among 5- to 14-year-olds is markedly different from that for the 15- to 29-year-olds, and differences between males and females are quite small. Communicable diseases and respiratory illnesses account for much larger proportions of DALYs for this age group compared with the 15 to 29 age group, whereas neuropsychiatric and sexual and reproductive conditions account for much smaller proportions. HIV/AIDS accounts for less than 4 percent of DALYs for both males and females age 5 to 14.

Health Risk Behaviors among Adolescents and Young People

Young people's vulnerability to risky or unwanted sex and other unhealthy behaviors is tied to a host of individual, family, and community factors that influence their behavior and that are closely related to their economic and educational opportunities. Good health and other physical, moral, and intellectual development outcomes are often mutually reinforcing. For example, healthy children do better in school. Similarly, having more years of schooling provides essential information and skills that are linked to more protective and less risky behaviors.

Injuries. Violence and war account for more than a quarter of injury-related deaths among young men age 15 to 29. Adolescent boys and men in their 20s are an important part of the military forces in all countries that have such forces. As such, they are at high risk, particularly in areas where armed conflict is occurring. The United Nations Children's Fund estimates that approximately 300,000 soldiers under the age of 18 are involved in armed conflicts worldwide (National Research Council and Institute of Medicine 2005). Homicide is also an important cause of death for young men, in particular, and it is the leading cause of death for young men in some Latin American countries (WHO 2001b). In addition, road accidents account for significant proportions of injuries and deaths among young people. Self-inflicted injuries, including suicide, which are often related to mental illness, are also a major health problem for young people, accounting for 4 percent of DALYs in men age 15 to 29 and 3 percent of DALYs in women age 15 to 29.

Mental Health. Depression, schizophrenia, and other mental illnesses are important causes of illness and death among young men and women and account for a significant proportion of DALYs for both men (18 percent) and women (23 percent) age 15 to 29; for 5- to 14-year-olds, it is about 9 percent for boys and 8 percent for girls. The relative importance of mental illnesses is much greater in the high-income countries.

Smoking, Alcohol, and Drug Use. Most adult smokers worldwide begin smoking in adolescence or earlier (World Bank 1999a). An estimated 15 percent of young men and 7 percent of women age 13 to 15 are currently smoking cigarettes, according to more than 100 surveys that have been conducted since 1999 by the Global Youth Tobacco Survey Program and carried out under the auspices of WHO and the U.S. Centers for Disease Control and Prevention (National Research Council and Institute of Medicine 2005). Every day, worldwide, almost 100,000 young people start smoking, more than two-thirds of them in LMICs (World Bank 1999a). Of the 300 million young people smoking today, half will eventually die from tobacco use (WHO 2001b). By 2030, tobacco is expected to be the single biggest cause of death worldwide, accounting for about 10 million deaths per year (World Bank 1999a).

Although discouraging young people from starting to smoke and providing means for them to quit is extremely important, deaths caused by tobacco tend to occur many years later. Therefore, tobacco use as an underlying risk factor accounts for very few DALYs in the 5 to 29 age group (WHO 2002). Alcohol and drug use account for 8 percent of all DALYs for young men age 15 to 29 but for only 2 percent for young women. Evidence indicates that young people are starting to drink at earlier ages. Longitudinal studies have found that the earlier young people start drinking, the more likely they are to experience alcohol-related injuries and alcohol dependence later in life (WHO 2001a).

Nutrition and Exercise. Nutritional deficiencies such as anemia are widespread in both young men and women. Worldwide, these conditions account for almost 5 percent of DALYs among girls age 5 to 14 and almost 4 percent among boys of the same age, with anemia being an important component for both girls and boys. Although nutritional deficiencies are relatively less important among 15- to 29-year-olds (just over 1.0 percent among young men and about 1.5 percent among women), anemia accounts for the bulk of these deficiencies. Chronic undernutrition that causes stunting among young people delays growth and physical maturation, increases risks to pregnant mothers and their newborns, and decreases the capacity to learn and to work (Behrman and others 2004; Hoddinott and Quisumbing 2003). Malnutrition can take other forms, some of which lead to being overweight or obese, thereby increasing the risks for diseases such as diabetes. Such forms of malnutrition are of increasing relevance in middle-income countries such as Brazil, China, the Arab Republic of Egypt, Mexico, and South Africa and at times coexist with undernutrition (see, for example, Doak and others 2000).

Nutritional deficiencies increase the risks that girls and young women face during pregnancy and childbirth (Delisle, Chandra-Mouli, and de Benoist 2001), and evidence is emerging about the connection between poor maternal nutrition and

greater risk of transmission of HIV from mothers to their infants (Piwoz and Greble 2000).

Diet and lifestyle-related chronic diseases—many with their roots in childhood and adolescence—are emerging as one of the most important health problems in LMICs. Cardiovascular diseases, which are responsible for 10 percent of DALYs lost in LMICs, typically occur in middle age or later; however, risk factors are determined to a great extent by behaviors learned during childhood and adolescence and continued into adulthood, such as dietary habits and smoking. Throughout the world, these risks are starting to appear earlier. Physical activity has decreased markedly in adolescence, particularly in girls, and obesity has increased substantially (MacKay and Mensah 2004).

Sexual and Reproductive Behaviors. Worldwide, the majority of young people initiate sexual activity during adolescence. Significant proportions—in some regions and countries, the majority—marry and become parents (table 59.2). Globally, the age of onset of puberty has been decreasing progressively for both boys and girls (National Research Council and Institute of Medicine 2005). The age at first marriage has also increased in most parts of the world over recent decades, except in Latin America (Mensch, Singh, and Casterline 2003). The decline in the age at puberty, combined with the general trend toward later marriage, increases the period of time during which adolescents may be sexually active before marriage and may result in sexual initiation at an earlier age (National Research Council and Institute of Medicine 2005).

Young women typically make the transition to marriage and parenthood at an earlier age than young men, and early marriage predisposes girls to HIV infection through unprotected sex, because the partner, by virtue of age, has an elevated risk of being HIV positive. In addition, marriage changes adolescent girls' support systems, thereby limiting their access to knowledge about HIV/AIDS (Bruce and Clark 2003).

All these key transitions to adulthood bring with them the potential for risks to health that may have both immediate and longer-term effects. Among young women age 15 to 29, illnesses related to pregnancy and childbearing account for 16 percent of their DALYs. Some have unwanted pregnancies, and in countries where abortion is legally restricted, unsafe abortion is an important source of mortality and morbidity for young women, with abortion complications accounting for almost 3 percent of DALYs worldwide among females age 15 to 29. (WHO 2004c).

Even though adolescent childbearing has declined in recent years, the proportion of young women who become mothers during adolescence remains high in most LMICs, and very early childbearing remains an issue in some regions (table 59.2). Childbearing before age 16 also brings with it a high risk of health consequences, both for the mother and for the newborn (Save the Children U.S.A. 2004; WHO forthcoming-b).

In the most recent surveys carried out in LMICs, high proportions of adolescents report that they have heard of contraceptive methods; however, little is known about the quality and accuracy of young people's knowledge of contraception. Moreover, substantial proportions of young women appear to have an unmet need for contraception; they are not using contraception even though they are sexually active and do not want to have a child (CDC and ORC Macro 2003; Westoff and Bankole 1995).

In addition to having a risk of early and unwanted pregnancy, adolescents are also at risk of acquiring sexually transmitted infections (STIs), including HIV. HIV/AIDS accounts for most of the sexual and reproductive health DALYs lost by young men age 15 to 29 (almost 9 percent). Among young women age 15 to 29, HIV/AIDS accounts for a higher proportion of DALYs than for young men (almost 12 percent) because of their higher levels of susceptibility. STIs and other sexual and reproductive health disorders together account for just over 5 percent of young women's DALYs, much more than among young men. About half of all HIV infections occur in people under age 25, and for biological, social, and economic reasons, young women are disproportionately affected, especially in Sub-Saharan Africa, where young women have twice the prevalence rate of young men (UNAIDS 2003).

Poverty and Adolescent Health

Poverty and inadequate health systems compound adolescents' vulnerability to sickness and early death. At the same time, poor health exacerbates poverty by disrupting and cutting short school opportunities, by weakening or killing young people in the prime of their working lives, or by placing heavy financial and social burdens on families.

Poor adolescents bear a disproportionate burden of the health problems in their age group. An analysis of data from demographic and health surveys (Macro International 1990–98, unpublished raw data) indicates a strong association between poverty and the health status of adolescents and between poverty and adolescents' use of health services. For example, the poorest 20 percent of young women are between 1.7 and 4.0 times as likely to have an early birth as the richest 20 percent of young women. Similar disparities between rich and poor adolescents are seen for indicators such as early marriage, skilled attendance at birth, use of contraception, and knowledge of HIV/AIDS transmission, and these disparities tend to be greater for adolescents than for older women. For example, surveys in 45 countries show that the poorest 20 percent of women age 15 to 49 have a total fertility rate almost double that of the richest 20 percent, whereas among adolescents age 15 to 19, total fertility among the poorest 20 percent is more than triple that of the richest 20 percent (Macro International 1990–98, unpublished raw data).

Table 59.2 Indicators of Sexual and Reproductive Behaviors among Adolescents and Youth by Gender and Age Group, Late 1990s to Early 2000s

a. Sexual Activity

Region	Percentage of females age 20–24 who became sexually active before age			Percentage of males age 20–24 who became sexually active before age

INTERVENTIONS

Improving the health of young people is complex and difficult, arguably more so than for other age groups. Compared with children, adolescents are less protected by their families and communities and less amenable to simple solutions to their health problems, many of which are behavior based. Compared with adults, adolescents know less about how to stay healthy and have fewer resources to prevent or treat health problems. By contrast, their behaviors are less firmly entrenched, and they are often involved in institutional activities, such as schools, training programs, and the military, where programs with high coverage can be sustained. The influences on young people's behaviors are becoming better understood (Blum and Mmari 2004; Pitts and others 2004), but even given what is known about such influences, the challenge of designing interventions to reinforce protective factors and mitigate risk factors remains. Many of the factors associated with less risky health behaviors, such as family connectedness and academic performance, go far beyond the purview of health program managers.

Programs will have to seek multisectoral solutions that link health sector interventions with other types of interventions delivered through other sectors, either at the program level or at the policy level. The difficulty in attributing improvements in health outcomes among adolescents to interventions delivered in multiple settings or sectors reflects the challenges involved. Programs aimed at young people are relatively new and untested. Nevertheless, accumulated experience, backed by an increasing body of research, has created international consensus around a multi-intervention approach centered on the following (WHO 1999):

- Young people need information and skills to make the right decisions about behaviors that affect their health, such as whether and when to have sex and whether to use tobacco.
- Young people need access to a broad range of health services that give them the means to act on their knowledge, including access to condoms.
- Young people need a social, legal, and regulatory environment that supports healthy behaviors and protects them from harm.

Interventions to improve adolescent health have typically reflected this consensus and are echoed in goals that have been adopted internationally.

This section summarizes what is known about the effectiveness of such interventions. Note that the health community's consideration of adolescent health has only occasionally advocated attention to those health conditions that are of relatively greater importance to the adolescent age group, at least as measured by indicators such as DALYS. Much of the focus has been on sexual and reproductive health and on risky behaviors

such as tobacco and drug abuse. The lack of age-specific data and traditional reliance on mortality and morbidity statistics contribute to the unbalanced attention. Another factor may be that such behaviors tend to have longer-term health consequences that are not reflected in standard DALY calculations. An additional reason for the imbalance in adolescent data may be the significant social impacts of sexual and reproductive behavior (for example, the contribution of high fertility to rapid population growth); the social and economic implications of large proportions of HIV-infected adolescents in many countries; the mortality implications of initiating tobacco use during adolescence; and the antisocial behavior associated with substance abuse. Public health systems' efforts to address health problems associated with road safety, malaria, and mental health have devoted inadequate attention to developing and implementing programs that target adolescents.

Evidence on Sexual and Reproductive Health Interventions

Two recent reviews summarize research on the effectiveness of adolescent sexual and reproductive health interventions. Table 59.3 presents the results of the FOCUS on Young Adults (2001) review. The FOCUS report looks at interventions in LMICs and is based on relatively rigorous evaluations of 40 programs. The general findings from the FOCUS review, supplemented by more recent research findings, are as follows:

- *Almost all programs are effective in promoting positive knowledge and attitudes.* Almost all the rigorously evaluated programs that FOCUS reviewed improved knowledge of reproductive health and selected attitudes.
- *Most programs effectively influence behaviors.* A majority of programs significantly changed at least one important adolescent behavior pertaining to reproductive health. Often, however, programs tried and failed to improve many important behaviors. Where research has found programs to be effective in changing behaviors, such changes have typically not been large.
- *All six categories of interventions studied proved effective at influencing reproductive behavior in at least one study.* However, maintaining that certain models are more effective than others is impossible because the period of observation and the behaviors that were influenced varied by study. Moreover, further replications in multiple settings are necessary to provide a basis for identifying the key features or elements of successful interventions.
- *The evidence base is limited in a number of ways.* Few studies look at the effects on ultimate health outcomes, such as pregnancy rates or rates of HIV infection. Furthermore, many promising approaches have not been rigorously evaluated. Only a few studies assessed effects on the use of health services, and none examined the effect of creating a

Table 59.3 Effectiveness of Adolescent Sexual and Reproductive Health Programs, LMICs

Type of program	Number of studies ^a	Number of programs showing significant impact/Total number of programs studied					
		Improved knowledge and attitudes	Impact on key behaviors				
			Delayed sex	Reduced number of partners	Increased contraceptive use	Increased service use	Improved at least one behavior

— = not available.

a. Numbers of studies in parentheses are subsets.

supportive environment on behaviors. Furthermore, much of the available evidence from strong studies is for small-scale programs that are carried out over short periods of time, and little evidence is available on long-term effects on behaviors (Speizer, Magnani, and Colvin 2003). A recent study in Tanzania provides the first rigorous evidence that the benefits of adolescent sexual and reproductive health programs in low-income countries can last for at least three years (AMREF, LSHTM, and NIMR 2003).

Kirby's (2001) review covers roughly 70 rigorously evaluated programs in Canada and the United States. The review divides programs into three categories: (a) programs that focus on sexual antecedents, such as sexuality and HIV education and clinical programs; (b) programs that focus on nonsexual antecedents; and (c) programs that incorporate both youth development and reproductive health components. Kirby finds that programs in all three categories proved effective in reducing sexual risk taking, pregnancy, and childbearing among teens. In relation to youth development programs, Kirby finds that a type of intervention known as *service learning*, in which students work on community projects, had the strongest evidence of effectiveness. By contrast, other types of youth development programs were not effective in improving reproductive health outcomes. Programs that incorporate both youth development and reproductive health components were effective over long periods.

In synthesizing U.S. and international data, Kirby (2003) finds that programs are effective with different groups of adolescents in different countries. Also, programs seem to be particularly effective for adolescents who are at especially high risk of negative sexual and reproductive behaviors. In addition, programs do not hasten or increase sexual activity—a common criticism of opponents of adolescent programs. Of all the programs that have been rigorously evaluated, none has reported a decrease in the age of sexual debut or an increase in sexual activity among young people. A recent effort to review the evidence on interventions for preventing HIV among young people has made tentative conclusions about the effectiveness of and subsequent support for wide-scale implementation (WHO 2004b).

On the basis of these international reviews, relatively strong evidence of effectiveness on a range of outcomes has emerged for the following interventions:

- *Life-skills and health and sexuality education in schools.* Well-designed, well-implemented sexuality and reproductive health education can provide young people with a solid foundation of knowledge and skills to enable them to engage in safe and responsible sexual behavior.
- *Peer education.* Peer education programs are especially appropriate for young people who are not in school and for hard-to-reach, at-risk subsets of the youth population, including sex workers and street children.

- *Mass media and community mobilization.* Mass media and community mobilization efforts that engage influential adults, such as parents, teachers, community and religious leaders, and music and sports stars, can help normalize positive adolescent behaviors and gender roles as well as direct young people to appropriate health services.
- *Youth development programs.* Youth development programs typically address a range of key adolescent needs, including life skills, education, jobs, and psychosocial needs. U.S. programs with a voluntary community service component have successfully improved key reproductive health behaviors, but no evidence is available for developing countries.
- *Clinical health services.* Although some young people seek care through the formal health system, many others are deterred by the often judgmental attitudes of health workers, particularly when seeking care and advice on matters related to sexuality.
- *Social marketing.* This approach involves the use of public health messages to promote healthy behaviors and the use of condoms and other health products and services. Effective programs bring products and services to places in the community that young people frequent, such as shops, kiosks, and pharmacies.
- *Workplace and private sector programs.* Programs that reach young people do so at their places of work and through private channels, such as pharmacies and for-profit medical services, where many young people prefer to seek care. Many successful U.S. youth development programs have a work component.

Evidence of Other Adolescent Health Interventions

Data on the effectiveness of other adolescent health interventions are more scattered, partly because some issues have not been recognized as adolescent-specific problems that require youth-focused interventions.

Nutrition. Because anemia is a critical health problem in many countries, many efforts have focused on improving the iron intake of adult women. Interventions aimed at adolescent girls have found that daily iron supplementation effectively lowers anemia and iron deficiency (Elder 2002; MotherCare 2000). Obesity is rapidly becoming a serious health problem among adolescents in many middle-income countries and is often also associated with loss of self-esteem among adolescents. A few studies show that preventing obesity is more successful among adolescents than among adults (Delisle, Chandra-Mouli, and de Benoist 2001).

Mass Deworming. In the Busia district of western Kenya, an ongoing World Bank study is evaluating the effect on learning outcomes of providing deworming treatment to all students in

a school. After two years, observed effects of deworming treatment included fewer absences and lower dropout rates, but no effect on test scores (World Bank 2002a). The treatment also resulted in health and school participation benefits among untreated children in the same schools, as well as in neighboring schools, suggesting that the deworming had positive externalities.

Tobacco. Price increases are the most effective tool for reducing or deterring the use of tobacco products by young people. Studies in the United States have shown that price increases have a greater effect on tobacco use by young people than on use by older age groups (University of Illinois at Chicago Health Research and Policy Centers 2001). Other interventions have also reduced tobacco use among young people, such as comprehensive bans on all advertising, including bans on the promotion of tobacco products and trademarks (World Bank 2002c). Programs that give young people the skills to resist peer pressure and other social pressures to smoke have demonstrated consistent and significant reductions or delays in adolescent smoking. School-based programs are also more effective when combined with communitywide supportive efforts. Information campaigns that help young people see how the tobacco industry tries to manipulate their behavior through advertising have been highly effective in changing behavior and attitudes toward smoking among young people in the United States (American Legacy Foundation 2002).

Promising but Unproven Interventions

Many promising adolescent-focused interventions have not yet been rigorously evaluated. These interventions include programs aimed at providing young, newlywed couples with reproductive health information and services (Alauddin and MacLaren 1999); programs that combine livelihoods skills with reproductive health information and services (Rosen 2001b); voluntary counseling programs on and testing for HIV (YouthNet 2002); actions aimed at changing social norms such as gender roles (Horizons 2004); and interventions that address the political and social context (WHO forthcoming-a). A few studies of multipronged approaches are just becoming available and have shown mixed results. Findings from a four-country study found little or no effect of such an approach on key reproductive health behaviors among adolescents (Frontiers, Horizons, and YouthNet 2004). By contrast, a study in Tanzania found that a multicomponent approach had a significant effect on key reproductive health behaviors but no effect on health outcomes (AMREF, LSHTM, and NIMR 2003).

Other possibly promising efforts include suicide prevention programs, tuberculosis education linked with health education (interpersonally or through the mass media), and malaria treatment programs that focus on young people. Adequate

evaluation is available on the efficacy of programs promoting the use of seat belts and crash helmets through enforcement of related laws and the support of intensive publicity and information campaigns, as well as on the efficacy of programs preventing alcohol use among adolescents. The evaluations are sufficient for building confidence for investment, and they serve as a basis for intervention design (National Research Council and Institute of Medicine 2004; WHO 2004d).

COSTS AND COST-EFFECTIVENESS OF INTERVENTIONS

Good cost studies of adolescent health programs in LMICs are rare. The reported cost of such programs varies greatly depending on the country, type of intervention, target group, and so on. For example, such programs cost between US\$0.03 per adolescent reached in a family life education radio program in Kenya and US\$71.00 per year per adolescent reached in a school-based HIV prevention program in Zimbabwe. Of the 32 programs studied, 12 have a unit cost of less than US\$10 per year, and others have a unit cost of US\$10 to US\$25 (table 59.4). Cost estimates are available only for certain types of interventions, with most of the estimates being for reproductive health and HIV education programs. A few studies have tried to measure cost per DALY of adolescent sexual and reproductive health interventions; however, the estimates vary widely. For example, in India, a youth-focused HIV prevention program costs US\$66.20 per DALY gained; in Honduras, the cost of a voluntary counseling and testing program aimed at youth is US\$5,873 per DALY gained.

The estimates shown in table 59.4 should be interpreted with great caution. Comparing costs across types of programs and countries is difficult, but so is choosing comparable effectiveness measures.^{3,4}

ECONOMIC ANALYSIS

Economic analysis of adolescent health programs can provide important information on their value relative to other interventions.

Economic Benefits of Interventions

The macro approach to measuring the economic benefits of interventions is to define the benefits of investing in youth in terms of the investments' effect on economic growth, which typically is measured in terms of growth in gross national product per capita. Some research suggests that investments in young people—whether in access to reproductive health care, in education, or in other key facets of their lives—have

synergistic effects that promote overall economic development (Birdsall, Kelley, and Sinding 2001). For example, shifts to smaller family size and slower rates of population growth in East Asia appear to have played a key role in the creation of an educated workforce, the accumulation of household and government savings, the rise in wages, and the spectacular growth of investment in manufacturing technology. The shift to smaller families that is taking place in many countries will open another window of opportunity as workers have proportionately fewer old and young dependents to support.

If societies invest in health, education, and job creation, the resulting economic gains will improve their overall quality of life. Education, particularly for girls, is strongly related to reproductive behavior. In most countries, girls who are educated are more likely to delay marriage and childbearing, whereas girls with less education are more likely to become mothers as adolescents. Unfortunately, the causal relationships involved are not clear. Are girls more likely to get married when they leave school, or do some girls prefer to terminate their schooling and marry early? The difference is critical. In the first case, the appropriate policy response would focus on improving schooling opportunities for girls. In the second case, research would need to be done first to determine the underlying reasons for girls'—and their parents'—preferences for early marriage instead of additional schooling. The next step would be to assess whether these reasons appear to reflect the girls' (and society's) best interests and, if not, to find interventions to address the root causes of this preference.

The micro approach to measuring the economic benefits of interventions is to build on microeconomic estimates of direct productivity effects that can be measured in monetary terms. For other effects that cannot readily be translated into monetary terms, analysts can use the cost of the most cost-effective alternative to achieve the same effects. Knowles and Behrman (2003a) use this approach to estimate the benefits of various youth-focused investments, including in health. They summarize the three types of effects: (a) those that can be directly valued in monetary terms, (b) those that may require indirect valuation, and (c) those that are particularly difficult to monetize. Table 59.5 presents examples of these effects.

Cost-Benefit Analysis

Cost-benefit analysis is well suited to the economic analysis of projects aimed at youth, in part because many investments in young people yield multiple benefits, such as additional schooling and improved health. Finding any effectiveness measure that adequately reflects the wide range of benefits obtained from some types of investments in youth is difficult, but cost-benefit analysis has the advantage of allowing comparisons across a range of interventions that may vary considerably in terms of type and effects.

Table 59.4 Cost and Cost-Effectiveness of Adolescent Health Programs

Region and country	Program type (name)	Number served per year	Unit cost (US\$)	Unit	Cost per DALY gained (US\$)	Source
Sexual and reproductive health interventions						
<i>Latin America</i>						
Brazil	School-based HIV/AIDS prevention program	—	0.70	Per condom	—	Antunes and others 1997
Honduras	School-based reproductive health program to prevent HIV/AIDS	—	10.44	Per targeted adolescent	1,323	World Bank 2002b

One of the few cost-benefit analyses specific to adolescent health is Knowles and Behrman’s (2003a) study that examines three interventions: a program to provide iron supplementation for secondary schoolchildren, a school-based program of health education to prevent HIV/AIDS, and a tobacco tax. The study estimates benefits and costs over a youth’s life cycle, discounted back to the age of 18. The study uses direct estimates of benefits that could be readily estimated in monetary terms (such as gains in labor productivity) and indirect estimates of other benefits, such as reduced fertility and improved health, that could not be easily monetized. The latter were estimated as

the least cost of investments currently made to obtain the same benefit; for example, the cost per birth averted in a family planning program was used to value reduced fertility. Table 59.6 summarizes the findings of these cost-benefit studies, together with estimates of the benefit-cost ratios for selected other youth-targeted interventions.

The examples of cost-benefit studies cited here and other calculations of benefit-cost ratios show that health interventions aimed at adolescents can be good public investments; however, the results must be interpreted with some caution. For example, the relatively low benefit-cost ratio of an HIV

Table 59.5 Types of Effects of Adolescent Health Interventions Categorized According to Ease of Monetization

Type of effect	Examples
Directly monetizable effects of investments in youth	Enhanced labor productivity Reduced underutilization of labor Increased or decreased work effort Expanded access to risk-pooling services Reduced age at which children achieve a given level of schooling Reduced cost of medical care
Indirectly monetizable broad effects of investments in youth	Increased education Averted teen pregnancy Averted HIV infection Averted tuberculosis infections Improved health Improved nutritional status Delayed marriage Averted abortion Reduced tobacco use
Effects that are particularly difficult to monetize	Increased social capital Averted infertility Averted social exclusion Improved self-esteem Enhanced national security (an effect of military training)

Table 59.6 Estimated Benefit-Cost Ratios, Selected Investments in Youth

Investment	Estimated benefit-cost ratio (assuming 3 percent annual discount rate)	Plausible range of estimated benefit-cost ratio
Scholarship program (Colombia)	4.4	2.8–25.6
Adult basic education and literacy program (Colombia)	27.6	8.1–1,764.0
School-based reproductive health program to prevent HIV/AIDS (Honduras)	0.5	0.1–4.6
Iron supplementation administered to secondary schoolchildren (hypothetical low-income country)	45.2	25.8–45.2
Tobacco tax (hypothetical middle-income country)	20.2	7.0–38.6

Source: Adapted from Knowles and Behrman 2003a.

prevention program in Honduras was for a program in a country where HIV incidence among young people is relatively low (0.1 percent). Where the incidence is much higher, as in many of the hardest hit countries in Africa (1 percent or more), this ratio would be proportionately higher. In addition, in the Honduran study, the benefits included were limited to the prevention of HIV/AIDS and did not include other possible benefits, such as increased education, reduced STIs other than HIV, and reduced teen pregnancies and abortions. The Honduran study also assumed that the effects of the intervention would not continue beyond one year; however, if they were to continue at the same level to age 29 (assuming that any decrease in the effect of the intervention over time would be offset by increases in the incidence of HIV infection with age), the benefit-cost ratio would increase from 0.5 to 4.6. More than anything else, Knowles and Behrman's estimates demonstrate the sensitivity of the benefit-cost ratios of investments in youth to wide variations in key assumptions, which may be equally plausible because of the limited information available on the costs and effects of many investments in youth.

Beyond the question of how sensitive such estimates are to the underlying assumptions and the context, the basic question is what guidance they provide for public policy. High benefit-cost ratios certainly point to areas that merit further consideration for possible policy interventions, but they do not indicate whether using public resources for interventions has an efficiency rationale, because they generally do not identify differences between private and social benefit-cost ratios. If the purely private benefit-cost ratios for an investment are high, then presumably incentives to use private resources for this investment are high, but an efficiency rationale for using public resources does not exist unless the social benefit-cost ratio exceeds the private one because of factors such as spillovers or market imperfections. High benefit-cost ratios that do not distinguish between social and private returns, therefore, call for further investigation. Interventions may warrant the use of public resources on efficiency grounds, but they also must answer that important question of whether the benefits are social or private.

PROGRAM IMPLEMENTATION AND LESSONS OF EXPERIENCE

Relatively few adolescent-focused programs have been tried on a large scale. Sexual and reproductive health interventions and suicide prevention are some of the few that have gone to scale, and even in those areas, large-scale interventions are relatively infrequent. The vast majority of interventions have been in relatively small programs, often through nongovernmental organizations.

Perhaps the main lesson learned from the experience to date is an obvious one: programs to reach young people are not

simply programs for adults applied to a younger population; they require different thinking and a different approach.

Determining Key Principles of Health Programming for Adolescents

Experience to date suggests that effective, youth-focused efforts share a set of common general principles. These principles include the following:

- *Recognize the diversity of the youth age group.* A sexually inexperienced 11-year-old has vastly different needs than a married 20-year-old. Programs should apply different strategies to reach youth, who vary by age, sex, employment, schooling, and marital status.
- *Involve young people.* Policies and programs are more effective when young people are involved in all aspects of their design, implementation, and evaluation. Involvement must go beyond tokenism and be genuine, meaningful, and sustained.
- *Make health services appealing to youth.* A key to rapidly expanding young people's access to health services is to make them more youth friendly by using specially trained health workers and by bolstering the privacy, confidentiality, and accessibility of care.
- *Address gender inequality.* Gender inequalities expose young girls to coerced sex, HIV infection, unwanted pregnancy, and poor nutrition. Efforts should focus on changing the factors that perpetuate gender inequalities.
- *Address the needs of boys.* Adolescence presents a unique opportunity to help boys form positive notions of gender relations and to raise their awareness of health issues. At the same time, boys seem to be disproportionately exposed to a number of adolescent health risks, including accidents and injuries, suicide, tobacco use, substance abuse, and violence. Program design should take into account the specific needs of boys and young men as well as of girls and young women.
- *Design comprehensive programs.* Comprehensive programs that provide information and services while addressing the social and political context are more effective than narrowly focused interventions.
- *Consider all important benefits.* Many adolescent health interventions focus on only one benefit. For example, a school-based sex education program may focus exclusively on HIV prevention and may neglect other possible benefits from the intervention, such as increased education, averted teen pregnancy and abortions, and other averted STIs.
- *Address the many nonhealth factors that influence adolescent health.* Linking school and livelihood opportunities to adolescent health programs, at either the policy or program level, is key to helping young people avoid risky behaviors.
- *Address underlying risk and protective factors.* Factors such as feelings of self-efficacy, attitudes and behaviors of friends, connectedness with parents and other influential adults, and

involvement in the community can either increase (risk factor) or decrease (protective factor) the chances that a young person will engage in unhealthy behaviors.

Making a Difference on a Large Scale

Adolescent health programs are complex and may not be easy to scale up because of technical, management, and political challenges. The following are examples of adolescent health programs that are national in scope. Unfortunately, little is known about the costs and effectiveness of such large-scale efforts.

National Suicide Prevention Program in New Zealand.

Among industrial nations, New Zealand has one of the highest suicide rates for both males and females age 15 to 24 (New Zealand Ministry of Health 2002). In 1998, on the basis of international good practice, the government developed the National Youth Suicide Prevention Strategy. This strategy, which includes a component for the general population and one that focuses on the indigenous Maori community, provides a framework for understanding suicide prevention and signals the steps that government agencies, communities, and service providers must take to reduce suicide. Even though the national strategy has not been in place long enough to adequately gauge its effects, in 1999, the first year following the adoption of the strategy, youth suicide rates fell to their lowest levels since 1991.

Sexuality Education in Mongolia.

Mongolia has implemented a locally developed and tested sexuality education curriculum in 60 percent of schools nationwide. Current challenges include increasing the number of hours allocated to sexuality education; developing more and better written resources for adolescents, including textbooks; developing materials that will help parents communicate better with their children on sexuality; expanding access to clinical services for adolescents through the public health system; reaching out-of-school youths and the broader community with sexuality education; and monitoring and evaluating the program regularly to assess its weaknesses and strengths and how it could be improved (Gerdt 2002).

Addressing the Health Needs of Poor Youth

The following strategies, based on what is known about services for poor people more generally and about the specific needs of young people, show promise for meeting the needs of poor youth:

- *Targeting out-of-school youth.* Out-of-school youth of a given age are likely to be more marginalized than those who are in school, and they are often those most in need of critical services, such as pregnancy prevention and prevention of HIV/AIDS and other STIs. A number of countries, including Paraguay, South Africa, and Zimbabwe, have launched effective programs targeting out-of-school youth

that combine the use of mass media, peer education, and community-based efforts. For instance, the *Arte y Parte* project targeted out-of-school youth in three cities in Paraguay using a booklet about adolescent sexuality, street drama, radio programming, newspaper columns, and distribution of promotional items (Magnani and others 2000).

- *Focusing efforts on vulnerable youth.* Young people who have been orphaned or left vulnerable by AIDS typically rely first on their extended families and communities for support. Efforts to help vulnerable youth should strengthen those safety nets. One example is the COPE program in Malawi, where a nongovernmental organization–sponsored effort works through existing government structures to help orphans and other vulnerable children (Phiri, Foster, and Nzima 2001).
- *Tailoring subsidized programs to poor youth.* Social marketing of reproductive health products and services—such as contraceptives and condoms for pregnancy and disease prevention or promotion of iron supplementation—often targets young consumers, but such efforts should ensure that they reach the desired clients—namely, those who are poor and less likely to be able to afford market prices. The Social Marketing for Adolescent Sexual Health Project in four African countries combined the use of mass media with peer education to encourage young people to practice safer sex, including condom use (Agha 2000).

Improving Health Systems to Meet Adolescents' Health Needs

The shortcomings of health systems in LMICs are well known, and adolescents in particular would benefit from the following health system improvements:

- *Strengthening human resource capacities.* The poor quality of the interaction with health workers is one of the main barriers to adolescents' use of health care in public sector facilities. Through training, supervision, and other means, health systems should encourage health workers to adopt a more youth-friendly outlook. In addition, health systems should integrate such training into the curricula of medical, nursing, and nurse auxiliary schools.
- *Involving the private sector.* Many young people already seek care from private doctors, nurses, and nurse-midwives or from local pharmacies or other drug distribution outlets. Along with encouraging private for-profit health providers to serve youth, government policies should encourage efforts to tap into the private sector as a source of health care for adolescents by means of interventions such as social marketing, contracted services, youth-focused social franchising, and programs that serve young people at their place of work. (Carranza 2003; LaVake and Rosen 2003; Rosen 2001a; Senderowitz and Stevens 2001).

- *Strengthening the stewardship oversight function of governments.* Governments have a key role to play in developing supportive policies, both within the health sector and across sectors; in contributing to cross-sectoral policies such as national youth policies; and in providing input into policy making in other sectors, especially education and labor. Ideally, governments should have an overarching adolescent health policy with specific reference to adolescent health in policy documents for specific programs or diseases, such as for AIDS, tuberculosis, malaria, sexual and reproductive health, and population (WHO forthcoming-a; POLICY Project and YouthNet forthcoming).

RESEARCH AND DEVELOPMENT AGENDA

The striking lack of good research and evaluation of adolescent health interventions limits countries' ability to address serious health problems. At this juncture, research in the following broad areas is critical:

- *Refining estimates of DALYs for adolescents.* Available DALY information is inadequate to fully explore the burden of disease for adolescent age groups. Future DALY estimates should be made for five-year age groups in the 10 to 24 age range.
- *Documenting the effectiveness of current approaches.* This area includes better process evaluation to understand the functioning of successful programs. Such evaluation necessitates more rigorous research designs so that the effectiveness of programs can be better documented, both in terms of health outcomes and in terms of DALYs saved. Another area in which more research could help is better documentation of the nonhealth effects of adolescent health interventions. Greater investment is also needed to evaluate the effects of health promotion strategies on reducing smoking, including the smoke-free spaces prevalent in the Americas and life-skills education.
- *Testing new interventions.* This area includes more research on multicomponent programs and on new types of interventions. In relation to sexual and reproductive health, new interventions include approaches such as providing anti-retroviral therapy to HIV-infected youth and voluntary counseling and testing for HIV, encouraging adolescents to have fewer sexual partners, reducing the trafficking of young people, preventing and addressing the health consequences of early marriage, and reaching young married women with information and services. Research must better inform interventions so that they reach groups at particularly high risk of poor health outcomes, such as child prostitutes, child workers, refugees, AIDS orphans, and street children. More research is also needed on a broad range of other adolescent

health interventions, especially for those health problems that are among the biggest killers and disablers of young people: HIV/AIDS and mental illnesses for both males and females, maternal conditions for females, and road accidents for males. In addition, research is needed on programs that attempt to influence gender roles and social norms and investments designed to avert drug and alcohol abuse and to improve mental health.

- *Enhancing understanding of the risk and protective factors influencing young people's behavior.* Even though our understanding of the major influences on youth behaviors has come far, more refinement of such understanding is needed, along with a better understanding of how to incorporate such knowledge into the design of programs and policies.
- *Improving cost and cost-benefit analysis.* Good cost estimates are rare, and more needs to be done to more fully estimate the costs of the range of adolescent health interventions. This effort means collecting more data on program costs and more accurate data that include programs' nonmonetary costs. Few full cost-benefit analyses of youth programs exist, and more need to be done to improve evaluations of the economic value of investments targeted at young people.

CONCLUSIONS

The health community has only recently recognized the importance of adolescent health problems. To address the unique health problems associated with the adolescent years, policy makers and the health community must expand the knowledge base on effectiveness, costs, and economic benefits and pay more attention to areas such as road safety, nutrition, mental health, and malaria. Well-documented implementation experiences from mostly small programs have produced a sound body of knowledge about how programs function. These experiences can provide the foundation for scaled-up efforts and can help the health community improve health systems in ways that will benefit adolescent health efforts.

NOTES

1. The United Nations defines *youth* as those age 15 to 24. The World Health Organization defines *adolescence* as age 10 through 19 and uses the term *young people* to refer to those age 10 to 24.

2. Regional data cited from this report here and elsewhere in the chapter are based on nationally representative surveys carried out between the mid 1990s and 2001.

3. Knowles and Behrman (2003b) find that many cost estimates incorrectly treat income transfers as costs and frequently fail to include estimates of administrative and distortionary costs (for example, the distortionary cost of financing programs through taxes).

4. In cost-effectiveness analysis, as in cost-benefit analysis, estimates are needed not only of what has actually happened, but also of what would have happened in the absence of the program or intervention (that is, an estimate of the counterfactual). There are no exceptions to this rule.

Chapter 60

Occupational Health

Linda Rosenstock, Mark Cullen, and Marilyn Fingerhut

Workers around the world—despite vast differences in their physical, social, economic, and political environments—face virtually the same kinds of workplace hazards. These hazards are traditionally categorized into four broad types: chemical, biological, physical, and psychosocial. What emerges from our incomplete knowledge of their risk, however, is that the more than 80 percent of the world's workforce that resides in the developing world disproportionately shares in the global burden of occupational disease and injury. Several classic occupational diseases, such as silicosis and lead poisoning, that have been substantially eliminated in industrial countries remain endemic elsewhere in the world. Whether this high and preventable burden of ill health faced by workers in the developing world is the result of ignorance, inattention, or intent, compelling evidence indicates that work-related health conditions could be substantially reduced, often at modest cost.

NATURE AND CAUSES OF OCCUPATIONAL HEALTH CONDITIONS IN THE DEVELOPING WORLD

Despite country-to-country differences, some commonalities exist within the workforce of the developing world that are worth noting. Workforce distribution by economic sector is different from that in the industrial world. Compared with industrial countries, where single-digit percentages prevail—for example, approximately 2 percent in the United Kingdom—developing countries employ about 70 percent of their economically active population in the agricultural sector (World Bank 2003). For many of these workers, the distinction between health at work and health at home is blurred, because

health in the workplace is integrated into all aspects of daily life for these often subsistence agricultural workers. For example, pesticide poisoning is a hazard faced by workers and their families and communities.

The informal workforce, which in industrial countries is rarely larger than 10 percent of total employment, looms large in developing countries. This workforce includes self-employed, household-based unpaid labor (family members, for example) and independent service workers such as street vendors. In the developing world, employment in the informal sector may reach 70 percent, with the contribution to the gross domestic product (GDP) ranging from 10 to 60 percent (ILO 2002).

Informal economy workers are often unprotected in the regulatory arena even in the industrial world. This circumstance is exacerbated when the vulnerable employment status in the developing world is coupled with problems of poverty and ill health. Cottage-industry workers abound in the informal sector, and home-based work can fully blur distinctions between occupational and other environmental hazards. Not uncommon across the developing world are lead-poisoned adults who manufacture batteries in crude facilities at home and their lead-poisoned children, exposed to the lead while sleeping and playing in the next room.

The migrant workforce, which is increasing worldwide, is estimated to be 120 million (ILO 2000). In the industrial world, immigrant workers often perform work deemed unattractive (seasonal agricultural work in the United States, service sector work in the United Kingdom), but the issues of a migrant workforce in some parts of the developing world take on even greater import. In southern Africa, for example, migrant mining workers face the extraordinary burden of risk for the triad

of silicosis, tuberculosis, and HIV/AIDS—diseases that are inextricably linked to interactive determinants of workplace, housing, and social and economic factors (Trapido and others 1996).

Workers in the developing world face different risks in the health transition than do their counterparts in the industrial world. They may be exposed to the combined and often synergistic risks of both traditional and emerging hazards. Workers may also face unregulated and unprotected exposures to known hazards just as those same hazards—silica and asbestos, for example—were faced decades ago by millions of workers in the industrial world. A significant difference, though, is that workers in the developing world are being exposed when widespread knowledge is available about the risks and effective preventive measures (Kjellstrom and Rosenstock 1990). Even as these workers are forced to replay history, despite the availability of information and knowledge transfer unthinkable just a generation ago, they face other hazards, including the production, marketing, and importation of environmental hazards such as cigarettes. In the instance of asbestos and tobacco, both products are being aggressively marketed and exported by the industrial world (especially asbestos from Canada and tobacco from the United States) to the developing world.

A real example of hazards faced by developing workers in what might be called the *risk transition* is that posed by dual exposure to asbestos and cigarette smoke and risk for lung cancer. This example is especially troubling not only because the risk is dauntingly high but also because exposures to both are occurring with full knowledge of their individual and cumulative effects. As shown in table 60.1, against a background of relative risk for lung cancer of 1 for a nonsmoking, nonasbestos-exposed population, a working population with significant asbestos exposure but no tobacco exposure may face a relative risk of lung cancer of 5; a smoking population not exposed to asbestos faces a relative risk of 10; and rather than these risks being additive (that is, 15) the smoking, asbestos-exposed population has the extraordinary relative risk of lung cancer of 50. Most important, in this well-recognized multiplicative-effect scenario, if the smoking exposure alone were eliminated among the asbestos-exposed workers, the overall risk of lung cancer

would be reduced by 90 percent; even if the smoking exposure continued, elimination of the asbestos exposure would reduce the overall risk by 80 percent. Those considerations are not theoretical but well supported by empirical data. In parts of China and elsewhere in the developing world, asbestos exposure abounds as cigarette smoking is rising. Effective intervention strategies will be those based on a comprehensive approach to the overall burden rather than those addressing the individual burdens of specific exposures, recognizing that organizational or institutional interventions (such as eliminating asbestos from the workplace) are far more effective than those targeting individual behaviors (such as smoking cessation).

GLOBAL BURDEN OF DISEASE FROM OCCUPATIONAL HEALTH RISKS

The overall picture that emerges from all parts of the developing world is one of increased health and safety risks in all occupations for which data are available.

Dramatic changes in the global labor force will occur as globalization and population growth continue to affect the global economy. For example, the labor force in Latin America and the Caribbean is one of the fastest growing in the world, with 217 million workers in 2000; the number of workers is expected to reach 270 million in 2010 (PAHO 2002). The burden of disease and injury attributable to workplace risks in the formal and informal sectors is grave and will continue to rise. Inadequate data and reporting systems make capturing the effect of workplace risks problematic. Nonetheless, several recent efforts by international bodies have shed some light on the staggering burden, although in general attempts to derive evidence-based estimates are likely to systematically and significantly underrepresent the extent of the problem.

The gravity of workplace risks is seen in the recent International Labour Organization (ILO) estimate that among the world's 2.7 billion workers, at least 2 million deaths per year are attributable to occupational diseases and injuries. The ILO estimates for fatalities are the tip of the iceberg because data for estimating nonfatal illness and injury are not available for most of the globe. The ILO also notes that about 4 percent of the GDP is lost because of work-related diseases and injuries (Takala 2002).

A recent effort of the World Health Organization (WHO) has provided insight into the global dimensions of several selected occupational health risks. WHO included five occupational risk factors in its comparative risk assessment in a unified framework of 26 major health risk factors contributing to the overall global burden of disease and injury (Ezzati and others 2004; WHO 2002). The WHO comparative approach used a common statistical model that allows a reader to compare the contribution (attributable fraction) of several risk

b. If smoking eliminated, eliminate 90 percent lung cancers in asbestos workers.

factors to a single outcome—lung cancer, for example. Stringent requirements for consistency in describing risk factors limited the number of occupational risk factors that could be included in the study. For all risk factors, it was necessary to estimate an exposed population and exposure levels for 224 age, sex, and country groups in the 14 WHO geographic regions of the world. Where possible, data could be extrapolated to age, sex, and country groups for which data were not available, based on similarities in demographic, socioeconomic, or other relevant indicators. Because knowing the existing burden of disease and injury globally was necessary, the only outcomes included were those for which WHO had rates of disease or injury for all regions calculated by International Classification of Disease (ICD) codes. Finally, estimates of the risk factor–burden relationships by age, sex, and WHO subregion were generated. Risk measures (relative risks or mortality rates) for the health outcomes resulting from exposure to the risk factors were determined primarily from studies published in peer-reviewed journals. Adjustments were made to account for differences in levels of exposure; exposure duration; and age, sex, and subregion, as appropriate. The information about each risk factor was entered into the WHO common model for comparative analysis. The resulting burden was described as the attributable fraction of disease or injury, using mortality and disability-adjusted life years (DALYs) lost, with one DALY being equal to the loss of one healthy life year—the common currency measure that includes mortality and morbidity.

Because of the requirements for global data, only five occupational risk factors could be described: risks for injuries, carcinogens, airborne particulates, ergonomic risks for back pain, and noise. The exposed worker populations were estimated using an approach based on the International Standard Industrial Classification of All Economic Activities (ISIC), an economic classification system of the United Nations that organizes all economic activities by economic sectors and relevant subgroupings (UN 2000). The ISIC system is used almost universally by national and international statistical services to categorize economic activity; therefore, it allows global comparisons. The ILO has developed economically active population (EAP) estimates by applying economic activity rates, by sex and by age group (older than age 15), to the population estimates and projections of the United Nations (ILO 1996). The EAP provides the most comprehensive global accounting of people who may be exposed to occupational risks because it includes people in paid employment, the self-employed, and people who work to produce goods and services for their own household consumption, both in the formal and in the informal sectors (ILO 2002). For the WHO comparative risk assessment, the EAP was further divided into nine economic subsectors (where people work) and seven occupational categories (what type of work people do), on the basis of country-level data for 31 countries (ILO 1995).

The absence of data in much of the developing world limited the range of occupational risk factors that WHO could measure, and the available data excluded children under age 15 who work. The WHO comparative risk assessment also excluded important occupational risks for reproductive disorders, dermatitis, infectious disease, coronary heart disease, intentional injuries, musculoskeletal disorders of the upper extremities, and most cancers. Psychosocial risk factors such as workplace stress could not be studied, nor could pesticide, heavy metal, or solvent exposures. The potential consequences of omitting just pesticides from the global burden analysis can be illustrated by the situation in Central America (PAHO 2002). The isthmus is primarily an agricultural and forested area of .5 million square kilometers, of which 40 percent is arable. Pesticide imports almost tripled from 15,000 metric tons in 1992 to 41,000 in 1998, and 35 percent of the pesticides were restricted in the exporting countries. In 2000, the subregion imported some 1.5 kilograms of pesticides per inhabitant per year, a quantity 2.5 times greater than the world average estimated by WHO. Exposures in the formal and informal sectors extend to the homes and families of the pesticide workers. Although this situation is common in developing nations, the WHO comparative risk assessment captured none of these exposures.

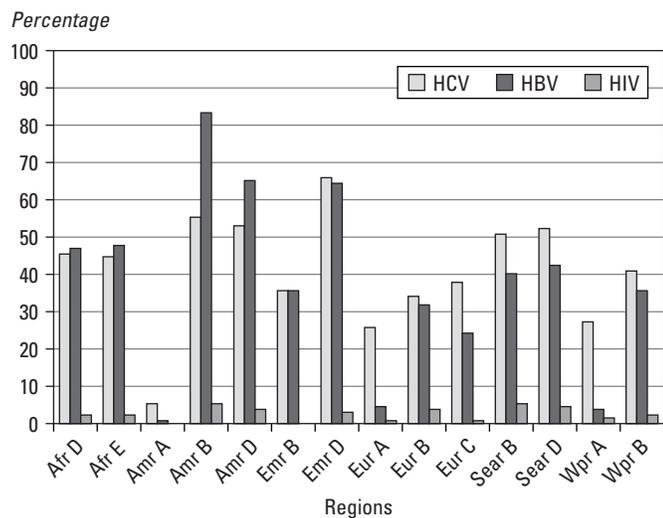

The ILO and WHO data provide the most current, yet still incomplete, picture of the overall problem of occupational health risks. Nonetheless, with just the few occupational risk factors studied in depth by WHO a picture emerges of the significant effect of largely preventable conditions (Ezzati and others 2004). WHO found that occupational injuries result in about 312,000 deaths per year for the world's 2.7 billion workers; this figure contrasts to the approximately 6,000 deaths per year caused by occupational injuries for the 150 million workers in the United States. As in the industrial world, high injury fatality rates in the developing world are clustered in certain sectors, including agriculture, construction, and mining. Using this metric, occupational injuries account for more than 10 million DALYs and 8 percent of unintentional injuries worldwide.

The second occupational factor WHO analyzed was the effect of exposure to workplace lung carcinogens (such as asbestos, diesel exhaust, and silica) and leukemogens (such as benzene, ionizing radiation, and ethylene oxide). WHO concluded that occupational exposures account for about 9 percent of all cancers of the lung, trachea, and bronchus and about 2 percent of all leukemias. Overall, about 102,000 deaths were attributable to these two occupational cancers and about 1 million DALYs.

Estimates of the global burden of chronic lung disease demonstrate the significant contribution of occupational exposures, which account for about 13 percent of all chronic obstructive pulmonary disease (COPD) and about 11 percent

of asthma. In total, WHO found the annual worldwide burden of work-related COPD to be about 318,000 deaths per year and about 3.7 million DALYs. The occupational risk contribution to the worldwide asthma burden was about 38,000 deaths and about 1.6 million DALYs, reflecting the fact that a great deal of asthma occurs at younger ages and is not fatal. WHO found that 37 percent of all back pain worldwide is attributable to work, resulting in an estimated 800,000 DALYs, a significant loss of time from work, and a high economic loss. Worldwide, 16 percent of all hearing loss is attributable to workplace exposures, resulting in 4.2 million DALYs.

WHO made a special risk analysis of hepatitis B, hepatitis C, and HIV infections among health care workers caused by contaminated sharps, such as syringe needles, scalpels, and broken glass (WHO 2002). This analysis illustrates the general problem of high risks existing in the small worker population having exposure. WHO found that, among the 35 million health workers worldwide, there were 3 million percutaneous exposures to bloodborne pathogens in 2000. This finding is equivalent to between 0.1 and 4.7 sharps injuries per year per health worker. WHO concluded that of all the hepatitis B and hepatitis C present in health care workers, about 40 percent was caused by sharps injuries, with wide regional variation. WHO also found that between 1 and 12 percent of HIV infections in health care workers was caused by sharps injuries. The comparative risk assessment by region and type of infection indicates where special emphasis is needed (see figure 60.1). Clearly, solutions exist to these problems, as shown by the

Figure 60.1 Fraction of Hepatitis C Virus, Hepatitis B Virus, and HIV Infections in Health Care Workers Attributable to Injuries with Contaminated Sharps, Ages 20 to 65

countries that have engaged in serious prevention efforts. Proper needle handling and waste management, substitutions for sharps, hepatitis B virus (HBV) immunization, postexposure prophylaxis, training, and legislative measures have been successful. Beyond the personal and workplace consequences, the potentially devastating societal impact of loss of this critical worker group can be anticipated if prevention measures are not ensured in developing countries, where the proportion of health care workers in the population is already small.

In total, the few occupational risk factors considered here were responsible for about 800,000 deaths worldwide in 2000. Not considered by WHO because of lack of global data are the additional 1.2 million deaths that ILO estimated are attributable to work-related risks (Takala 2002). The leading occupational cause of death was unintentional injuries, followed by COPD and lung cancer. Workers who developed outcomes related to these occupational risk factors lost about 25 million years of healthy life. Among the occupational factors analyzed in this study, injuries, hearing loss, and COPD accounted for about 80 percent of years of healthy life lost. Low back pain and hearing do not directly produce premature mortality, but they do result in substantial disability. This feature differentiates these conditions from the others analyzed in the study. Figure 60.2 provides summary results for the occupational risk factors.

The WHO comparative risk assessment has accounted for only about 800,000 (40 percent) of the 2 million deaths estimated by ILO to occur each year because of occupational illness and injury. Deaths attributable to a wide range of occupational exposures could not be included because of the

Source: Adapted from Nelson and others 2005.

Figure 60.2 Fraction of Global Disease and Injury Attributable to Occupational Risk Factors (percent)

strict requirements for global data. Missing are deaths attributable to asbestosis, silicosis, and other dust diseases; infectious diseases; cardiovascular diseases; and violence. Deaths attributable to workplace exposures to pesticides, heavy metals, solvents, and other chemicals are not included. Outcomes such as dermatitis, psychological disorders, and upper-extremity musculoskeletal disorders that cause little mortality but substantial disability are also not captured by the WHO comparative risk analysis. Additionally, the consequences of underreporting in existing systems and the dearth of record-keeping systems in the developing nations lead to substantial undercounting by both the ILO and WHO. Nonetheless, the analyses provide important insights into the immense global burden of disease and injury attributable to occupational risk factors.

INTERVENTIONS

Strategies for controlling injury and occupational disease, developed by industrial hygienists and others over many decades in industrial countries, are as fully applicable in developing countries. The strategies include a hierarchy of controls in the following decreasing order of preference: substituting major hazards for less hazardous materials or processes; applying engineering controls to separate workers from hazards that remain; using administrative controls to minimize contact uncontrollable by engineering; and, as the last line of defense, using personal protective equipment such as respirators and protective garments. What differs in developing countries is the context in which the paradigm must be applied. Options are often sharply limited, and knowledge of them even more so; economic and political factors may impede otherwise obvious or desirable solutions; and the differing workplace context may demand that attention be paid to certain problems and concerns that would not be relevant in industrial countries in temperate climates.

The following generic factors associated with work in developing countries may alter industrial hygiene practice and must be considered in every effort to intervene to improve working conditions and occupational health:

- Access to industrial hygiene consultation is limited; professionals, sampling equipment, and laboratories are all in short supply.
- Knowledge level about occupational health among managers and workers is often limited.
- Markets for production materials as well as safety equipment may be limited and may include more hazardous materials or less effective protective equipment “dumped” from industrial countries where they are no longer marketable (Hecker 1991; Ives 1985; Jeyaratnam 1990).

- Regional conflict, economic pressures, climatologic factors, and lack of foreign exchange may make otherwise straightforward choices impractical.
- Supply of labor is often high, as is turnover, so economic incentives for investment in health capital are lower than in industrial countries.

Strategies for Improving Working Conditions

With these differences in context in mind, we now consider the major types of intervention: international, national, workplace, and individual.

International Interventions. The ILO–WHO Joint Committee on Occupational Health was formed in 1950 to provide guidance to the ILO and WHO regarding international occupational health issues. The committee meets periodically. At its 13th session, held in December 2003, the committee recommended that WHO and ILO pursue the following priorities (ILO and WHO 2003):

- Guide and support national occupational safety and health programs. Such guidance and support includes providing models for organizing at national or subnational levels; providing basic occupational health services; promoting management systems and tools, including control banding; developing national profiles and indicators; assessing the cost-effectiveness of interventions; and establishing effective enforcement agencies.
- Enhance regional collaboration and coordination, including the development and dissemination of models for cooperation, such as the African Joint Effort.
- Coordinate and enhance information and educational programs and materials (for example, by developing a joint Internet-based global portal) and statistics.
- Provide awareness-raising activities and instruments through campaigns, events, and special days.

State or Government Interventions. The major role the government can play is to establish workplace rules and provide a system of dissemination and enforcement. Evidence from industrial countries is overwhelming that conditions are substantially improved when both a strong regulatory framework and enforcement are achieved. An added benefit of government, rather than private sector, control is to “level the playing field”: all employers in an economic sector carry the same burden. Conversely, improved health of the workforce, achieved by developing strategies beyond the minimum required, could be used to confer competitive advantages, a message to reluctant employers that has been used in different parts of the world with some success.

Regulatory decisions, such as the choice of exposure limits or allowable practices, often stimulate the biggest discussion—

for example, the debate about dust levels to be allowed in South African mines—but the larger issue for most countries is garnering resources to ensure compliance, to attract adequately trained personnel to conduct inspections, and to establish and monitor laboratories to support regulatory efforts. The most stringent exposure levels (often referred to as *threshold limit values*, or *TLVs*) are useless if the offending hazard cannot be routinely and accurately measured. Indeed, the South African experience, despite the presence of excellent regulations, is not encouraging in this regard (Joubert 2002).

Other forms of government intervention may indirectly improve working conditions. Among these are workers' compensation regulations and stipulations that employers of certain sizes must engage professionals in health and safety (most often nurses). Each of these interventions has the advantage of stimulating certain behaviors and practices without requiring the government to maintain the elaborate and technically complex machinery required for direct monitoring of workplace conditions.

Constraints on governmental regulatory and other interventions are many. Occupational and environmental regulations are often perceived as burdensome costs that impede investment and growth, perhaps creating what has been referred to as “the race to the bottom,” in which threat of outmigration of industry from one jurisdiction enhances reluctance to regulate or enforce control strategies (Frumkin 1999). Moreover, the costs to the government itself, notwithstanding technical support from such agencies as the ILO, may be considerable in terms of personnel and equipment, and occupational health has to compete with other public health priorities for scarce resources. The result may be the promulgation of minimal standards or emasculated enforcement of those that already exist. The general impression of those working throughout the developing world is that the level of regulation and enforcement is woefully inadequate compared with that in industrial countries. Detailed case examples from Brazil (Bedrikow and others 1997); Kenya (Mbakaya and others 1999); Nigeria (Asuzu 1996); and Taiwan, China (Chen and Huang 1997), underscore the ubiquity of this problem.

Workplace-Based Interventions. Issues beyond the economic and legal ones impede application of the principles of industrial hygiene. A primary factor is ignorance; many employers may be uninformed about available controls and their value. Insurance agencies, local safety groups, and—in some regions of the world—trade unions may serve as facilitators of positive influence. In general, however, such resources fall short of the benefit of on-site industrial hygiene expertise that is lacking in many regions of the world.

Economic factors often impede efforts to institute voluntary controls. Materials used are frequently far cheaper than safer substitutes, often precisely because these materials no longer

have markets in industrial countries that have banned or restricted their use—for example, solvent mixtures containing benzene and construction materials containing asbestos. Similarly, equipment such as machines that are well guarded to prevent injury or well baffled to limit noise may be prohibitively expensive in a marketplace geared to “hand-me-downs” compared with respirators or gloves. Unfortunately, even these last lines of defense may be difficult to obtain or relatively expensive unless local suppliers are available.

The single strategy for which no compelling economic disincentive exists—training—may also be difficult. Through the efforts of the ILO and numerous nongovernmental organizations and with widening access to the Internet, vast resources have become available. Ample documentation from the industrial and developing world indicates that even rudimentary knowledge by supervisors and workers about risks and risk-prevention measures is beneficial. Major impediments remain, however, such as educational proficiency, language barriers, and the applicability of training materials—often developed in other contexts—to local situations. Thus, for example, although the ILO has recently reported success with information programs in rural Thailand (Kawakami and Kogi 2001), a report from Ghana (Smith-Jackson and Essuman-Johnson 2002) suggests that workers and supervisors were unable to correctly interpret four of the most common warning signs used for hazard identification, despite having been trained in their use. Worker training appears, on the whole, widely underused.

Problems of infections in patients and health care workers from reused needles and needlestick injuries have prompted the international organizations to develop model interventions that can be transferred elsewhere. WHO initiated Project Focus: Ensuring Immunization Safety in Burkina Faso in July 2002 as a pilot project to use WHO materials in a focused effort to address all issues related to injection and immunization safety: availability of equipment and supplies (auto-disposable syringes, safety boxes, incinerators); safe injection practices; safe vaccine delivery; and safe waste management (WHO 2002). In 2000, WHO conducted a survey to assess the safety of injections in a study group of a random sample of 80 health centers. The situation was reassessed in June 2003 to evaluate the use of safety boxes (which had been provided in a WHO immunization campaign in Burkina Faso in 2001) and the impact of Project Focus. Table 60.2 shows results of the reassessment. Dramatic reductions were found in needle recapping, needlestick injuries, and misuse of safety boxes. Additionally, the number of clinics using safety boxes increased from fewer than half to 86 percent.

Small enterprises present special challenges because they lack resources and expertise to address health and safety problems. Thailand's National Institute for the Improvement of Working Conditions and Environment has used the ILO

Table 60.2 Prevalence of Risk Factors and Injuries at 80 Observed Health Centers (percent)

Year	Needle recapping	Needlestick injuries	Lack of safety boxes	Misuse of safety boxes

training approach called WISE (Work Improvement in Small Enterprises) with some success. In one example, six enterprises in the metal industry in Bangkok with between 15 and 115 workers participated in the WISE program, in which practical workshops involved workers and management in deciding on changes to be made in the workplaces. A wide range of inexpensive changes were put in place, and a booklet to illustrate good practices for others was prepared (Krungkrai Wong 2000).

Individual Interventions. The general principle that, for most public health intervention, organization-level change is more effective than strategies targeting the individual is even more true when it comes to the workplace. With the exception of self-employed workers, such as those in the informal sector and subsistence farmers, occupational health and safety does not lend itself readily to individual solutions, with the same factors limiting employees more likely to limit individuals.

Improvement of Access to Health Care

In a few developing countries, workers enjoy broad access to high-quality health care. Chile, for example, has a system of nonprofit employer mutual associations that provide advice on reducing risks in workplaces and medical treatment and sick pay for work-related illness and injury (Contreras and Dummer 1997). In most countries, the role of on-site services is generally limited to emergency services for an injury or accidental overexposure and the conduct of medical surveillance examinations for workers at risk for chronic conditions such as noise-induced hearing loss, pneumoconiosis, or cancer.

In the developing world, access to health care is critical both for work-related and other health issues. In many areas, especially remote or rural areas, on-site service may be the only health care services available to workers and their families. Moreover, the blurred distinction between “general health” and “occupational health” in societies where people live and work in the same community and environment, and where children and spouses of workers may share common exposures and adverse conditions with workers, serves to confer some advantage to a more holistic approach to health services often best provided at or near the workplace itself.

Control of Nonoccupational Exposures

In industrial countries, a sharp demarcation exists between environmental risks associated with work and those associated with home life. This differentiation is not the case in many developing countries, especially at large, remote industrial complexes and farms. Workers—with or without their families—often cohabit with the workplace—and often with many or all of its risks, including noise, chemicals, and biohazards. The most dramatic examples of this situation were the industrial disasters at Chernobyl and Bhopal. It is not just in disaster, however, that risk occurs. Pesticides, for example, result in hundreds of thousands of cases of poisoning a year, a high fraction from the misuse of farm chemicals for nonwork applications, such as the appropriation of empty (but not clean) drums for transporting water or other household goods, a disturbingly common practice. In the industrial setting, carcinogens, neurotoxins, and other hazardous chemicals often pollute homes, drinking supplies, and common areas for recreation on a daily basis, adding to the exposure of workers and placing nonworking family members at risk from what would normally be seen as workplace hazards.

The remedy is often complex and beyond traditional industrial hygiene practice. Housing, which in any event may be substandard, needs to be modified to exclude the possibility of contamination by effluent from farm or factory under any foreseeable circumstances. Children and family members need to be apprised of the hazards of all materials used for work and prevented from even accidental access, a situation complicated by the fact that children are themselves often inappropriately engaged in the workplace. Food and water supplies need to be secure and protected from cross-contamination, a particular problem in the farm setting.

Surveillance and Reporting

Even in industrial countries, the strategies for recording any aspect of workplace harm beyond acute injury has been an issue; in most developing countries, even injury reports are largely nonexistent. Still, broad agreement exists on the value of statistical summaries of occurrences.

Unfortunately, a strong disincentive exists for such reporting unless it is required by law or by a parent company (as in the case of some multinationals). If reporting is required, as in the formal laws of many countries, successful implementation calls for resources for systematic review, verification, and maintenance of the information. Even records whose limitations are otherwise legion, such as workers’ compensation records or regional reporting schemes, have proven highly advantageous to control efforts in industrial countries. These, too, have a role in developing countries, helping target even rudimentary and limited control efforts.

Capacity Building

Human capital in the form of professional capacity is critical to improving working conditions. Professional capacity varies greatly in developing nations but is higher where recognition of the field is high and the need for professionals and for workplace expertise is driven by occupational safety and health legislation and enforcement. In Malaysia, for example, four decades of rapid industrialization have included a series of legislative acts; development of federal agencies; and inclusion of training at various levels in occupational health in universities, the public sector, and the private sector (Rampal, Aw, and Jefferelli 2002). Key international events, such as joining the World Trade Organization, encourage the development of an economic culture that better recognizes the value of safe workplaces. Enforcement of national regulations, adoption of International Standards Organization standards, and establishment of management systems lead to broadening of training for workers and managers, although the scarcity of trained professionals is a major obstacle to adequately implementing regulations and policies and providing occupational health services (Christiani, Tan, and Wang 2002; Wang, Cheng, and Guo 2002).

In countries with some capacity, the expertise tends to be medical, rather than in other areas, such as industrial hygiene, engineering, or ergonomics. In most countries, ministries of health and of labor have jurisdiction over working conditions but often have too few experts and inadequate coordination. Moreover, the large percentage of work conducted in the informal sector presents a special challenge to these ministries. Because globalization has brought the need for professionals in occupational health to a crisis level, it is appropriate for international trade and development bodies to support national and international capacity-building programs.

In 1970, when the United States enacted the Occupational Safety and Health Act that established the National Institute for Occupational Safety and Health (NIOSH), the country had little professional capacity in that field. The new law charged NIOSH with ensuring an adequate number of trained professionals and accomplished this task successfully by funding graduate programs in U.S. universities. A follow-up 25 years later found that 90 percent of NIOSH-supported trainees pursued careers in the field, with more than 50 percent working in private organizations and the balance in government and academia (U.S. DHHS 1996). Similar results could be achieved by a determined, large-scale effort focused on assisting developing countries in achieving adequate professional capacity.

Both infrastructure and programs are necessary to build adequate capacity. In the international arena, a number of successful coalitions exist that provide experienced institutions and individuals. The WHO Global Network of Collaborating Centers in Occupational Health is a strong international coalition of 70 national, governmental, and academic centers of

occupational health that work together with WHO and ILO headquarters and regional offices and three international non-governmental organizations: the International Commission on Occupational Health, the International Occupational Hygiene Association, and the International Ergonomics Association (Fingerhut and Kortum-Margot 2002). These partners, located in approximately 40 countries, work together in 15 priority areas within a 2001–2005 Work Plan. More than 300 projects are under way, independently or jointly, to benefit workers in developing and industrializing nations in about 15 priority areas (WHO 2003).

Another strong regional coalition, coordinated with and benefiting from the Global Network of Collaborating Centers, is the WHO–ILO Joint Effort on Occupational Health and Safety in Africa (WHO and ILO 2002b). This partnering coalition—where centers outside Africa assist African partners—includes individual occupational safety and health professionals, employers, labor unions, and governmental and academic institutions in all countries in Africa.

Enlarging small but successful existing programs is one approach to capacity building. The U.S. National Institutes of Health Fogarty International Center, NIOSH, and the National Institute of Environmental Health Sciences sponsor a successful program, International Training and Research in Occupational and Environmental Health, which has developed small but strong programs between U.S. universities and institutions in more than 30 developing nations (NIH 2003).

Capacity building requires high-quality educational opportunities. Advances in information technology over the past decade are revolutionizing methods of education, and universities worldwide are developing large numbers of Internet-based courses. Fostering access of students from developing nations to these courses in leading universities is now feasible, but a national or international program is needed to address issues such as tuition, competition, intellectual property, and degree requirements. This effort might be called Access to Universities, following the model WHO program Access to Biomedical Journals, through which WHO and the world's largest medical journal publishers have provided about 100 developing countries with Internet access to journals at no cost or at deeply reduced rates (WHO 2001).

Professional associations have a long history of assisting in capacity building through training, research, and conferences. Recently, when the University of Witwatersrand in Johannesburg developed the first Diploma Occupational Hygiene program in South Africa, the country had too few industrial hygienists to provide mentors for the field research of the graduate students. The American Conference of Governmental Industrial Hygienists responded to a request of the International Occupational Hygiene Association, and 11 U.S. industrial hygienists volunteered to be occupational hygiene field practitioner long-distance mentors for the

incoming students during the 2003 course year. This approach will continue until there are adequate industrial hygienists in country to serve as mentors to future classes (WHO and ILO 2002a).

The U.K. Health and Safety Executive developed a model program that provides clear solutions to chemical control problems in workplaces. This Web-based, user-friendly product was launched to enable small business owners in the United Kingdom to use information from the suppliers of chemicals to proceed through a series of simple steps to identify practical control solutions that reduce worker exposures to levels that present no danger to health (U.K. HSE 2002). This approach, which eliminates the need to measure exposures and meets the regulatory requirements of the United Kingdom, has immense potential value for employers in developing nations, who could devote scarce resources to controlling exposures rather than to measuring exposures. The approach has gained momentum through adoption by the International Program on Chemical Safety and through formation of an international workgroup to advance the approach in developing nations. To enable global use of this approach, the ILO has translated the U.K.-specific system into a product called the ILO Chemical Control Banding Toolkit (ILO 2003).

ECONOMIC ASPECTS OF INTERVENTION

Measures to prevent occupational risks are not cost-free, and where those costs ultimately come to rest affects the willingness of employers to implement the preventive measures.

Who Bears the Costs of Preventive Measures?

In industrial countries, compelling economic incentives exist for employers to control risks for injury and illness on the job, especially those that result in demonstrable near-term lost work or function. These include the high cost of medical care (especially in the United States), the burden of workers' compensation payments, high replacement costs for the labor, risk of litigation and liability, and negative business consequences of adverse publicity. Although these factors may differ by country and sector, they are less likely in the developing world to confer on employers a strong economic imperative for prevention—labor is plentiful, its replacement cost is low, and—most important—a high portion of the real cost of injury and illness will not be borne by the employer. The statistics in Latin America are staggering: although an estimated 2 to 4 percent of the GDP of the region is lost because of occupational fatalities alone, no evidence exists of private sector investment to reduce the risk (Giuffrida, Iunes, and Savedoff 2002). Multinational companies appear to be an exception. For many, the costs of injury and illness may accrue to the parent

country in terms of legal liability and adverse publicity, a lesson well taught by Union Carbide's experience in the aftermath of the Bhopal disaster in 1984.

One approach to align economic incentives is to use regulatory and legal reform to shift the existing cost burden to those in a position to remedy the situation—that is, to employers. Increasing workers' compensation benefits, especially those for long-term effects and disabilities, is an example of such an approach. Some evidence exists that, at least in southern Africa, this approach does stimulate preventive behavior by employers. An alternative is to critically reexamine the assumption that employers do not harbor substantial underrecognized costs of injury and illness even under the current situation, especially in terms of indirect costs such as lowered productivity and morale. Harari and his colleagues in Ecuador (Cullen and Harari 1995) have been studying the effect of such exposures as solvents and organophosphate pesticides on production levels. They are attempting to make the case that relatively inexpensive strategies for exposure control are economically advantageous to employers.

Intervention Costs and Cost-Effectiveness

Workplace illness and injury produce personal suffering and high economic costs. The ILO estimates that about 4 percent of GDP worldwide is lost because of work-related diseases and injuries (Takala 2002). The European Agency for Occupational Safety and Health at Work (1998) indicates that the costs to society in European countries ranged from 0.4 percent to 4 percent of gross national product.

Examining Industrial Countries. Identifying interventions to successfully reduce or prevent workplace injuries and illnesses will benefit society, employers, and workers. In 1996, stakeholders in the United States identified intervention effectiveness research as one of 21 priority areas in occupational health research for the next decade (U.S. DHHS 1996). From 1996 to 2002, research conducted or funded by NIOSH to develop and evaluate the effectiveness of solutions to prevent work-related injury and illness has increased nearly sixfold, from about US\$5.5 million to US\$33 million (U.S. DHHS 2003).

Research studies of workplace interventions often use surrogate or implied measures for economic evaluation. For example, economic benefit is assumed to occur following an intervention if symptoms of illness or injury in a workforce decrease while productivity remains constant. Intensive data-entry workplaces are increasing rapidly in both industrial and developing nations. Three studies of U.S. Internal Revenue Service data-entry clerks by NIOSH found that short, strategically placed rest breaks of 5 to 15 minutes during the regular daily schedule reliably reduced eyestrain, fatigue, and

Use of a Toolkit to Determine Return on Investment in Central American Garment Factories

The Regional Occupational Safety and Health Center (Centro Regional de Seguridad y Salud Ocupacional) Project in Central America developed an occupational safety and health toolkit to enable managers and line workers in garment factories to self-diagnose plant and workstation hazards and to estimate the costs and benefits of interventions (Amador and others 2003). Managers and employees at more than 100 Central American garment factories have been trained to use the toolkit. An in-depth evaluation of the use of the toolkit in three garment factories, each employing between 700 and 1,000 workers, in El Salvador, Guatemala, and Nicaragua found that within one year the factories generated savings that were four to eight times the costs of the interventions.

The overall investment by Confecciones La Palma in 2002 was US\$6,360, and the savings attributed to that year were US\$27,242 from reduced injury, illness, and absenteeism and an increase in productive days (see table).

musculoskeletal discomfort for video-display terminal operators without decreasing productivity (Galinsky and others 1999, 2000). Similar benefits of improved comfort and reduced stress from short rest breaks were observed among workers in a meat-processing plant without affecting productivity (Dababneh, Swanson, and Shell 2001).

Including economic costs of interventions is more difficult but is an important measure to allow employers to make decisions about interventions. A model intervention study, “Evaluation of a Best Practices Back Injury Prevention Program in Nursing Homes,” received the 2003 National Occupational Research Agenda Partnering Award for Worker Safety and Health (APHA 2003; Collins and others 2004). Members of the partnership that carried out the intervention study included a large nonprofit U.S. health care system that owns nursing homes; manufacturers of lifting equipment; researchers at Washington University, West Virginia University, and NIOSH; and health care workers. The prevention program combined measures to reduce back injury by identifying the movements and postures that put nursing assistants at risk of back strain, stress, and injury in lifting and moving residents. Mechanical lifting devices for reducing those stresses and strains were evaluated in the laboratory and then in the nursing homes. A best-practices training and lifting program was put in place on the basis of researcher and employee input, and

rates for key measures of success were recorded for the three years before the intervention and for the three years after the intervention. The successful project reduced the frequency of back injuries in six nursing homes by 57 percent, lowered injury rates by 58 percent, and decreased workers’ compensation expenses by 71 percent. Box 60.1 illustrates the value of evaluating costs of interventions in garment factories in Central America.

Reducing Risk for Back Pain. The WHO summary of a variety of cost-effectiveness studies for interventions addressing all aspects of global health illustrated that the cost-effectiveness of interventions in some areas of personal health has been well studied but that environmental and occupational topics have had relatively few studies. The WHO comparative risk assessment concluded that about 37 percent of back pain globally is attributable to occupational risk factors (WHO 2002). A cost-effectiveness study of interventions to reduce occupational back pain was also reported, using economic models developed to calculate costs of interventions in three WHO geographic regions that illustrate different levels of development. Intervention studies were obtained from the published and unpublished literature. All costs of running the interventions were measured in international dollars (not exchange rate dollars, as in the analysis reported later in this chapter) and

Figure 60.3 Cost-Effectiveness of Interventions for Lower Back Pain

effectiveness was measured as age-weighted DALYs gained by the intervention. The interventions for the prevention of back pain were grouped into three major categories: worker training (awareness education and hazardous job training); engineering control (physical measures that control the exposure to the hazard, including equipment that assists lifting, pushing, and pulling); and the full ergonomics program (which includes both of the previous interventions and implementation procedures).

As shown in figure 60.3, the analysis found that the most effective intervention is the full ergonomics program, offering a 74 percent reduction in back-pain incidence. Lesser benefits are obtained by engineering control (56 percent reduction) and training (20 percent reduction). The total costs of worker training are largely labor related, the costs of engineering control are primarily capital costs, and the full ergonomics program costs are equally shared between the two. Training was found to be the most cost-effective intervention, as indicated by the lower slopes of the lines from 0 to T, and was recommended as the first choice when resources are scarce. However, the incremental cost-effectiveness ratios for the other options (indicated by higher slopes of the lines) demonstrated that both engineering control and the full ergonomics program are attractive alternatives. Thus, even the full ergonomics programs were found to be cost-effective in all three regions for their health effects alone, without even considering the possible increase in productivity that could be brought about by the interventions (WHO 2002). Recalculating these results according to Disease Control Priorities Project methods—using exchange rate dollars and removing the age weights from DALYs (see chapter 15)—would increase effectiveness somewhat because back pain is more common at later ages and would reduce the apparent costs in both Europe and Southeast Asia. It would have little effect on costs in the high-income countries of the

Americas. The relative cost-effectiveness of the three interventions would be unchanged in each region.

Reducing Risk for Silicosis. Silicosis is a disabling and often fatal workplace lung disease caused by inhalation of silica dust. The high-risk sectors of the economy include construction, mining and mineral processing, foundries, and manufacturing of pottery and glass. Large numbers of workers in both industrial and developing nations are exposed. Box 60.2 illustrates control of silica caused by grinding wheels in the agate cottage industry in India. In the United States, more than 3.2 million workers are exposed to silica dust, even though methods exist to eliminate exposure (Harley and Vallyathan 1996).

A study was conducted to evaluate the cost-effectiveness of alternative interventions to reduce silicosis in industrial and developing nations (Lahiri and others 2005). The authors used the limited published and unpublished data on costs of the various interventions and on the efficacy of exposure reduction. To analyze the cost-effectiveness of each intervention in reducing disease incidence, they used models developed for WHO (Murray and others 2000). The WHO DALY concept was used to combine mortality and morbidity resulting from silicosis. Two WHO regions were studied: the highly developed America A region, represented by the United States and Canada; and the developing Western Pacific B1 region, represented by China, the Democratic People's Republic of Korea, the Republic of Korea, and Mongolia. Exposure estimates were taken from the WHO comparative risk assessment study (Ezzati and others 2004).

The interventions included engineering control interventions that protect many workers (use of the wet method—that is, spraying a surface or wetting a blade to reduce dust; of local exhaust ventilation; and of total plant ventilation) and worker training plus personal protective equipment, an intervention that protects the individual worker. The training involved four types of personal protective equipment: comfort masks, dust masks, full-face respirators, and half-face respirators. Lahiri and others (2005) summarize the evidence of reduction in exposure through the use of selected interventions from the literature. The difference in the health life years gained with and without the intervention represented the effectiveness of the intervention and was used as the denominator for the cost-effectiveness ratio.

The engineering control interventions involve large capital expenditures, whereas the implementation of personal protective equipment requires ongoing large equipment costs (filters and cartridges) as well as labor costs for training the workers. Costs of interventions vary from region to region, depending on wage rates and raw material costs, but the costs of equipment seem not to vary. The authors found the least expensive alternative is training associated with use of a comfort mask. However, that intervention has a relatively low efficacy of

Box 60.2

Economic Evaluation of an Engineering Control for Silica Dust in India

The agate industry is a cottage industry concentrated in residential settings in Khambhat and Dahegam, in the state of Gujarat, India, where 15,000 grinders and 60,000 other workers, family members, and neighbors are exposed to silica dust. The making of key chains, necklaces, and art pieces involves baking, chipping, grinding, and polishing agate stones. The grinding-machine wheels are driven at speeds of 1,440 rpm, generating large amounts of dust containing respirable silica. The table shows the extraordinary prevalence in the total exposed populations (noted above) of silicosis and tuberculosis caused by silica exposure.

Prevalence of Diseases in Agate-Dominated Areas of Khambhat and Dahegam

Category	Silicosis		Tuberculosis ^a	
	Percent	Number	Percent	Number
Grinders	30	4,500	36	5,400
Nongrinding workers, family, and neighbors	8	4,800	16	9,600

Source: Bhagia, Ramnath, and Saiyed 2003.

a. National tuberculosis prevalence in India of 4 percent and resulting cases have been subtracted.

The National Institute of Occupational Health in India designed and distributed 10 dust control devices for the grinding machines to employers, who generally employ 5 to 10 workers (see figure). The efficacy of the devices was found to be 93 percent, and dust was greatly reduced

(Bhagia, Ramnath, and Saiyed 2003). Economic analysis was based on 600 dust control devices that could be installed in the communities. The total costs include the initial one-time cost of the devices (Rs 8,000, or approximately US\$92); depreciation (10 percent per year); maintenance of machines (equivalent to the costs saved by recycling the dust to be used in polishing); and the cost of treating the diseases (about Rs 4,000, or approximately US\$184 per year per case). The gains included annual income per avoided case of silicosis. Total savings per year were estimated to be between Rs 23 million and Rs 29 million (US\$527,039 to US\$664,528). The conclusion is that installation of dust control devices in all the agate-grinding units of Gujarat would reduce silicosis and tuberculosis as well as yield financial and health benefits to the workers, families, and the greater society that bears the cost of illness.

Traditional Grinding Machine with Dust Control System

30 percent exposure reduction. Although the initial capital expenditures are high for engineering controls, the annualized costs based on a 10-year horizon are encouraging, with exposure reduction of about 70 to 85 percent. The greatest exposure reduction of 95 percent was achieved at the highest cost, with training plus use of a full-face respirator, but an 80 percent reduction was achieved at half this cost when training was combined with a dust mask.

Table 60.3 shows that engineering controls in both industrial and developing regions are the most cost-effective

Table 60.3 Average Cost-Effectiveness Ratio (US\$/DALY gained)

	America A region	Western Pacific B1 region
Engineering control	105.89	109.35
Comfort mask	111.04	117.19
Dust mask	191.38	173.90
Half-face respirator	299.82	272.45
Full-face respirator	304.87	265.74

Source: Lahiri and others 2005.

interventions, with expenditures of between US\$105 and US\$109 per healthy year saved in the two regions. Although exposure reductions with respect to each intervention type are identical in both regions and the cost of interventions is somewhat higher in the America A region, it might seem perplexing that the cost per unit of health gain is relatively lower in the America A region than in the Western Pacific B1 region. The reason for this result is that effectiveness (the denominator of the average cost-effectiveness ratio) is represented by health outcomes that are higher for this region because life expectancy in the America A region is higher than in the Western Pacific B1 region. Therefore, lives saved through interventions in industrial regions contribute more toward the healthy years generated by the model.

The study concluded that engineering controls are the most cost-effective interventions in both regions and should be considered as the first choice in cases in which resources are scarce. The results underestimate the health gains because other silica-related diseases such as tuberculosis and cancer are not considered.

IMPLEMENTATION

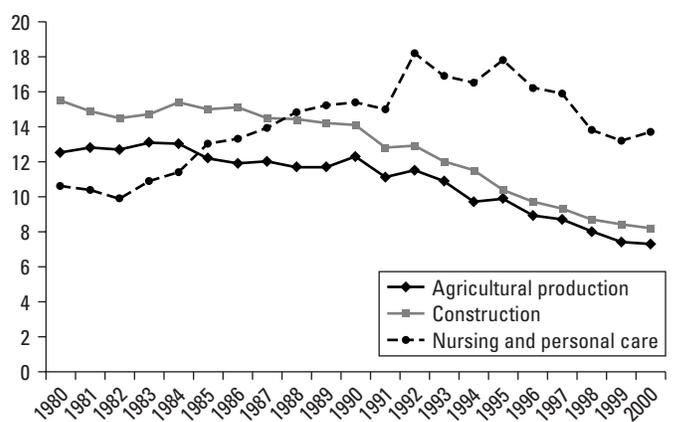

The health of a country's workforce, even more than the health of the country's overall population, is critical to its economic and national security. No country has become a successful economic power without sustained attention to the health of workers, who create the successful economy. Responsibility for the safety and health of workers lies with the government, the employers, and the workers themselves. However, it is the governmental framework, whether at a national or local level or both, that is the linchpin on which other efforts rest.

Institutions and Programs

The potential to continually improve work-related health status, as measured by morbidity and mortality data across multiple economic sectors and across many countries, has been compellingly demonstrated. Not surprisingly, because these conditions are inherently preventable, what may be the lowest achievable level of risk is debated in industrial countries. In the United States, for example, occupational injury fatality rates have been steadily declining, now approaching 3.8 per 100,000 workers, down from 7.5 just 20 years earlier (NIOSH 2000).

Key elements in improving worker health and safety, regardless of the level of development, include regulatory and enforcement framework; worker, employer, and health professional education; surveillance and reporting systems; and dissemination and implementation of best practices. Often these elements overlap in multifaceted approaches to addressing complex and disparate work settings.

Injury rate per 100 full-time workers

Source: BLS 2002.

Figure 60.4 Incidence Rates of Nonfatal Occupational Injuries (Total Recordable Cases) by Selected Industry Sectors, 1980–2000

In the developing world, a patchwork of some of these approaches has brought success: in Vietnam by reducing silicosis through industrial hygiene practices of wetting the process and through surveillance (effective but much less so than protective equipment or, better yet, substitution of a safer product), and in Nicaragua by efforts to reduce pesticide poisoning through worker and health professional education and reporting systems. Even in highly developed countries, the continued need for a responsive and broadly based framework, with government involvement at the center, is evident.

An example recently identified in the United States is the comparison of injury indicators for workers across three prominent sectors: construction, agriculture, and health care (figure 60.4). Two decades of data demonstrate improving nonfatal injury rates for construction and agricultural workers (falling steadily from about 16 and 12 per 100 full-time workers, respectively). This rate is in contrast to injury rates for health care workers, which have risen by about one-third from a starting point of about 10 per 100 workers (BLS 2002). Why the difference? Although the reason is not fully delineated, major efforts (including government regulation, research investment and policy setting, education, and best-practice efforts)—plus, in the case of construction workers, active trade union involvement—in the two industrial sectors clearly were under way in this time period. In contrast, in the health care worker sector, no such national program existed in the period, and industry pressures resulted in a number of potential workforce problems, such as increasing work demands on a stressed and ill-prepared workforce.

Lessons Learned

As countries undergo rapid economic development, industrialization, and the effects of globalization, leaders can examine

available occupational health system models as they develop their national occupational health systems. The Republic of Korea has experienced major economic and societal changes since it emerged from the Korean War in the 1950s with a need to establish occupational safety and health programs without any historical experience. The system directed by the Industrial Safety and Health Act of Korea is modeled after the specialist-based system of Japan, which relies on medical screening and specialists outside the workplace to deliver health and safety services (Paek and Hisanaga 2002). Paek and Hisanaga note that national traditions and culture strongly influence the choice of system when developing countries examine models from which to choose—for example, from the code-based system of the United States, the performance-based system of the United Kingdom, and the management system of the Nordic countries.

Government involvement is necessary but not sufficient, regardless of the level of development. Because national and local legislation and policies create the framework within which a society functions, international influence, assistance, and requirements play a key role in encouraging developing and industrializing nations to create appropriate laws and policies to support healthy workers. International trade, development, and funding organizations have immense power, which is not fully exercised to date, to influence countries on working conditions. The large multinational trade agreements have also failed to ensure that worker health and safety is adequately addressed, and multinational corporations have generally not transferred the safety and health systems of the industrial world to developing nations. The consequences are grave, as seen in the deaths of 2 million workers each year from occupational injuries and illness. Great power lies in these institutions and trade agreements to produce direct changes in the health of workers globally.

The ILO provides strong guidance internationally for industrial and developing nations through its tripartite conventions and recommendations. Each year the ministers of labor of all member nations, employer representatives, and worker representatives agree on policies in conventions, which the member states are asked to ratify. The models provided by the ILO are regularly used by some countries as they create their national systems. Brazil, for example, has been a member country of the ILO since 1919 and has ratified 75 ILO conventions. Set in place by legislation in the 1970s, the Brazilian model for occupational health services followed the ILO's Recommendation 112 (1959) as a paradigm (Dias, Mendes, and Schwartz 2002). Although few countries ratify most conventions, more than 150 countries have ratified Convention 182, which was passed in 1999 and addresses the worst forms of child labor. A current critical need is assistance to developing nations to meet the obligations required by ratification. WHO sets international policies on health, including worker health, at its annual meeting of health

ministers of all member nations. Both ILO and WHO regional offices provide technical assistance and training. An unfortunate gap exists, however, because often the national ministries of labor relate to the ILO and the ministries of health to the WHO. Because working people are influenced by the national ministries of both labor and health, the international organizations have been advised to correct the situation (WHO and ILO 1995). A promising WHO/ILO Joint Effort on Occupational Safety and Health in Africa has embraced partners across ministries and broadly within and outside Africa to work together to assist countries, workers, and employers in the formal and informal sectors (WHO and ILO 2002b).

Several coalitions of organizations have successfully assisted developing countries to increase professional capacity and to improve worker health and safety. A regional illustration is the Association of Southeast Asian Nations Occupational Safety and Health Network, which was established to promote regional cooperation in training and research as well as harmonization of standards in safety and health. The primary international coalition is the WHO Global Network of Collaborating Centers in Occupational Health, described previously. The U.S. Fogarty International Training and Research Program in Occupational and Environmental Health is another stable and experienced network, consisting of U.S. universities working with universities in more than 30 developing nations to increase professional capacity. Some of the institutions are also WHO Collaborating Centers, and others are partners in Africa. The relationships have provided opportunities for synergy and streamlining of training and technical assistance (WHO and ILO 2002b).

Globalization has brought work-related hazards to developing countries lacking the infrastructure and professional capacity to handle them adequately. It is incumbent on the national and international bodies responsible for globalization to assist the recipient nations. Organizations with proven track records in occupational health could play key roles if international and national laws provide the appropriate context and funding.

Globalization

Increased globalization has caused important changes for many developing countries. Dias, Mendes, and Schwartz (2002) identify the series of developmental stages through which a country passes: underdevelopment and poverty, industrial revolution and accelerated economic development, internal adjustments to strengthen national competitive power to enter globalized markets, adjustments to foreign policy to integrate globalized markets, and aims toward long-term sustainable human development. These authors also analyze the positive and negative effects on occupational health conditions in countries such as Brazil, where crises and opportunities are experienced simultaneously. On the risk side, for example, free trade agreements have intensified rapid industrialization and the export of

industry and materials—many hazardous—to regions with poor occupational infrastructure. These effects are likely increasing risk and rates of injury and occupational disease.

Globalization has also engendered major occupational health and safety development projects, most notably sponsored by Scandinavian governments (Partanen and others 1999). These initiatives have infused developing countries with expertise, training programs, and equipment and have provided much-needed (external) economic incentives for adoption of change on national, regional, and local levels. The major concern is sustainability, because the incentives are external.

Globalization has resulted in a rapid increase in the number of multinational companies operating outside industrial countries. Indeed, this outcome was the underlying economic intent of recent free trade agreements such as the North American Free Trade Agreement (NAFTA). In general, these companies bring with them a highly developed infrastructure in occupational health practice from their base countries. Unfortunately, although these model companies undoubtedly upgrade the availability of high-quality services and training, enhance workers' awareness, and create pressure on other industries in the region to conform, the pressure likely goes in both directions. The competitive advantage of lowered investment in health and safety, as long as the labor markets are plentiful and the direct costs to employers of illness and injury low, results in strong pressure to minimize—or at least reduce—the intensity and quality of services.

Even at their best, multinationals may inadvertently create an occupational health and safety “caste system.” Many provide extremely high levels of care and service for their international managers and for technical support staff members, while offering local resources to indigenous workers. More broadly, occupational clinics, industrial hygiene services, and the like are often developed but available for the exclusive use of the multinationals, creating communities inside which modern occupational health exists but outside which nothing changes except the incorrect perception that progress has occurred. Often the reverse of progress has actually occurred because the limited numbers of trained physicians, occupational health nurses, industrial hygienists, and safety professionals are siphoned off to the higher-paying, more prestigious positions.

Free trade zones, established by treaties such as NAFTA, create special considerations. Although the agreements offer the potential to incorporate strong industrial world rules regarding labor, environment, and health in underdeveloped zones, the host countries often resist such changes, perceiving these rules as trade restrictions. The final language regarding health and safety in NAFTA, for example, is significantly less stringent than rules in the United States. Moreover, some multinationals resist even these rules, seeking broad economic relief as a foundation of moving across the border (Frumkin 1999).

Nonetheless, globalization does offer potential solutions. One is the link provided by international lending agencies such as the World Bank and International Monetary Fund of health and safety considerations to development loans. As a condition of receiving the development funds, control of health and safety conditions could be mandated and enforced. A second opportunity is voluntary initiatives, as were recently developed in the Apparel Industry Partnership, wherein a consortium of European and U.S. garment manufacturers agreed to control labor and safety practices in their facilities in developing countries by joint consent.

Implications for Health System Development

Workers' health and safety in most of the developing world may fall under the jurisdictions of both the ministry of labor and the ministry of health, with little collaboration and coordination between the two. The ministry of labor most commonly is the governmental focus of any regulatory and enforcement efforts, even though without requisite expertise and access to follow-up care, it may mandate services falling squarely within the traditional health system (for example, pulmonary function testing as ongoing screening for individual response to exposure to pulmonary toxicants). Whatever the country-specific organizational and structural constraints, the following set of principles can be applied in providing health services to workers:

- *Coordination between occupational health services and overall health services.* Occupational health services, consisting of efforts to prevent work-related disease and disability as well as to recognize and treat them once they occur, must be coordinated with overall health services. The separation between work-related and other health conditions, often driven by regulatory and liability concerns, insurance, and other external constructs (workers' compensation system or the disability system, for example), is not only clinically challenging but inefficient in optimizing individual health status. Although many work-related injuries and a few specific illnesses, such as asbestosis, can be readily pinpointed as stemming from work alone, most health problems result from multiple causes. This fact is as true in the developing world as in the industrial one—whether it be cumulative pesticide exposure from work and community sources, the interaction of poverty and poor health status with chemical work exposures, or the cumulative psychosocial stressors of life both inside and outside work. A holistic approach to the individual, recognizing the multisectoral, multiple determinants of health on overall health status, should be the goal in the provision of health services.
- *Attribution of causality and access to health services.* In parts of the developing world, as in the industrial world, a phenomenon exists wherein some threshold of causality (such

as “more probably than not work related”) is the trigger to workers’ compensation or other employer responsibility for taking care of the illness or injury. All too often in this setting, the incentive for the employer to disclaim responsibility leaves the worker, whatever the cause or causes of the condition under question, falling through the cracks of occupational health care and traditional health care. Universal access to health care, unfortunately not available in the United States or in much of the developing world, can mitigate this problem.

- *Health professional workforce expertise in occupational health.* As discussed in the section on capacity building, adequate expertise does not exist in the developing world to address traditional and emerging occupational health problems. Occupational health services are multidisciplinary, including nonmedical (industrial hygiene and engineering expertise, for example) in addition to health (nursing and physician) expertise. Without being prescriptive, health systems need to ensure the existence of an adequately prepared workforce (whether through broadly based training for all health personnel, training for occupational health specialists, or most likely some combination of the two) if they are to grapple even minimally successfully with reducing the human and economic burden of work-related injuries and illnesses.

Unifying the three principles identified above is the need to recognize that occupational health should be in the mainstream of both health education (at the professional, employer, and individual level) and health care. An argument against this approach is the perception that doing so will result in an untenable burden on already underfunded health care. We suggest that not so doing will create a greater burden, in both financial and human terms.

RESEARCH AGENDA

Before 1996, there was no known national effort to identify and promote an occupational health research agenda. That changed with NIOSH taking the lead to launch the National Occupational Research Agenda (NORA) (U.S. DHHS 1996). Since then, a number of other countries in the industrial world have launched similar efforts (for example, Italy, Sweden, and the United Kingdom). Although all these efforts are relevant to the developing world, the reality is that country-specific research, even at the risk of reinventing the wheel, is often needed to strengthen political will to effect policy. Moreover, although traditional epidemiological etiologic research in occupational health is not a priority or even feasible for much of the developing world, research targeted at local conditions and institutions is often what is most needed. Six areas are identified, with appropriate modifications for local conditions, as ongoing research priorities to address injury and disease

control strategies in the developing world. This research need not be undertaken solely—and sometimes not even in part—in the countries of concern, but rather is likely to be aided by the capacity building derived from partnership between academic institutions and government agencies across countries of different levels of development.

Public Health Systems Research

Although health services research has emerged as an important area of inquiry in the health field in the industrial world over the past few decades, scant attention has been paid to public health systems research (Institute of Medicine 2003). Given that occupational health sits at the interface between individual and population health, this area of inquiry is particularly germane to research in the field. This research would examine the effectiveness of government systems working in coordination with other sectors (academic institutions, employers, unions, voluntary agencies) in promoting occupational health status.

Occupational Health Policy Research

Public policy to address improving occupational health in the developing world should rest on a sound scientific base (that is, be evidence based) and should be coupled with an understanding of the local and national frameworks for policy (whether through legislative, regulatory, or other means). Adequate research has not been undertaken to evaluate policy development and implementation in public health in general and occupational health specifically. As with the need for new health systems research, this area of inquiry would undoubtedly benefit from partnerships among countries in the industrial world and in the developing and industrializing world.

Intervention Effectiveness Research

Intervention effectiveness research, a cornerstone of the U.S. NORA initiative, is critical to advancing occupational health in the developing world. The absence of data in this chapter to demonstrate cost-effectiveness of occupational health measures is indicative of the need for more such information to target what will always be a demand for limited resources. Recognizing the relative dearth of intervention effectiveness research in countries with high research investments, this recommendation is made cautiously for countries with fewer resources. However, it is assumed all too often that an accepted intervention in a country with higher economic productivity might not be viable in one with fewer resources. The research agenda for the developing world in this arena needs to be tailored to what is known and proven coupled with local and national conditions and needs.

Control Technology and Protective Equipment Research

Investigation of control technology and protective equipment, another NORA priority, is critical for developing effective and feasible control strategies in the developing world. Much of the primary research in this category can be done in the industrial world, but along with investments in intervention effectiveness research, new technologies may still need to be tested in real situations in developing countries. Simplified approaches to management of chemicals suitable to the local work settings have been developed in Indonesia and are being evaluated, and the International Program for Chemical Safety is helping other countries modify, implement, and evaluate the U.K. system, which was originally designed for use by small enterprises in the United Kingdom (ILO 2003).

Disease and Injury Research

Many questions of epidemiologic importance to improving the health of all workers can best be answered in settings in the developing world. This situation is not unique to occupational health, but in the occupational health arena, it is important to recognize that workers are often the first exposed and are exposed to the highest levels of potential hazards (as compared with their community counterparts). So, too, are levels of exposure to many hazards far greater in the developing world than elsewhere, and undertaking studies becomes efficient and feasible in these settings that would prove difficult if not impossible in settings where exposures are lower and larger numbers of study participants are needed to detect meaningful differences in risk. Not surprisingly, then, sentinel studies of health effects of interest to the industrial world have been undertaken in other countries—for example, studies in Latin America identifying the potential for acute pesticide intoxication to cause chronic neurological effects (Rosenstock and others 1991).

Surveillance Research

Surveillance is a critical component of all effective occupational health programs; thus, continuing research is needed into the most effective ways to gather and interpret this information. Surveillance systems are often limited at best in many developing countries, and evaluation research needs to be undertaken to determine the benefits of investing in gathering both generic (absences from work, for example) and specific (blood lead levels, for example) information on which to target public health action.

CONCLUSIONS

The burden of occupational health problems is staggering in both human and economic costs, and workers in the developing world bear this burden disproportionately. Moreover, the

most vulnerable—children and the poor—are also disproportionately at risk. Compounding this tragedy is that many effective and economically feasible interventions are available to address these largely preventable health conditions.

Despite relatively little systemic data on cost and cost-effectiveness, even this “tip of the iceberg” picture demonstrates work-related conditions contributing significantly to overall mortality and morbidity and demonstrates the overall societal benefit of their prevention and treatment. Externalization of costs by employers—to the society as a whole—often obscures the actual overall benefit of a framework that relies on government regulation and enforcement, education, and best practices. Effectively addressing these problems takes active involvement from national and local government, employers, and workers and their representatives. The challenges to reducing the burden are heightened to the degree that public health and health care delivery systems isolate occupational health from the mainstream of health and health care.

Despite structural and political barriers to overcoming this high burden of disease and injury, evidence exists of enormous progress in the industrial world and of isolated progress in parts of the developing world. Targeted future investments in research and public health and health systems are critical to ensuring that progress continues and is more equitably distributed.

Natural Disaster Mitigation and Relief

Claude de Ville de Goyet, Ricardo Zapata Marti, and Claudio Osorio

Sudden-onset natural and technological disasters impose a substantial health burden, either directly on the population or indirectly on the capacity of the health services to address primary health care needs. The relationship between communicable diseases and disasters merits special attention. This chapter does not address epidemics of emerging or reemerging diseases, chronic degradation of the environment, progressive climatic change, or health problems associated with famine and temporary settlements.

In line with the definition of *health* adopted in the constitution of the World Health Organization (WHO), the chapter treats disasters as a health condition or risk, which, as any other “disease,” should be the subject of epidemiological analysis, systematic control, and prevention, rather than merely as an emergency medicine or humanitarian matter. The chapter stresses the interdependency between long-term sustainable development and catastrophic events, leading to the conclusion that neither can be addressed in isolation.

DISASTERS AS A PUBLIC HEALTH CONDITION

According to the International Federation of Red Cross and Red Crescent Societies, internationally reported disasters in 2002 affected 608 million people worldwide and killed 24,532—well below the preceding decade’s annual average mortality of 62,000 (IFRC 2003). Many more were affected by myriad local disasters that escaped international notice.

Disaster has multiple and changing definitions. The essential common element of those definitions is that disasters are unusual public health events that overwhelm the coping capacity of the affected community. This concept precludes the universal adoption of a threshold number of casualties or vic-

tims. What would be a minor incident in a large country may constitute a major disaster in a small isolated island state. Not only are “quantitative definitions of disasters unworkably simplistic” as noted by Alexander (1997, 289), but when based on the economic toll or the number of deaths, they are also misleading with regard to the immediate health needs of the survivors or their long-term impact on the affected country.

Classification of Disasters

In the early 1970s, a series of well-publicized disasters (the civil war and resulting famine in Biafra, the cyclone in Bangladesh, and the earthquake in Peru) triggered the scientific interest of the international public health community.

Disasters can be classified as *natural disasters*, *technological disasters*, or *complex emergencies*. The latter include civil wars and conflicts. These classifications are arbitrary and refer to the immediate trigger—a natural phenomenon or hazard (biological, geological, or climatic); a technologically originated problem; or a conflict. In reality, all disasters are complex events stemming from the interaction of external phenomena and the vulnerability of man and society.

The human responsibility in so-called natural disasters is well acknowledged. The term *natural disaster* remains commonly used and should not be understood as denying a major human responsibility for the consequences.

Disaster Terminology

The following definitions are adapted from those proposed by the Secretariat of the International Strategy for Disaster Reduction (ISDR), a United Nations (UN) body established to sustain the efforts of the International Decade for Natural

Disaster Reduction (UN/ISDR 2004) and the WHO *World Health Report 2002* (WHO 2002):

- *Hazards* are potentially damaging physical events, which may cause loss of life, injury, or property damage. Each hazard is characterized by its location, intensity, frequency, and probability.
- *Vulnerability* is a set of conditions resulting from physical, social, economic, and environmental factors that increase the susceptibility of a community to the effects of hazards. A strong coping capacity—that is, the combination of all the strengths and resources available within a community—will reduce its vulnerability.
- *Risk* is the probability of harmful consequences (health burden) or economic losses resulting from the interactions between natural or human-induced hazards and vulnerable or capable conditions. In a simplified manner, risk is expressed by the following function:

$$\text{Risk} = f(\text{Hazards} \times \text{Vulnerability})$$

A public health approach to disaster risk management will aim to decrease the vulnerability by adopting prevention and mitigation measures to reduce the physical impact and to increase the coping capacity and preparedness of the health sector and community, in addition to providing traditional emergency care (response) once the disaster has occurred.

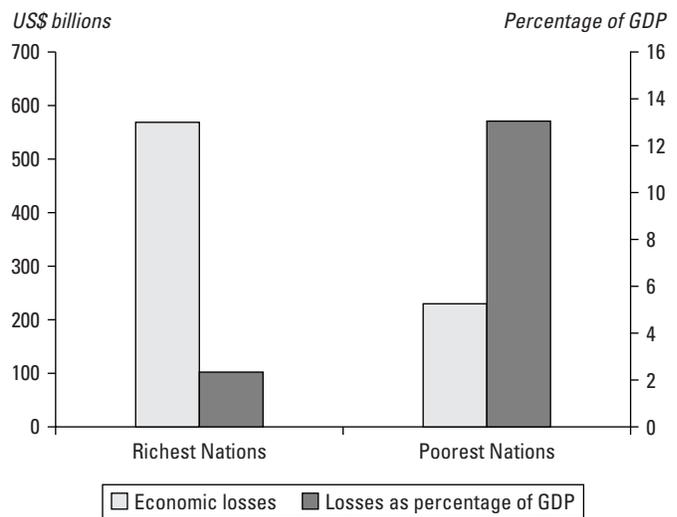

Distribution and Risk Factors

Health and relative economic losses of natural disasters disproportionately affect developing countries (Alexander 1997; UN/ISDR 2004). More than 90 percent of natural disaster-related deaths occur in developing countries. Even though the economic losses are far greater in industrial countries, the percentage of losses in relation to gross national product (GNP) in developing countries far exceeds that percentage in industrial countries (figure 61.1). At an individual level, a sudden reduction of US\$5,000 from an annual income of US\$50,000 is worrisome; however, the ongoing loss of US\$50 from a monthly income of US\$100 may be catastrophic.

For this reason, statistics of economic damage and mortality alone are not true indicators of the effect of disasters on the health and development of people and communities.

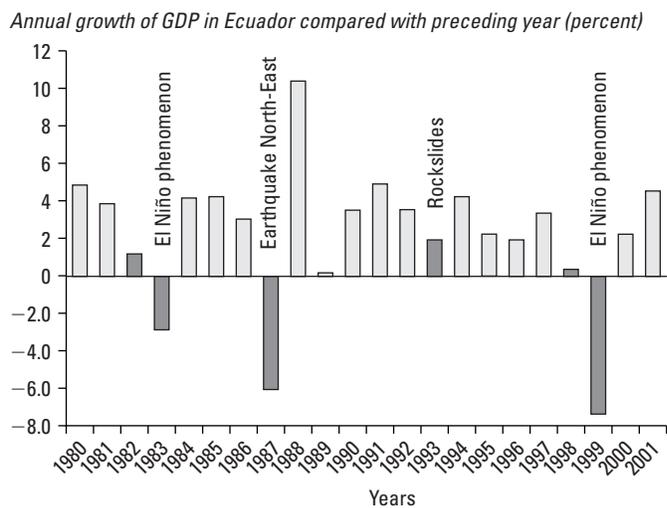

Disaster impact statistics show a global trend: more disasters occur, but fewer people die; larger populations are affected, and economic losses are increasing (IFRC 2000).

Geographic Distribution of Risk. Natural disasters do not occur at random. Geological hazards (earthquakes and volcanic eruptions) occur only along the fault lines between two tectonic plates on land or on the ocean floor. However, the local population often does not recognize the implications (the risks), as shown in the December 2004 tsunami in the Indian Ocean.

Source: UN/ISDR, 2004.

Figure 61.1 Disaster Losses, Total and as Share of Gross Domestic Product, in the Richest and Poorest Nations, 1985–99

Source: UN/ISDR, 2004.

Figure 61.2 Annual Growth of Gross Domestic Product and Occurrence of Major Natural Disasters in Ecuador, 1980–2001

Hydrometeorological hazards do not follow a well-established distribution. Although the areas subject to seasonal flood, drought, or tropical storms (cyclones, hurricanes, or typhoons) are well known locally, global warming may possibly redraw the map of climatic disasters. As the National Research Council (1999, 34–35) notes, “This change is far from uniform. A pattern of response ‘modes’ appears to be involved, in which warming is concentrated in northern Asia . . . while large regions of the northern Pacific and North Atlantic Oceans and their neighboring shores have actually cooled.” El Niño–related fluctuations in relation to the gross domestic product (GDP) of Ecuador are shown in figure 61.2.

The risk of massive technological disasters, such as the catastrophic release of chemicals in Bhopal, India (methyl isocyanate), in December 1984, is serious in countries with significant industry (WHO 1992, 1996). Very few countries are immune to public health risks from hazardous chemical substances (from insecticides to industrial by-products) or discarded radioactive material from therapeutic or diagnostic use. Technological hazards increase rapidly with the unregulated industrialization of developing countries and the globalization of the chemical industry, suggesting that chemical emergencies may become a major source of disasters in the 21st century.

Factors Affecting Vulnerability. Vulnerability to all types of disasters—and to poverty—is linked to demographic growth, rapid urbanization, settlement in unsafe areas, environmental degradation, climate change, and unplanned development.

Age The importance of age as a factor of vulnerability can be significant in situations where physical fitness is necessary for survival. The higher fatality among children, elderly, or sick adults following the 1970 tidal wave in Bangladesh (250,000 fatalities) and the 2004 tsunami in Asia (more than 180,000 dead or missing) illustrates this point.

Gender Reports on immediate morbidity and mortality according to gender are not as conclusive. An Inter-American Development Bank paper indicated that 54 percent of the 3,045 people who died as a result of Hurricane Mitch in Nicaragua were male (IDB 1999). Stereotypes of gender vulnerability at the time of impact often do not apply. Depending on the type of disaster, far more significant vulnerability factors than gender or age are the time of day of the impact (and, therefore, the occupational activity of each group) and the structural vulnerability of housing, factories, and public buildings, including the location of the victims within the buildings. Following disasters, increased vulnerability of women is commonly noted in temporary settlements, where violence and sexual abuse are common. Specialized health care also may not be available (Armenian and others 1997).

Poverty Economic vulnerability might play a much greater role than age and gender. What has been noted regarding the greater vulnerability of poor countries also holds true at the community and family levels. Disasters predominantly affect the poor. Poverty increases vulnerability because of the unequal opportunity for healthy and safe environments, poor education and risk awareness, and limited coping capacity. A notable exception was the 2004 tsunami in Banda Aceh, Indonesia, where the middle- and upper-class neighborhood close to the shore was particularly affected.

A major example is the settlement of a large number of economically disadvantaged populations in highly vulnerable

locations, particularly urban areas. Following Hurricane Mitch in Tegucigalpa, Honduras, families that were relocated from flooded areas to safer (but inconveniently remote) ground were rapidly replaced by new illegal settlers. In 2003, families killed by a landslide in Guatemala had been warned about their vulnerability but were unable to afford resettlement in safer (and more costly) areas. Subsidies alone may not have prevented this effect, given the overarching issue of land ownership by a few in Central America.

Short-Term Health Burden

Losses fall under three categories, which may have both direct and indirect components:

- lives and disabilities (both direct damage and an indirect consequence)
- direct losses in infrastructure and supplies (direct impact)
- loss or disruption in the delivery of health care, both curative and preventive (indirect impact).

The immediate health burden is directly dependent on the nature of the hazard. National health budgets of developing countries are, in normal times, insufficient to meet the basic health needs of the population. In the aftermath of a major disaster, authorities need to meet extraordinary rehabilitation demands with resources that often have been drained by the emergency response (as distinct from the resources destroyed by the event). Beyond the immediate response, decision making in the allocation of resources among sectors is mostly influenced by the magnitude of the economic losses rather than by the health statistics (principally the disability-adjusted life year, or DALY, losses) or social costs.

Earthquakes. As noted by Buist and Bernstein (1986), in the past five centuries, earthquakes caused more than 5 million deaths—20 times the number caused by volcanic eruptions. In a matter of seconds or minutes, a large number of injuries (most of which are not life-threatening) require immediate medical care from health facilities, which are often unprepared, damaged, or totally destroyed, as was the case in the earthquake in Bam, Iran, in 2003. In the aftermath of that earthquake, which resulted in 26,271 deaths, the entire health infrastructure of the city was destroyed. All traumas were evacuated by air to the 13 Iranian provinces long before the arrival of the first foreign mobile hospitals. Table 61.1 illustrates the accelerated pace with which priorities evolve and overlap in the first week following an earthquake.

After a few weeks, national political solidarity and external assistance wane, and the local budgetary resources are drained. At the same time, health authorities face the overwhelming task of providing services to a displaced population, rehabilitating

Table 61.1 Health Priorities Following Earthquakes

Priority	Time period	Comments
Search and rescue	0 to 48+ hours	Returns are rapidly diminishing. Most effective work is done by local teams.
Trauma care	0 to 48 hours: initial lifesaving care ^a 48 hours to 6 months: secondary care	External assistance generally arrives too late for initial care. Traumas may include burns and crush syndrome, especially in urban areas. Paraplegics and amputees require long-term care.
Routine medical emergencies and primary health care	Resumes as soon as the need for acute lifesaving care subsides (within 24 hours)	Emergencies include earthquake-related cardiovascular emergencies and premature births.
Attention to the dead	Varies. Not a public health issue but a social and political one	Priorities are identification and ritual burial.
Disease surveillance	Urgent—within 48 hours, unsubstantiated rumors of impending epidemics will be circulating	Surveillance is a sensitive public information and education issue. A simple, syndrome-based system is needed that will involve humanitarian organizations.
Provision of safe water	A predominant issue within 48 hours	The challenge is to provide a sufficient quantity of reasonably safe water.
Temporary shelter	48 hours to several months	Sanitation and provision of health services is a main issue. Accommodating families near their residence is preferable to setting up camps.
Provision of food	3 days to 6 weeks	Food provision is a social or economic issue. Food stocks and agricultural output are not affected by earthquakes.
Psychosocial care	7 days to 6 months	Mental health assistance is best provided by local personnel, if available.

a. Following the earthquake in Mexico City in 1985 (10,000 deaths), bed occupancy rates did not exceed 95 percent despite the loss of 5,829 hospital beds.

health facilities, restoring normal services, strengthening communicable disease surveillance and control, and attending to the long-term consequences, such as permanent disabilities, mental health problems, and possibly long-term increases in rates of heart disease and chronic disease morbidity (Armenian, Melkonian, and Hovanesian 1998).

Tsunamis. Earthquakes on the ocean floor may cause catastrophic tidal waves (*tsunamis*) on faraway shores. Waves caused by the seismic event crest at less than a meter in open seas, but they are travel several hundred kilometers per hour, so when they reach shallow waters, they can be 10 meters high. Damage on the coast can be extensive. Usually, the number of survivors presenting severe injuries is small in proportion to the number of deaths.

Volcanic Eruptions. Volcanoes persist as a serious public health concern, though they are often overlooked by authorities and communities lulled by long periods of inactivity. Eruptions are preceded by a period of volcanic activity, which provides an opportunity for scientific monitoring, warning, and timely evacuation.

Some issues, such as ash fall, lethal gases, lava flow, and projectiles, although of concern to the public, are of minimal health significance: Ash fall causes a significant burden on medical services but is unlikely to result in excess mortality or significant permanent problems. However, ash fall affects transportation, communications, water sources, treatment

plants, and reservoirs. Studies by Bernstein, Baxter, and Buist (1986) following the 1980 eruption of Mount St. Helens (United States) reviewed the transient, acute irritant effects of volcanic ash and gases on the mucous membranes of the eyes and upper respiratory tract as well as the exacerbation of chronic lung diseases with heavy ash fall. Concentrations of volcanic gases are rapidly diluted to nonlethal levels, which lead to inconvenience but negligible morbidity for the general public. Lava flows present little health risk because of their very slow speed of progression. Mortality caused by ballistic projectiles from a volcanic eruption is minimal.

Attention to these public concerns may distract the authorities from preparing for the greatest factors of mortality: the pyroclastic flows (Mount Pelé in Martinique, in 1902, with 29,000 deaths) and lahars. *Lahars* are mud flows or mud and ash flows caused by the rapid melting of a volcano's snowcap, as in Colombia in 1985 (23,000 deaths), or caused by heavy rains on unstable accumulations of ash, as in the Philippines in 1991. Historically, pyroclastic explosions or lahars have caused about 90 percent of the casualties from volcanic eruptions.

Potential contamination of water supplies by minerals from ash; displacement of large populations for an undetermined period of time (over five years in Montserrat, a small island in the Caribbean); accompanying sanitation problems; and mental health needs are of great public health significance (PAHO 2002a). Among the long-term problems, the risk of developing silicate pneumoconiosis requires further investigation.¹

Climatic Disasters. Many communities and health services have learned to live with seasonal floods of moderate intensity. Periodically, the magnitude of the phenomenon exceeds the local coping capacity and overwhelms the resources of the health systems. The health burden associated with seasonal floods is well known locally: increased incidence of diarrheal diseases, respiratory infections, dermatitis, and snake bites. The actual risk of compromised water supplies depends on the level of contamination of the community's water supply before the disaster, compared with contamination after the flooding. Saline contamination is a long-term issue following sea surges and tsunamis. Prolonged flooding endangers local agriculture and occasionally requires food assistance on a large scale. The primary factors of morbidity remain overcrowded living conditions and poor water and sanitation in temporary settlements and other areas where water and sanitation services have deteriorated or are suspended.

Mortality and morbidity caused by tropical storms (hurricanes in the Atlantic Ocean and typhoons in the Pacific Ocean) result from, in increasing order of importance, high winds, heavy rainfall, and storm surge. When Hurricanes Mitch and George hit the Caribbean in 1998, traumatic injuries (lacerations or electrocution) caused by high winds of up to 150 miles per hour were relatively few; deaths from extensive rainfall (leading to flash floods and landslides) constituted the bulk of the more than 13,000 fatalities (PAHO 1999). In the Bangladesh delta, storm surges up to 6 meters traveled unimpeded over hundreds of kilometers and claimed between 250,000 and 500,000 lives in 1970 and up to 140,000 lives during five cyclones in the 1990s—primarily during one storm in 1991. Another cost is the need for specialized psychosocial assistance to large numbers of the population who survive the sustained violence of nature.

Cumulative mortality caused by small, undocumented mudslides and rockslides from water-saturated, unstable slopes probably approach the toll from well-known landslides (earthquakes in Peru in 1970 and in El Salvador in 2001, and the rains in Caracas, Venezuela, in 1999). Morbidity problems are often minimal, as survivors in the path of the landslide are few.

Impact on Communicable Diseases

Disasters related to natural events may affect the transmission of preexisting infectious diseases. However, the imminent risk of large outbreaks in the aftermath of natural disasters is overstated. Among the factors erroneously mentioned is the presence of corpses of victims, many buried beneath rubble. Dead bodies from a predominantly healthy population do not pose a risk of increased incidence of diseases (Morgan 2004). Catastrophic incidence of infectious diseases seems to be confined to famine and conflicts that have resulted in the total failure of the health system.

In the short term, an increased number of hospital visits and admissions from common diarrheal diseases, acute respiratory infections, dermatitis, and other causes should be expected following most disasters (Howard, Brillman, and Burkle 1996; Malilay and others 1996). This increase may reflect duplicate reporting (diarrhea cases were reported through both the emergency and the routine surveillance systems in Maldives after the 2004 tsunami), a temporary surge in surveillance, and medical attention available to an otherwise underserved population rather than representing a genuine change in the epidemiological situation.

In the medium term, heavy rainfalls may affect the transmission of vectorborne diseases. Following an initial reduction as mosquito-breeding sites wash away, residual waters may contribute to an explosive rise in the vector reservoir. When associated with a breakdown of normal control programs, this rise in the vector reservoir may lead to epidemic recrudescence of malaria or dengue. Retrospective studies (Bouma and Dye 1997; PAHO 1998; UN/ISDR 2004, 156) all confirm a direct but delayed relationship between the intensity of rainfall (regardless of the existence of flooding) caused by the El Niño phenomenon and the incidence of malaria. Flooding has contributed to local outbreaks of leptospirosis (in Brazil and Jamaica, for example; PAHO 1982) and hepatitis A in Latin America and Africa (WHO 1994).

In summary, what can be expected and prevented is a local surge in problems that the health services are normally used to handling.

Long-Term Impact and Economic Valuation

In addition to the delayed impact on transmission and control of endemic diseases and the burden of disabilities (paraplegia, amputation, burns, or chronic or delayed effects of chemical or radiological exposure), the health sector bears a significant share of the economic burden. Disasters must be seen in a systemic (that is, intersectoral) manner: what affects the economy will affect the health sector—and vice versa. After the emotional response of the first few days, decision makers in a crisis react primarily to political and economic realities, not to health indicators. Economic valuation of the social burden—that is, placing a monetary value on the cost—becomes a critical tool as the various sectors compete for scarce resources. The health sector, in particular, must learn how to use this tool in spite of being absorbed by its immediate relief responsibilities.

Valuation of Disasters. The Economic Commission for Latin America and the Caribbean (ECLAC) has developed over the decades a methodology for the valuation of disasters (ECLAC 2003). This tool, intended for reconstruction, has also proved its usefulness by developing historical records of major events, particularly of the health burden expressed in economic terms.

Valuation is made using all possible sources of information, from georeferenced satellite mapping and remote sensing to more conventional statistical data, direct observation, and surveys, with a reliance on information gathered immediately after the event. Economic valuation rests on the basic concepts of direct damage and indirect losses.

Direct damage is defined as the material losses that occur as an immediate consequence of a disaster.² Direct damage is measured first in physical terms. The physical loss includes assets, capital, and material things that can be counted: hospital beds lost, equipment and medicines destroyed, damaged or affected health service installations (number and type of installations, stocks of medicines, laboratory facilities, operating rooms, and so on), and pipes and water plants destroyed.

The physical plant then is valued both in terms of discounted present value and estimated replacement cost. Reconstructing facilities with the same vulnerability and level of service as before would be unacceptable; the affected health infrastructure must be replaced by more resilient and efficient installations to ensure better and sustainable service. This need is most evident in developing countries where impacts tend to be concentrated in those most at risk (the poor, marginalized, and less resilient sectors of the population).

Indirect effects refer to production of goods and services that will not occur as an outcome of the disaster, reduced income associated with those activities not occurring, and increased costs to provide those goods and services.

In the case of health services, indirect effects encompass both the income losses associated with the diminished supply of health care services and the increased costs of providing the services following the disaster. Indirect effects are valued at the current market value of goods or services not produced and the costs associated with the necessary provision of services under emergency, disaster-related conditions. Both compo-

nents of the cost of illness—the cost of treatment and the cost of lost opportunities (lost income and employment, loss of time and productivity)—are sharply increased. The social burden is heavier on the poorest, who are unable to adjust their willingness to pay to absorb the additional expenses of alternative (private) providers of care.

The same approach applies to the economic valuation of lives lost. Kirigia and others (2004) found a statistically significant impact of disaster-related mortality on the GDP of African countries. One single disaster death reduced the GDP per capita by US\$0.01828. Lost lives are given a higher economic value in places where productivity is high.

Because economic valuation uses standard sectorized procedures that allow comparability of results, it can be used in the decision-making process and for policy formulation since it identifies sectors, geographical areas, and vulnerable groups that are more severely affected economically. Over the years, a number of conceptual improvements have been made to allow for the measurement of aspects not included in national accounting systems—to bring attention to environmental losses as a cross-cutting issue; to highlight the contribution of specific groups, namely women, as agents for change; and to focus on the better management of both the emergency and the reconstruction processes. It is also a valuable tool for preparedness and mitigation of future damage.

Table 61.2 summarizes the valuations made by ECLAC over the years for Latin America and the Caribbean in terms of deaths, affected populations, and economic losses (2003 values). Of interest are the decrease in the number of deaths and the increase in total damage (in particular, indirect damage) over time.

The distribution of direct and indirect damage in the health sector also varies. According to ECLAC (2003), direct damage between 1998 and 2003 in Latin America ranged from 44.6 percent to 77.2 percent of total damage.

Table 61.2 Impact of Disasters in Latin America and the Caribbean

Date	Population		Damage (2003 US\$ millions)		
	Deaths	Affected	Total	Direct	Indirect
1972–80	38,042	4,229,260	9,376	5,420	3,956
1981–90	33,638	5,442,500	19,603	13,916	5,687
1991–2000	11,086	2,318,508	20,902	10,401	10,501
2001–2002	120	4,828,470	4,498	2,270	2,228
Total of major events 1972–2002	82,886	16,818,738	54,379	32,007	22,372
Overall estimate including small disasters ^a	103,608	21,023,422	67,974	40,009	27,965
Average per year	3,454	700,781	2,266	1,334	932

a. The full image should include the recurrent small disasters that do not make the headlines but have a cumulative negative effect. Such disasters can be more pervasive and damaging to the development process because their economic, social, psychological, and political effects are hardly perceived. An estimate of the average losses of small disasters would be at least 25 percent greater than those of large disasters.

Specific Damage to the Health Infrastructure. Damage to housing, schools, channels of communication, industry, and so on contributes to the health burden. However, the following analysis focuses on the health infrastructure (understood as health care facilities, including hospitals, health centers, laboratories, and blood banks) and the drinking water and sanitation infrastructure.

Damage to Hospitals and Health Installations Most data and examples presented here come from Latin America and the Caribbean because of the disaster reduction programs in the health sectors of those regions. In the past two decades, damage to approximately 260 hospitals and 2,600 health centers resulted in interruption of services at a direct cost of US\$1.2 billion. In the 1985 earthquake in central Mexico, 5,829 beds were destroyed or evacuated (PAHO 1985), at a direct cost of US\$550 million (ECLAC 1998). Hurricane Gilbert (1988) damaged 24 of the 26 hospitals on Jamaica, and the El Salvador earthquake (2001) resulted in the loss of 2,000 beds—40 percent of the country's hospital capacity (PAHO 2002b). The health burden is not limited to the loss of medical care. The control of communicable diseases and other public health programs suffer from loss of laboratory support and diagnostic capabilities of hospitals. Further research on the actual impact of these losses, in terms of DALYs, is essential.

A common misperception is that damage to critical health facilities is promptly repaired. Experience shows that damaged health infrastructure recovers at a slower pace than infrastructure in other service sectors, such as trade, roads, bridges, telecommunications, and even housing. For example, as a result of the earthquake that affected El Salvador in 1986, renovation of the general hospital, the most sophisticated referral hospital in the capital, was completed 15 years after the earthquake. The only national pediatric facility was fully rehabilitated and strengthened six years after the earthquake. Two years after the earthquake of 2001 in El Salvador, several key hospitals still remained vacated or services were transferred to unsuitable temporary facilities. The factors are many: low priority assigned to a nonproductive sector, the sector's inexperience in developing comprehensive proposals for funding, conflicting attempts to use the reconstruction process to influence the ongoing reform and decentralization processes, the novelty of the engineering and design issues for safe hospital construction, the complicated negotiation process for loans, and the administrative inexperience of the health sector in executing large investment projects. Indeed, few large health installations have been built directly by developing countries in the past decades.

Damage to Water and Sewage Systems The primary goal of water and sewage systems is to safeguard the public health of the population. For that reason, these systems are considered part of the health infrastructure.

The developmental burden is significant. In the past 30 years in Latin America and the Caribbean alone, an estimated 400 urban water supply systems and 1,300 rural systems (in addition to 25,000 wells and 120,000 latrines) were severely damaged, at an estimated cost of almost US\$1 billion—a major setback to efforts to expand coverage and improve those services. In severe flooding, the sudden interruption of these basic services coincides with the direct effect on the transmission of waterborne or vectorborne diseases. In the case of earthquakes, the number of people who are adversely affected by water shortage may far exceed those injured or suffering direct material loss.

As in the case of health care facilities, the rehabilitation of public water systems is slow, particularly for community-owned or community-operated rural systems, which may not be repaired for decades. The foregoing demonstrates the need for water authorities to harmonize their short-term objectives, which are oriented almost exclusively to increasing the coverage of these services, with the long-term objective of reducing vulnerability to extreme natural hazards.

INTERVENTIONS: FROM RESPONSE TO PREVENTION

The immediate lifesaving response time is much shorter than humanitarian organizations recognize. In a matter of weeks, if not days, the concerns of both the population and authorities shift from search and rescue and trauma care to the rehabilitation of infrastructure (temporary restoration of basic services and reconstruction). In Banda Aceh, Indonesia, after the December 2004 tsunami, victims were eager to return to normalcy while external medical relief workers were still arriving in large numbers.

Response and Rehabilitation

Immediate emergency response is provided under a highly political and emotional climate. The public demands visible, albeit perhaps unnecessary, measures at the expense of proven low-key approaches. The international community, eager to demonstrate its solidarity or to exercise its "right of humanitarian intervention," undertakes its own relief effort on the basis of the belief that local health services are unwilling or unable to respond. Donations of useless medical supplies and medicines and the belated arrival of medical or fact-finding teams add to the stress of local staff members who may be personally affected by the disaster. The cultural disregard of the humanitarian community to cost-effective approaches in times of disaster and the tendency to base decisions on perceptions and myths rather than on facts and lessons learned in past disasters contribute to making disaster relief one of the least cost-effective health activities.

The responsibilities of the national or local health authorities are significant.

Assessment of the Health Situation. A country's ministry of health is expected to assess the health situation. To influence the course of humanitarian response, this assessment must be rapid and, therefore, simple; transparent in collaboration with the main actors—nongovernmental organizations (NGOs) and donors; and technically credible. The input of WHO, as the lead agency in health matters, is most valuable. Confusion should be avoided between assessing emergency needs and inventorying or valuating the damage. In the first hours or days, relief actors base their decision making on the ministry of health's assessment of what is required and, more importantly, what is not required for emergency response. Later, the international community will request detailed data, such as the number of persons affected, buildings damaged, and monetary valuation.

Mass Casualties Treatment. Following natural disasters, hospital capacity may be considerably reduced by actual damage to the facility or, in the case of a seismic event, an often unnecessary—but hard to reverse—evacuation. Triage of patients is required in order to first treat those likely to benefit most, rather than the terminally injured or those whose care can be delayed. Lifesaving primary care takes place in the first six hours (the golden rule of emergency medicine), making most of the foreign field hospitals irrelevant for intensive acute care of traumas (WHO and PAHO 2003). Effectiveness of immediate care will depend on local preparedness before the disaster, not on faraway resources.

Strengthened Surveillance, Prevention, and Control of Communicable Diseases. Because the surveillance, prevention, and control of communicable diseases are strengthened, the anticipated massive outbreaks generally do not actually occur.

Traditional surveillance systems that are based on periodic notification of diseases by the health services are inadequate in a crisis situation. Early warning requires flexible and simple syndrome-based monitoring in temporary settlements and health centers, with information collected not only by the official health services but also by the medical humanitarian organizations. Systems that do not include consultation with NGOs are unlikely to succeed.

Disease control programs in place before the disaster are the fruit of local experience and external technical advice. In a disaster situation, there is generally no need to resort to new and expensive control measures. The key is to quickly resume, strengthen, and better monitor the routine control programs. No public health concerns justify the hurried disposal of corpses through mass burial or unceremonious incineration. This practice is socially and culturally damaging. In addition, improvised mass immunization campaigns, especially by external relief groups, should be discouraged in favor of opportunistically strengthening national routine immunization coverage, especially in temporary settlements.

Environmental Health. Typical interventions in the aftermath of disasters include strengthening the monitoring and surveillance of water quality, vector control, excreta disposal, solid waste management, health education, and food safety.

A first priority is water supply. It is often preferable to have a large quantity of reasonably potable water than a smaller amount of high-quality water (UNHCR 1998). Massive distribution of water purification disinfectants can be effective if the public is already familiar with their use and not confused by the availability of many different brands and concentrations of donated chemicals.

Health education and hygiene promotion efforts target populations in shelters, temporary camps, collective kitchens, or prepared food distribution centers.

The cost-effectiveness of the external relief effort could often be increased by shifting resources from the overattended medical response to the improvement of environmental health in temporary settlements.

Transparent Management of Donations and Supplies. If donations and supplies are managed transparently during the emergency, the flow of assistance to the intended beneficiaries will be improved. Unsolicited and often inappropriate medical donations compete with valuable relief supplies for scarce logistical resources. Good governance is critical, and effective logistics cannot be improvised following a disaster. A humanitarian supply management system developed by PAHO and WHO successfully helped developing countries improve transparency and accountability in managing humanitarian supplies and donations (de Ville de Goyet, Acosta, and others 1996).

Coordination of the Humanitarian Health Effort. Coordination of the humanitarian health effort is essential to maximize the benefit of the response effort and ensure its compatibility with the public health development priorities of the affected country. Effective coordination in the health sector must do the following:

- Be comprehensive and include all external health actors.
- Be based on mutual respect rather than regulatory authority alone. Dialogue and consultation are more effective than enforcement.
- Benefit all parties, starting with the victims. It should aim to support and facilitate the activities of other partners.
- Be evidence-based and transparent. Information is made to be shared and used, not jealously guarded.

Coordination cannot be improvised in the aftermath of a disaster. Preparedness before the occurrence of the hazard is essential.

Emergency Preparedness of the Health Sector

Effective response by national health authorities cannot be impromptu. Ministries of health that neglected to invest in capacity building before emergencies have generally experienced serious difficulties in exercising their technical and political leadership in the immediate aftermath of a disaster. Disaster preparedness is primarily a matter of building institutional capacity and human resources, not one of investing heavily in advanced technology and equipment.

Building local coping capacity is one of the most cost-effective ways to improve the quality of the national response and the external interventions.

Disaster preparedness is not merely having a disaster plan written by experts. It must involve the following:

- Identifying vulnerability to natural or other hazards. The health sector should seek information and collaborate with other sectors and institutions (civil protection, meteorology, environment, geology) that have the primary responsibility for collecting and analyzing this information.
- Building simple and realistic health scenarios of a possible and probable occurrence. It is challenging enough to prepare for a moderate-size disaster; building and sustaining a culture of fear based on unrealistic worst-case scenarios may serve the corporate interests of the disaster community but not the interests of the public at large.
- Initiating a participative process among the main actors to develop a basic plan that outlines the responsibilities of each actor in the health sector (key departments of the ministry of health, medical corps of the armed forces, private sector, NGOs, UN agencies, and donors). What matters is the process of identifying possible overlaps or gaps and building a consensus—not the paper plan itself. Disasters often present problems that are unforeseen in the most detailed plans.
- Maintaining a close collaboration with these main actors. A good coordinator is one who appreciates and adapts to the strengths and weaknesses of other institutions. Stability is essential. Changes of key emergency staff members during a disaster situation or when a new administration or minister take over have occasionally complicated the tasks.
- Sensitizing and training the first health responders and managers to face the special challenges of responding to disasters. Participation of external actors (UN agencies, donors, or NGOs) in designing and implementing the training is critical. The incorporation of disaster management in the academic curriculum of medical, nursing, and public health schools should complement the on-the-job training programs of the ministry of health, UN agencies, and NGOs. Well-designed disaster management training programs will improve the management of daily medical emergencies and accidents as well.

Prevention and Mitigation

The slogan “prevention is better than cure” was invented by the health sector. However, this sector has been slow to adopt the concept of preventing deaths and injuries from disasters through the mitigation (that is, reduction) of damage to its own facilities. As is unfortunately often the case, political action is often triggered only by a major disaster, such as the collapse of Hospital Juarez in Mexico in the earthquake of 1985; in that disaster 561 patients and employees died, (Poncelet 1997). Evaluating the damage (the past vulnerability) helps establish mitigation criteria for the future.

The level of protection required for each health installation must be negotiated—from life protection, which prevents an immediate structural collapse to permit the evacuation of people; to investment protection, which minimized the economic losses; to operational protection, which guarantees the sustainability of services under any extreme circumstances. Though a commercial or office building may be structurally designed only to prevent loss of lives, key hospitals must remain operational during the times they are most needed.

Local engineering and architectural experts play a key role in developing the knowledge, technical abilities, and cost-effectiveness analysis to establish mitigation priorities. Technical mitigation guidelines prepared at a global level (PAHO, WHO, World Bank, and ProVention Consortium 2004) need to be adapted to local culture, conditions, and resources.

Reducing the physical vulnerability of infrastructure can take place on three different occasions (UN/ISDR 2004, 324):

- *When reconstructing the infrastructure destroyed by a disaster.* At that time, risk awareness is high, political will is present, and resources are available.
- *When planning new infrastructure.* Reducing vulnerability is most cost-effective and politically acceptable when it is included at the earliest planning and negotiation stage, whether it involves a 1 to 2 percent additional cost for wind resistance or a 4 to 6 percent additional cost for earthquake resilience. Full resistance to any damage is prohibitively expensive.
- *Strengthening of existing facilities (retrofitting).* This most expensive measure has been adopted by several developing countries (Chile, Colombia, Costa Rica, Mexico, Peru, and others) to protect their most critical health facilities. In the earthquake in Colombia in 1999, partial retrofitting of the main hospital is credited for saving the installation. Costs vary greatly (see table 61.3).

Mitigation of Damage to Hospitals. Mitigation does not pretend to eliminate all possible damage from hazards but aims to ensure the continuing operation of the health facility at a level previously defined by the health authority. Hospitals

Table 61.3 Retrofitting of Hospitals in Costa Rica

Hospital	Number of beds	Duration of retrofitting (months)	Cost of retrofitting (US\$)	Percentage of total value of the hospital
Hospital Mexico	600	31	2,350,000	7.8
Children's Hospital	375	25	1,100,000	4.2
Hospital Monseñor Sanabria	289	34	1,270,000	7.5

Source: PAHO and WHO 2000.

should be subject to stricter norms than other less critical facilities that are designed to prevent only total collapse and loss of life.

Hospital mitigation interventions fall into three categories:

- *Functional mitigation* to ensure that the necessary supporting infrastructure services permit continuing operation: water, electricity, road access, communications, and so forth. Improving routine maintenance will facilitate operations under normal circumstances and in the event of extreme hazards.
- *Nonstructural mitigation* to reduce losses and health injuries from falling or moving objects. Measures include, for instance, proper anchoring of equipment for earthquakes or strong winds or the location of only noncritical services on flood-prone floors.
- *Structural mitigation* to ensure the safety of the structure itself (columns, beams, load-bearing walls).

Given the high economic, health, and political costs represented by the avoidable loss of critical health facilities, health authorities and funding agencies should require that, in all new health infrastructure projects, natural hazards be a decisive factor for selecting the facility's location and for formulating the specifications at the earliest stage of the process.

Mitigation of Damage to Water Systems. Unlike hospitals, water supply systems are geographically extensive and thus are exposed to different types of hazards. The search for technical solutions is more complex, given the diversity of the water system's components. Finally, in many countries, the health authorities have no jurisdiction over the construction or operation of those services owned or administered by many local or municipal agencies.

Even a short disruption of water services may have serious and direct implications for the health of individuals, the operation of health services, and the community at large through its impact on business. A probabilistic model studied the disruptive potential of a water outage in the event of an earthquake in Los Angeles county in the United States. As noted by the authors, "water outage is more likely to be disruptive for businesses in some industries, such as health services, than for others" (Chang and Chamberlin 2004, 89).

The health sector should, therefore, coordinate with the institutions in charge of constructing, operating, and maintaining water and sanitation services, both urban and rural, to promote reduction of the vulnerability of existing systems. The health sector should also ensure that health aspects and mitigation of damage be included in the regulatory framework and operating procedures of water and sanitation services.

Protecting the water supply is feasible in developing countries. The Costa Rican Institute of Aqueducts and Sewage Systems reduced the vulnerability of one of the main aqueducts of the country, the Orosi Aqueduct. Over 10 years, Costa Rica invested almost US\$1.5 million in studies and reinforcements, an amount equivalent to 2.3 percent of the total cost of the aqueduct. This investment would prevent a loss of nearly US\$7.3 million in direct damages alone (FEMICA 2003).

INTERVENTION COST, COST-EFFECTIVENESS, AND ECONOMIC BENEFITS

The highly emotional and sensationalized climate of disaster response has long prevented the adoption of a cost-effectiveness approach in decision making. When survival of both people and political institutions is threatened, perceptions and visibility tend to prevail over facts and analysis, resulting in a lack of evidence-based studies on costs and benefits.

The willingness to spend hundreds of thousand of dollars per victim rescued from a collapsed building in a foreign country is a credit to the solidarity of the international community, but it also presents an ethical issue when, once the attention has shifted away, modest funding is unavailable for the mid-term survival of tens of thousands of victims.

Cost-Effectiveness of Selected Humanitarian Interventions

Emergency health interventions are more costly and less effective than time-tested health activities. Improvisation and rush inevitably come with a high price. The preferential use of expatriate health professionals; the emergency procurement and airlifting of food, water, and supplies that often are available locally or that remain in storage for long periods of time; and the tendency to adopt dramatic measures contribute to

making disaster relief one of the least cost-effective health activities.

Search and Rescue. Few developing countries have established the technical capacity to search for and attend to victims trapped in confined spaces in the event of the collapse of multistory buildings. Industrial nations routinely dispatch search and rescue (SAR) teams. Costs are high and effectiveness is reduced by delayed arrival and quickly diminishing returns. Following the 1988 earthquake in Armenia, in the former Soviet Union, the U.S. SAR team extracted alive only two victims at a cost of over US\$500,000. In Turkey in 1999, 98 percent of the 50,000 people pulled alive from the rubble were salvaged by relatives and neighbors. In Bam in 2003, the absence of high-rise and reinforced concrete buildings ruled out the need for specialized teams. Nevertheless, according to UN statistics, at least US\$2.8 million was spent on SAR teams. An alternative solution consists of investing these resources in building the capacity of local or regional SAR teams—the only ones able to be effective within hours—and training local hospitals to dispatch their emergency medical services to the disaster site.

Field Hospitals. The limited lifesaving usefulness of foreign field hospitals has been discussed. Again, the lessons learned from the Bam earthquake are clear. The international community spent an estimated US\$10.5 million to dispatch approximately 10 mobile hospitals,³ which arrived from two to five days after the impact, long after the last casualty had been evacuated to other Iranian provinces. This delay alone, hard to reduce further, rules out any significant contribution to immediate trauma care and led the hospitals to compete for routine outpatient care with the teams of Iranian volunteers from across the country. A few of the mobile hospitals, better prepared to meet nontrauma needs and to stay much longer than the usual two to three weeks, have been invaluable. No data are available on the number of lives actually saved by mobile hospitals (that is, lives that would not have been saved by local means). Less understood are the negative effects of such hospitals on local health services, which are often marginalized and discredited for their lack of technology and sophistication but which must cope once the external facility leaves.

The cost of mobilizing a mobile hospital for a few weeks often exceeds US\$1 million, funds that would be more productive in the construction and equipping of a simple but sturdy temporary facility. Such an approach was adopted by the U.S. Army Southern Command in Wiwili, Nicaragua, in the aftermath of Hurricane Mitch. In the case of Bam, Iran, the cost of rebuilding the entire primary and secondary health care facilities and teaching institutions was estimated by the government of Iran to be US\$10.75 million, an amount very similar to that expended for the dispatch of field hospitals

from the international community. Guidelines for the use of foreign field hospitals are available from WHO and PAHO (2003).

In-Kind Donations. Unsolicited donations of inappropriate medical supplies not only are of limited use, but often cause serious logistic, economic, and political problems in the recipient country. Warehousing those supplies and, in many instances, building facilities (incinerators, for example) for the safe disposal of pharmaceutical donations diverts humanitarian funds from more effective uses. Recipient countries collectively share part of the responsibility by not clearly indicating what they do not want to receive and by not speaking out once inappropriate items arrived.

Disease Prevention and Control. Postdisaster interventions in surveillance and control of communicable diseases should focus on strengthening existing programs. Benefits will outlive the crisis. Improvised mass immunizations (instead of improved sanitation and public awareness) and vector control by aerial spraying or fogging (instead of breeding-site reduction or waste disposal) are just two examples of wasteful managerial decisions.

Shelters. Tent cities should be a last resort. Family-size tents may be expensive and do not last long. Establishing large settlements is easy, but such settlements are difficult to sustain and nearly impossible to terminate. They come with their own sanitation problems and social shortcomings (lack of privacy, loss of family identity, and loss of empowerment). Distributing construction material (or, preferably, cash subsidies) is more cost-effective and tailored to the needs and priorities of end users.

Cash Assistance. Developed societies long ago abandoned the distribution of in-kind relief goods and services to their nationals in favor of direct financial assistance in the form of subsidies, grants, or tax relief. The individual is free to determine actual priorities and to seek the most cost-effective source of services (shelter, medical, food, or other). It is therefore surprising that external assistance from these same countries remains focused on the costly delivery of predetermined services or commodities.

The most immediate lifesaving needs can be addressed only locally with existing resources and capacity. No cash contribution will meet those immediate needs. Beyond the acute phase, in many countries with market economies, most other services and goods are easily procured by those with financial means, suggesting that income availability is often the single limiting factor in rehabilitation.

Undoubtedly, this approach would affect considerably the type (and number) of humanitarian actors by transferring

power and decision making to the local beneficiaries and relying on local economic forces for delivery to the end user. It may also bring its own set of problems (and abuses), though perhaps that is a small cost, considering the economic and social benefits of the most interested party—the victim—being in charge.

Cost-Effectiveness of Prevention and Mitigation

The social benefits of making hospitals and water systems more resilient to the effects of natural hazards are recognized but too rarely applied. On the economic side, mitigation also increases the investment capacity in the health sector by preventing losses and the need for reconstruction (PAHO and UN/ISDR 1996; Bitrán 1996).

The most compelling case for the cost-effectiveness of mitigation can be made during the planning phase for new installations, when costs of additional structural safety are minimal. Although the social benefits of prevention and risk management are more evident in the health sector than in others, further studies are needed to provide decision makers with quantified parameters of the economic benefits brought about by investment in risk management and disaster reduction.

PAHO and UN/ISDR (1996) studies indicate that such increased investment fluctuates between 4 and 8 percent of a hospital's local construction cost. When the value of services lost is added to the infrastructure loss, the additional investment is reduced to between 2 and 4 percent of direct and indirect losses observed. Even though this is a gross estimate that requires further research in other regions and types of health facilities, the figure is ratified by the estimated cost of reinforcement, which fluctuates but averages between US\$2,000 and US\$5,000 per bed, compared with the average cost of a new hospital bed of between US\$100,000 and US\$150,000 (at 1996 prices).

Prevention of chemical and radiation accidents can be a highly cost-effective expense that is normally absorbed by the respective industries. Respect for existing norms in the use of radiotherapy and diagnostic equipment and, once such equipment is decommissioned, its proper disposal reduces DALYs from accidents at a modest cost.

Mobilization of Resources

Funding for preparedness and response programs follows rules and procedures that are distinct from those applicable to development projects. Most donors maintain a specific office or department for humanitarian affairs with a separate budget line. Procedures are also streamlined for quick response to unexpected situations. Processing a request takes a matter of days in emergencies and takes months for preparedness or mitigation projects, but it can take years in typical development projects negotiated with donors or financial institutions.

From a ministry of health point of view, competition for disaster resources is with other sectors or humanitarian organizations, not within the sector (as it would be, for instance, with malaria or tuberculosis control projects).

Funding for Preparedness. “By strengthening our public health planning for natural disasters and disease outbreaks, we will be in a better position to care for our populations, regardless of the type of hazard that confronts our health departments” (Rottman 2003, 1). This message, addressed to the public health community in the United States, is even more pertinent for developing countries. Most humanitarian offices in more developed countries allocate a modest but increasing proportion of their funds for predisaster capacity building. The capacity of the ministries of health to secure directly nonreimbursable funding depends on the following:

- The existence of an established disaster program within the ministry, demonstrating a long-term commitment to health disaster preparedness.
- An ongoing dialogue with local representatives of donors and their prior involvement in disaster-related activities or meetings of the health sector.
- A realistic projection of concrete activities, taking into consideration the efforts of others, especially NGOs. One- or two-year training or capacity-building projects are more likely to be supported than those of longer duration that have recurrent costs or involve the purchase of equipment (radios, vehicles).
- The technical endorsement and support of WHO and other UN agencies.

A multisectoral preparedness component is also increasingly included in loans negotiated in the aftermath of disasters. Intended to strengthen the capacity of the civil protection agency, the funding is no substitute for local political commitment to assume recurrent expenses, the only guarantee of sustainability.

Resources for Emergency Response. The amount of external resources available for response, financial or material, is influenced by the type of hazard, geopolitical considerations, and the number of deaths (rather than that of survivors in need of assistance). Funding is channeled mostly through humanitarian NGOs, the Red Cross system, or multilateral organizations, rather than through national governments. Consequently, the priority of the health authorities, rather than to seek direct contributions to the ministry, should be to ensure that health needs are properly identified and adequately covered by those agencies benefiting from the donations. Ministries of health often can obtain indirect financial support for their own activities through UN projects.

Concentrating on several key factors will improve the flow of external resources toward health priorities:

- Issuing a rapid and reliable assessment of what is needed and what is not needed for the emergency response, rather than waiting for a detailed assessment of the physical damage.
- Focusing on tomorrow's emergency health problems. External response is unable to address today's short-lived problems.
- Keeping a long-term view. Funding for emergency response is limited to a few months, whereas the health problems caused by the disaster will stay much longer. Projects should offer sustained benefits beyond their conclusion.
- Recognizing shortcomings in governance when in contact with the many bilateral fact-finding or assessment missions coming to the disaster site.

Funding for Reconstruction. Funding for reconstruction is multisectoral and is often coordinated by an international financing institution (global or regional), together with a consortium of large donor countries. The health sector will compete with other social priorities and the "productive" sectors in an arena where the health burden (measured in DALYs) does not carry the same weight as economic factors. Success will depend on an exhaustive monetary valuation of the health damage, rapid formulation of projects, political support from the country's highest authorities, and technical support and endorsement of specialized UN agencies and larger NGOs.

Funding for Mitigation of Damage. Protecting the national capital investment of the health sector is primarily the responsibility of the country at risk. Development agencies or financial institutions may contribute only marginally to the actual cost of retrofitting installations or improving the design of new facilities.

Modest funding for pilot or demonstration prevention programs may be available from both the humanitarian and the development sources of donor countries. Humanitarian offices may support promotion of the concept, development of guidelines or studies on vulnerabilities, and training.

The health sector will benefit from close contacts with financial institutions, the ministry of foreign affairs, and other national ministries. Negotiations to ensure that new installations are able to withstand disasters must be initiated at the earliest opportunity, and the corresponding additional costs should be considered in the earliest stages of the project.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE AND CHALLENGES FACED

All countries in Latin America and the Caribbean have established programs and structures for disaster risk management

within their ministries of health. Some lessons can be learned from this process:

- The occurrence of a major disaster in the country or its neighbor is the initial catalyst for health authorities to recognize that disasters represent public health risks that must be addressed in an institutionalized manner.
- Access to and support from the political level has determined the success or failure in coordinating the external and domestic health response.
- A multihazard program covering the entire health sector is most effective. Assigning responsibility for coordination and management among different technical departments according to the type of hazard (chemical or natural, for instance) does not work.
- A risk management program should cut across departments (medical care, epidemiology, water supply, sanitation, nutrition, and so forth) of the ministry of health and become sector wide.
- The synergy between normal development, preparedness, and disaster response activities should be recognized. Poor development practices increase vulnerability, whereas preparedness improves the attention to daily health challenges. Programs narrowly focused on operational response have generally failed.

In Asia, the Asian Disaster Preparedness Center also has documented some interesting experiences (<http://www.adpc.ait.ac.th/>).

THE RESEARCH AND DEVELOPMENT AGENDA

Disasters in any one country are relatively infrequent. In addition to being a dangerous temptation for the authorities to postpone preventive actions, this infrequency is an impediment for research and institutional memory. On one hand, the humanitarian culture tends to raise ethical questions on the role of observers at a time when action at all costs is expected. On the other hand, few health academicians wish to embark on projects when control groups and time for advance planning are unavailable.

Particularly encouraging are the increased numbers of publications and guidelines by UN organizations and NGOs and the trend toward organizing workshops on lessons learned a few months after a major disaster. These meetings of national experts and officials together with representatives from external actors are invaluable for identifying and sharing operational or institutional successes and failures for the collective benefit of other countries at risk.

Epidemiological Research

Most of the DALYs attributable to disasters occur immediately at the time of the disaster. Epidemiological research should,

therefore, complement engineering studies to design better facilities and preparedness measures. After the initial disaster, basic questions need to be answered: How many secondary deaths and disabilities can actually be prevented by improving search and rescue and trauma care? How critical is the time factor in reducing DALY losses and assessing the effectiveness of foreign SAR and field hospitals teams? How can researchers objectively assess the risk of outbreak following disasters? In particular, how can they better differentiate between cases attributable to increased transmission and those resulting from improved surveillance and medical attention provided to the victims? What is needed are data to put to rest unquestioned assumptions and clichés. The alternative is to continue to divert scarce resources away from routine disease control programs and toward costly measures of doubtful effectiveness.

Strategic Research

Research is required that will compare the effectiveness of preparedness and response strategies and approaches:

- With respect to preparedness, how should researchers assess the effectiveness of training and coordination versus that of investing in hardware and stockpiles? For instance, will the accreditation of hospitals based on their safety and readiness improve their disaster performance?
- With respect to mitigation, how should limited funding for retrofitting health facilities be allocated? Is nonstructural mitigation a workable alternative in the absence of structural measures?
- With respect to response, what is the effect of international assistance in terms of reductions in DALY losses that could not be achieved locally? Is it contributing to strengthening the capacity of the developing countries? What type of humanitarian assistance has proven to be development friendly?
- Finally, how should researchers measure the effectiveness of preparedness or mitigation given the unpredictability of disasters?

Economic Research

Humanitarian response is resistant to concepts of cost-effectiveness. Economists should contribute to the comparative study of the immediate and long-term effects of external interventions versus less costly alternatives such as relying on local resources and building local capacity. A cost-benefit analysis of international medical interventions prior to and during a disaster situation is also overdue.

Economic assessment of the damage to the health sector remains focused on physical losses and fails to sufficiently consider the broader burden on a society caused by the loss of health services over a sustained period. Refining the existing

methodology and developing quantitative indicators to estimate those indirect costs should be a research priority.

CONCLUSIONS

Natural hazards are not likely to decrease in the foreseeable future. Though geological events may occur independently of any human control, available data suggest that mankind plays a role in global climate. Technological hazards may also increase rapidly as a result of the unregulated development of industries in most countries and possibly the use of weapons-grade hazardous substances against civilian populations. An increase in the number of hazards should not mean that the resulting health burden will also increase. A sustained effort is needed to minimize risk, both by reducing vulnerability through prevention and mitigation and by increasing capacity through preparedness measures.

A Strategic Approach

The prime objective of a developing country is to develop. Emergencies and disasters have proven to be major obstacles and setbacks in the path toward sustainable development. Conversely, the shortcomings in development programs and institutions reduce the effectiveness of the health response in times of crisis. Development and disaster risk management cannot be addressed separately. Reducing risk is not a luxury reserved for more developed societies; it is a necessity in countries with fragile economies and health systems. It is clearly a public health priority.

Disasters, as any other public health problem, need to be addressed on a long-term and institutionalized basis through the establishment in the ministry of health of a program or department for prevention, mitigation, preparedness, and response for all types of disasters. Trends in Latin America suggest that such an approach in the context of sustainable development contributes to narrowing the gap in disaster-related deaths and disabilities (as measured by DALYs) between industrial and developing countries.

Disaster risk reduction is not merely a health issue. The economic and political dimensions should not, however, be allowed to overshadow the fundamental fact that disasters are, above all, human tragedies incompatible with the definition of *health* adopted by the WHO constitution. On one hand, the health sector should adapt and use the methodology of economic valuation of disaster impact as developed by ECLAC; on the other hand, the financial world should also learn to give equal consideration to the health burden (DALYs) in its decision making for development or reconstruction. For this to take place, health and humanitarian actors need to dramatically improve the availability of data.

Disaster risk reduction is not the exclusive domain of a few experts or officials. It is the collective responsibility of all disciplines and programs in the health sector, as well as a remarkable tool or gateway for collaboration with other sectors. Alone, the ministry of health cannot reduce the health burden or play its coordinating role in the response.

Disaster risk reduction is unlikely to produce immediate results. It requires sustained commitment over the years.

Learning from Errors

Learning from past disasters is difficult. At a national level, the relatively long periods between major disasters result in few decision makers having prior disaster management experience. At an international level, the frequent turnover of relief workers ensures that many of the actors are relatively inexperienced and susceptible to adopting myths and clichés, which are rarely challenged by the media and the academic world. It is time for an international initiative to identify the best practices, and it is time for affected countries and scientists to point out the inadequacies of responses.

Humanitarian health interventions, as any other health intervention, should be subject to cost-benefit reviews that compare their benefits in terms of DALY loss reduction to other alternatives, including a possible shift of international emphasis from immediate medical response to preparedness or rehabilitation projects.

Local health services are best situated to address the health consequences of disasters. They should be better prepared to do so. A formalized mechanism to transmit and share those lessons learned from past errors and to build the response capacity is required in the health sector.

Finally, the greatest potential for saving lives is in reducing the risks and the vulnerability through better infrastructure, land-use management, public awareness, and training.

The challenge in risk reduction is to sustain public support and political will in periods of calm. International organizations—WHO in particular—have a unique and critical role to play as advocates for a long-term approach to disaster risk management in the context of sustainable development.

ACKNOWLEDGMENTS

The field of disaster epidemiology, a concept first introduced in the early 1970s by M. F. Lechat of the University of Louvain in Belgium, is now calling on many disciplines and fields of knowledge. The authors express their gratitude to Caridad Borrás for her contribution on radiological disasters and to Jean-Luc Poncelet, Karl Western, Guy Arcuri, Steve Devriendt, and Roberto Jovel for their advice, comments, and suggestions.

This chapter relies heavily on the successes and failures of the health sectors in Latin America and the Caribbean, a region

where a sustained effort over 25 years, with the support of PAHO, WHO, and donor countries, traced the way to the reduction of risks from extreme events. This chapter owes greatly to a large number of experts and professionals in the health sector of those countries.

NOTES

1. In a nonnatural phenomenon, such as the attacks in New York on September 11, 2001, a similar risk has been detected and is perceived as a remnant potential long-term health risk similar to the effect of air contamination from ash from volcanoes.

2. Evidently these direct losses are not easy to determine in long-developing events (such as the ones associated with slow processes or climatic variability), because over time there will be overlapping damage, in contrast to the damage that occurs in sudden events such as hurricanes or earthquakes.

3. Data came from reports of the UN Office of Coordinator for Humanitarian Affairs (<http://www.reliefweb.org>), supplemented by authors' estimated costs for donors that did not report actual costs.

Chapter 62

Control and Eradication

Mark Miller, Scott Barrett, and D. A. Henderson

The Controversy: Control or Eradication?

We cannot refrain altogether from examining the roots of this controversy if only because the extreme views for and against eradication have exerted and are still exerting a . . . highly detrimental influence on public health practice.

—P. Yekutieli, *Eradication of Infectious Diseases: A Critical Study*

Eradication of an infectious disease is an extraordinary goal. Its possibility became apparent as soon as Edward Jenner demonstrated an ability to provide immunity to smallpox. Writing in 1801, Jenner observed that, through broad application of vaccination, “it now becomes too manifest to admit of controversy that the annihilation of the Small Pox, the most dreadful scourge of the human species, must be the result of this practice” (Jenner 1801). Louis Pasteur claimed that it was “within the power of man to eradicate infection from the earth” (Dubos and Dubos 1953). And yet, by and large, public health has proceeded with more modest goals of local and regional disease control. Notable successes have occurred. Indeed, some diseases now thought of as “tropical” were previously endemic in temperate climates. Systematic application of hygiene, sanitation, environmental modification, vector control, and vaccines have led, in many countries, to the interruption of transmission of microbes causing such diseases as cholera, malaria, and yellow fever.

Intensive efforts to eliminate breeding sites of the yellow fever mosquito vector, *Aedes aegypti*, interrupted transmission of this disease in Havana in 1901 and throughout Cuba soon thereafter. Subsequently, yellow fever and malaria were able to be controlled in Panama, thus permitting construction of the Panama Canal. In 1915, the Rockefeller Foundation launched an effort to eradicate the disease worldwide. Transmission appeared to have ceased in the Americas by 1928, but then cases reappeared, and by 1932, it became clear that a nonhuman

endemic focus was serving to reinfest areas otherwise free of yellow fever. In the 1930s, F. L. Soper set out to eradicate the *Aedes aegypti* vector from the Americas. By 1961, Soper reported that he had largely succeeded except for the United States, where the program received little support. By the 1980s, *Aedes aegypti* had become reestablished in Central and South America.

In 1953, Brock Chisholm, the first director-general of the World Health Organization (WHO), tried to persuade the World Health Assembly (WHA) to undertake smallpox eradication, but a number of countries objected on the grounds that eradication was not technically feasible. Instead, in 1955, under the leadership of his successor, Marcolino Candau, WHO began a global effort to eradicate malaria primarily by means of household spraying of DDT. The relatively sophisticated science of malaria control was abandoned in favor of this simplistic technology (Jeffrey 1976). Despite an expenditure of more than US\$2 billion, the effort failed.

Even while the malaria eradication effort was under way, the Soviet Union, in 1958, proposed to the WHA that smallpox be eradicated. A resolution to this effect was offered in 1959 and passed unanimously. However, the resolution provided little international funding or support. Over the next seven years, disease transmission was interrupted in some 30 countries in Africa, Asia, and South America, but endemic smallpox persisted in the Indian subcontinent, Indonesia, most of Sub-Saharan Africa, and Brazil. WHO launched an intensified effort in 1967 to eradicate the disease within a decade. This new

resolution included an annual budget of US\$2.4 million, to be paid according to the WHO scale of assessments. The resolution passed by the narrowest of margins, but a reinvigorated effort was soon under way and paved the way for a historic public health achievement (Henderson 1988). Following an extraordinary worldwide effort, the last case of smallpox was isolated in October 1977, and the disease was certified as being eradicated in 1979, 170 years after Edward Jenner first dreamed of that possibility. Understanding how and why smallpox eradication succeeded is essential to the study of control and eradication.

The smallpox success was inspirational, even though the leaders of WHO's smallpox eradication effort cautioned that, among all the diseases that might be considered candidates for eradication, smallpox was unique (Fenner and others 1988) and that they foresaw no other disease as a candidate for eradication (Henderson 1982). At a meeting convened by the Fogarty International Center of the National Institutes of Health in 1980, scientists, public health officials, and policy makers discussed the merits of eradicating other diseases, with schistosomiasis, dracunculiasis, poliomyelitis, and measles identified as possible candidates (Henderson 1998a). However, no consensus was reached at that time on moving forward with any of those diseases.

Poliomyelitis became the next principal target when mass vaccination campaigns, proposed by Albert Sabin (1991), proved remarkably successfully in Cuba and Brazil. In 1985, an American Health Organization coordinated campaign was launched to interrupt poliovirus transmission in the Americas by 1991, and this effort succeeded. Some believed that global eradication might be possible, although others were concerned that the far less developed infrastructure of health, transportation, and communications services in many parts of Asia and Africa would make it an unachievable task. In 1988, the WHA adopted a resolution to eradicate polio, but at that time, a longer-term strategy for ending polio vaccination was neither formulated nor agreed on by the public health and scientific community.

The WHA has adopted only one other resolution to eradicate a disease—guinea worm, or dracunculiasis. The eradication of this disease can be achieved by applying simple technologies for providing water that is free of the vector copepod and parasite and for treatment of patients with the disease. This eradication program has made steady progress but has been hampered in part by civil and political unrest and lack of program priority because of low mortality and low incidence in some remaining endemic areas. However, given the environmental restriction of the parasite to rural tropical areas and its relatively low transmissibility, eventual global eradication seems within reach.

One other case—that of measles—is worth noting. A number of public health authorities have raised the possibility of

eradicating that disease. In the Americas, spurred on by the success of regional cessation of transmission of wild poliovirus, eventual consensus was reached to intensify measles control efforts, primarily through surveillance and periodic pulse application of measles vaccine in national campaigns. As a consequence, transmission of measles virus was temporarily interrupted in the Americas on several occasions but reestablished again by importations (CDC 1998a). Although the U.S. Centers for Disease Control and Prevention (CDC) and WHO have advocated extending measles “elimination” through vaccination campaigns and second-dose opportunities to other regions (Biellik and others 2002; CDC 1998a, 1998b, 1999a, 1999b, 2003d, 2004b, 2004d, 2004f), the intensive control efforts required to break transmission of this highly infectious agent make global eradication unlikely at this time.

DEFINITIONS

Yekutieli (1980, 5–8) provides an excellent treatise on the concept of *eradication*, which includes a summary of the multiple definitions that have been formulated (Andrews and Langmuir 1963; Cockburn 1961, 1963; Payne 1963a, 1963b; Spînu and Biberi-Moroianu 1969). A conference devoted to eradication held in Dahlem, Germany, in 1997 (Dowdle and Hopkins 1998) set out to provide precise definitions for *control*, *elimination*, *eradication*, and *extinction* in a biological, economic, and political context (Dowdle 1998, 1999; Ottesen and others 1998); however, a number of eminent public health officials (Cochi and others 1998; de Quadros 2001; Goodman and others 1998b; Henderson 1998b; Salisbury 1998) challenged these definitions at two subsequent meetings at the CDC (Goodman and others 1998a, 1998b) and the U.S. Institute of Medicine (Knobler, Lederberg, and Pray 2001).

Unfortunately, broadly accepted, standard definitions for key concepts pertaining to disease control and eradication do not exist in the literature. Making matters more confusing, certain of the concepts have been given names that are part of our everyday language and so are easily misinterpreted by non-specialists as meaning something different from the meanings understood by those who are preoccupied with eradication programs. Most unfortunate is the all too casual use of the words *elimination* and *eradication* to promote programs that cannot reasonably be expected to achieve the promise implicit in these words. Moreover, the two words themselves are commonly used interchangeably.

Control

Two concepts are central to this chapter: control and eradication. By *control*, we mean a public policy intervention that restricts the circulation of an infectious agent beyond the level that would result from spontaneous, individual behaviors to protect against infection (Barrett 2004).

Although control is a range rather than a level, a particular level of control may be an aim of policy. Because every choice entails consequences, choice of the “optimal” level of control requires economic analysis. *Optimal* here is defined in relation to the model that gives rise to the result. Control is local and so needs to be looked at from the local perspective. Because one country’s (or region’s) control may affect other countries (regions), a global perspective exists as well. The level of control that is optimal for one country (region) may not be optimal from the perspective of the world as a whole. Thus, a need exists to distinguish between, say, a locally optimal level of control and one that is globally optimal.

Finally, control requires ongoing intervention. Sustaining a given level of control requires an annual expenditure.

Eradication

Eradication differs from control in that it is global. The term denotes the certified total absence of human cases, the absence of a reservoir for the organism in nature, and absolute containment of any infectious source. Eradication permits control interventions to stop or at least to be curtailed significantly. Finally, eradication is binary. Control levels can vary, but a disease is either certified as eradicated or not.

Every disease can be controlled, even if only by using simple measures, such as quarantine. The ultimate achievement of control is eradication. But not every disease that can be controlled can be eradicated. Very few diseases, in fact, are potential candidates for eradication. The criteria for the feasibility for eradication as a preference over control are discussed in the section titled “Economic Considerations.”

Elimination

Control and eradication are the essential concepts, but two other terms bear mention. The first is *elimination*. Some who are concerned with eradication programs have explicitly defined this term to denote the cessation of transmission of an organism throughout a country or region. In contrast, *eradication* is defined as a global achievement. Like control, elimination is location-specific and would require ongoing interventions to be sustained in order to prevent reemergence of the disease from microbe importations.

Two problems exist with the term *elimination*. First, it has been used to describe different phenomena, not just that described in the definition given above. For example, some public health officials have promoted programs aimed at “eliminating a disease as a public health threat,” which is interpreted to mean reducing incidence to an “acceptable” level but not necessarily to zero. This usage is very different from the one outlined above and is almost certain to be misunderstood. Second, the definition of the word *elimination* in common use, as applied to disease control, is indistinguishable from eradica-

tion. The 1993 edition of the *New Shorter Oxford English Dictionary*, for example, defines *eliminate* as to “remove, get rid of, do away with, cause to exist no longer.” This same dictionary defines *eradicate* as “pull up or out by the roots, uproot, remove or destroy completely, extirpate, get rid of.” This ambiguity invites misunderstanding among those not intimately involved in an eradication effort. For purposes of clarity, we seldom use the term *elimination* in this chapter and then only to signify control measures sufficient to interrupt microbe transmission in a specified area.

Extinction

Finally, the literature sometimes refers to *extinction* as a possible policy goal. In the context of infectious disease control, the concept is problematic for two reasons. First, proving that an organism has become extinct is impossible. To do so would require demonstrating not only that the organism no longer exists in nature but also that it no longer exists in any controlled environment—a practical impossibility. Second, de novo synthesis of viral agents from published genomes (Cello, Paul, and Wimmer 2002) now put the concept in peril, although much research remains to be done in this area. Extinction, in the context of infectious diseases, may no longer be irreversible.

Clearly, policy making will be improved by stating the goal of any particular intervention in precise language.

FRAMEWORKS FOR ERADICATION

Numerous issues need to be considered in planning expanded control measures that lead, possibly, to regional cessation of transmission or global eradication of disease. These complex issues will be further examined in the chapter.

Scientific Considerations

Scientific considerations include the nature of potential reservoirs for disease-causing microbes or their vectors, technologies available for interrupting disease transmission, changes in host capabilities to deter infections and disease, and satisfactory containment of organisms in laboratories.

Geographic and Environmental Controls. The limit of endemicity for microbes and their associated diseases is determined in part by their ability to exist in nature outside the human host. Both geographic and temporal variations determine the ecological niche of microbes, resulting in variable annual incidence rates throughout the world. This niche limitation is further extended to intermediary vectors and hosts in complex biological systems. Natural environmental barriers also may isolate the habitats of helminths. Infectious agents that are not limited to an environmentally restricted intermediary

host or those that have longer latent periods, thereby allowing translocation, may have a global pattern of distribution. Examples include the highly transmissible viral agents such as measles, rubella, influenza, and varicella. Although these agents are not geographically constrained, their transmission patterns are directly and indirectly influenced by seasonal environmental factors and population-based immunity.

Potential Reservoirs. A microbe and associated disease can not be eradicated if the microbe is capable of persisting and multiplying in a reservoir. Microbes that thrive in nonhuman species may reemerge if control efforts cease, thus leaving human populations susceptible. Similarly, if the infectiousness of a human is long lived or could lead to potential recrudescence, surveillance efforts would have to continue as long as the last individual remained potentially capable of transmitting infection, as would be the case with tuberculosis or hepatitis B infection.

Transmissibility. The inherent rate of a microbe's ability to cause secondary infections is defined by an organism's reproductive rate in a fully susceptible (R_0) and partially susceptible (R) population. The reproductive rate of organisms that infect individuals only once because of durable immunity is inversely proportional to the average age of infection in an endemic area. Agents that cause childhood infections, such as viral respiratory agents, are far more transmissible than helminths and subsequently require more intensive control efforts to interrupt transmission.

Natural Resistance to Reinfection. Many natural infections induce long-lived immunity to reinfection. Although the most commonly used vaccines have been available for fewer than 50 years—less than the lifetime of an individual—they, too, are assumed to offer long-lasting immunity. Because eradication depends on reducing susceptible populations in potentially endemic areas, long-lived protection through immunization or natural disease is important to successful programs.

Laboratory Containment. Laboratory specimens containing the organism targeted for eradication could serve as reservoirs. Considerable effort may be necessary to ensure their maximum security. That these microbes may be inconspicuous in specimens collected for other purposes poses special challenges. This situation is especially true for the poliomyelitis virus, which may be found in many stool specimens collected for studies completely unrelated to current poliomyelitis eradication efforts.

Operational Considerations

Optimization of control requires a fundamental appreciation of the biological systems that govern the ecology of microbes

and their intermediary and human hosts. The reproductive rate, R , is influenced by many local factors, including population density (of vectors, intermediary hosts, and humans) and other environmentally determined conditions, all highly variable throughout the world. For a disease to be controlled to stop transmission, the intervention-altered reproductive rate must be maintained below 1.0. At the same time, all reservoirs of the responsible microbe must be controlled.

Three main components of possible eradication programs are

- surveillance, including environmental sampling where appropriate and clinical testing
- interventions, including vaccination and chemotherapy or chemoprophylaxis or both
- environmental controls and certification of eradication.

Each of these components must be undertaken at local, community, national, regional, and global levels. Eradication differs from control in that it is expected to be permanent. Success depends on having adequate surveillance to identify potentially infectious persons and on stopping transmission before infection of a new cohort of susceptible persons arises as a result of births, migration, or the waning effectiveness of prophylactic measures.

Disease Surveillance. Effective surveillance requires a sensitive system to detect the presence of microbes within the environment, intermediary hosts, and clinical cases. Surveillance and response systems need to be more efficient than the rate of transmission of the targeted agent. As eradication progresses, the sensitivity of detection systems must be steadily enhanced to detect all existing foci. Nonclinical or latent infections pose formidable barriers to eradication efforts. Operationally, the need for near-perfect sensitivity comes at the expense of lower specificity. Thousands of skin lesions from suspected smallpox patients were tested in reference laboratories during confirmation of smallpox eradication, and tens of thousands of stool specimens are being examined for poliovirus. Highly sensitive systems used to detect measles cases in the Americas began to identify a greater proportion of rubella and parvovirus infections because of the nonspecific surveillance of rash illness. Such findings are important because the identification of other diseases that mimic the targeted disease can lead to a misdirection of resources. However, the ability to detect such similar clinical cases can serve as a proxy measure for the adequacy of surveillance. For example, identification of a minimum incidence of cases of acute flaccid paralysis that is not related to polio has served as an indicator of adequate efforts of case finding for polio.

Interventions. Interventions to block transmission of the targeted infectious agent should be easy to deploy and adaptable

to diverse conditions, given the global goal of eradication. Cost considerations and local acceptance of the required sacrifices (both short and long term) are crucial for success. Interventions may be designed for environmental control of microbes, isolation (quarantine) of clinically infectious individuals to limit their contacts with susceptible persons, treatment of clinical cases to limit the duration of infectiousness, or reduction in the infected pool of individuals through immunologic or chemoprophylaxis.

Certification. The last tool for eradication is a certification process whereby independent, respected parties certify the absence of disease transmission or the existence of any specific microbe in an uncontrolled reservoir, including laboratories (Breman and Arita 1980). Although certification can be implemented on a regional basis, it must ultimately be done globally. Certification is one of the greatest challenges in any eradication effort, given the exceedingly great difficulty of verifying a negative finding in a reasonably short period of time. When certification is completed, curtailment of control measures should be possible.

Strengthening control efforts sufficiently to achieve eradication is a difficult and expensive task. It requires that scaling up of such efforts occur over a wide area—at the community, national, regional, and global levels. Its efficacy depends heavily on the adequacy of local financial and human resources, as well as on a broad range of logistical factors.

Economic Considerations

Control and eradication programs have many economic dimensions: private versus social net benefits, short-term versus long-term net benefits, and local versus international net benefits. Such interventions also have implications for existing public health programs.

Private versus Social Net Benefits. Individuals have private incentives to protect themselves from disease—by means of vaccination, for example. But when individuals protect themselves—when they elect to be vaccinated—they offer a measure of protection to others by helping limit the spread of infection. In brief, the social benefit of vaccination is greater than the private benefit alone. As more people become vaccinated, the *marginal* private and social benefit of vaccination—that is, the benefit of vaccinating an additional susceptible person—declines. The marginal private benefit is likely to fall because, as more people are vaccinated, the probability of a susceptible person becoming infected falls. The marginal social benefit is likely to fall for the same reason and for one other: as more people become protected, the total number of susceptible persons falls. The marginal social benefit of vaccination falls sharply at the *critical* level of immunization—the level at which

herd immunity is conferred on all susceptible persons. When a population is immunized to this level, a disease ceases to be endemic, and imported infections cannot spark an epidemic.

This level is determined by the epidemiology of a disease, but whether it pays to vaccinate to this level depends on the economics, and the economics depend in turn on the social costs and not only the social benefits of vaccination. These costs consist of the direct costs of producing, distributing, and administering a vaccine. The economics depend also on the costs borne by the individuals who are vaccinated, such as those incurred by individuals who experience vaccine complications. The proportionate costs of reaching people who live in remote areas and those who are at special risk, such as migrants and the homeless, increase as the fraction of the population vaccinated increases.

The economics of varying levels of disease control depend on the relationship between the marginal social benefits and the marginal social costs of vaccination. As vaccination levels increase, the marginal social benefits of vaccination fall, whereas the marginal social costs rise. Social welfare is maximized where these two relations intersect, which might be called the “optimal” level of vaccination—a level that may or may not achieve cessation of transmission or eradication.

Short-Term versus Long-Term Net Benefits. Control programs require ongoing intervention. Sustaining a given level of protection requires that, over time, a certain proportion of new susceptible persons be vaccinated. Eradication differs from control in being permanent. The economics of eradication must therefore take account of long-term benefits as well as short-term costs.

The long-term benefits of eradication consist of avoided future infections and vaccination costs—a dividend. To calculate this benefit, one projects future infection and vaccination levels in the absence of eradication, attaches values to these, and discounts them. If this sum exceeds the costs of eradication, then eradication enhances social well-being, and it therefore should be undertaken.

In deciding on the benefits of eradication, the cost of future infections and vaccination should ideally be compared with the best alternative to eradication: the level of optimal control (Barrett and Hoel 2003).

The costs of eradication must also take into account ongoing surveillance requirements, laboratory containment, and perhaps the maintenance of stockpiles of vaccine in the chance event of disease reemergence. From an economic perspective, attractive candidates for eradication are those diseases that some countries have themselves targeted for interruption of transmission nationally or regionally.

Local versus International Net Benefits. Control differs from eradication in another important way. Control refers to

location-specific interventions. Eradication, by contrast, is global. In economic terms, eradication is a global public good. No country can be excluded from the benefit of eradication, and no country's consumption of that benefit diminishes the amounts available to other countries. Control, by contrast, supplies only a local public good.

Eradication requires a global effort. A disease can be eradicated only if microbe transmission ceases everywhere. This spatial dimension to eradication is of fundamental importance because no world government can implement an eradication policy; the WHA can declare its support for eradication, but WHO does not have the power to enforce the execution of a national program in support of that goal. The outcome experienced by any country depends not only on whether the country itself eliminates the disease within its borders but also on whether all other countries do so. Indeed, eradication is a weakest-link public good.

Whether eradication is achieved depends on the level of control adopted by the country that undertakes the least control. In practical terms, any country in which disease is endemic can prevent eradication from being achieved. In 2004, the global polio eradication initiative, after investing more than US\$3 billion and involving some 20 million volunteers over a period of 16 years, was placed at risk of failure by the actions of one local administration. In the Kano state of Nigeria, local leaders claimed that the polio vaccine was tainted with the AIDS virus and sterility drugs and declined to participate in a national immunization day program. The European Union then declined to pay for the national program in Nigeria, believing the money would be wasted (Roberts 2004). One consequence was the subsequent spread of polio to nine formerly polio-free countries. Concerted efforts by WHO later persuaded local leaders in Nigeria to rejoin global efforts, but special vaccination programs had to be launched over a population area of more than 300 million persons. This situation dramatically illustrated the vulnerabilities inherent in a weakest-link public good.

What are the incentives for states to participate in an eradication effort? To begin, assume that countries are symmetric, meaning that all countries have the same benefits and costs of control. Assume as well that eradication is feasible. Four possible situations then exist (Barrett 2003):

- First, the global net benefit of eradication may be negative—the cumulative programmatic costs outweigh the net present value of the cumulative benefits. In this case, elimination would also yield a negative net benefit to every country, and so no country would eliminate the disease.
- Second, the global net benefit of eradication may be so large that each country would choose to eliminate the disease even if others did not. In this case, all countries would eliminate the disease, and the disease would therefore be

eradicated. In these two cases, no need exists for an international policy.

- Third, each country may have an incentive to eliminate a disease only if all other countries have eliminated it. In this case, achieving global eradication requires coordination. Here a role exists for international policy, but all that is required is for each country to be assured that all others will eliminate the disease.
- Finally, and noting that the “last” country to eliminate a disease would get just a fraction of the global dividend from eradication, under some circumstances no incentive may exist for this country to eliminate the disease—even if all other countries have done so and even if the entire world would be better off if it did. This case is the most worrisome, because implementation of the efficient outcome would likely require enforcement.

All this hypothesizing assumes that countries are symmetric, and of course they are not. Some countries gain less from control and would gain less from eradication than others. Some are unable to implement an elimination program, even if they would very much like it to succeed. In these situations, achieving an eradication goal will require international financing and technical assistance, with the countries that benefit most from eradication compensating the other countries for the costs of eradicating the disease. National and international reproach are often expressed if a country lags in its eradication efforts. International financing has been a key element in all eradication programs.

We have thus far looked at eradication from the perspective of only the self-interests of states. But eradication also has implications for development. In particular, eradication has two advantages over control programs. The first is that the rich countries may gain directly if the goal is achieved, giving them a vested interest in ensuring that the goal is achieved. The second is that eradication is permanent, making an investment in eradication financially sustainable. This second advantage is important because financial sustainability has proved to be a key problem for disease control programs in developing countries (Kremer and Miguel 2004).

Vertical versus Horizontal Programs. Control and eradication programs cannot be viewed in isolation. All programs have implications for the delivery of comprehensive primary care services. An important question is whether targeted, or so-called vertical, programs draw critical resources away from other health care programs or whether they serve instead to augment competence and capacity. The evidence is mixed.

Evidence suggests that disease-specific systems can serve to expand polyvalent services (Aylward and others 1998). Smallpox eradication, for example, gave many national governments the confidence to introduce the Expanded Program on

Immunization, with the ability to deliver vaccines and micronutrients in routine schedules and through national campaigns. However, other evidence suggests that some vaccination programs have adversely affected primary health services (Steinglass 2001; Taylor, Cutts, and Taylor 1997) and may have even increased costs. Implementation of international initiatives can also expose conflicts of priorities. The polio eradication initiative, for example, has successfully vaccinated children in the poorest of countries against this disease, but in some of these countries it has failed to timely include the co-administration of measles and other common childhood vaccines, which would have had a much greater effect on child mortality.

DISEASE-SPECIFIC CASE STUDIES

In this section, we apply the reasoning developed previously to provide an empirical analysis of the three most recent eradication programs—smallpox and the two ongoing programs, poliomyelitis and dracunculiasis.

Smallpox

As noted before, smallpox eradication was achieved in October 1977, 11 years after the intensified program began. Following implementation of a rigorous certification procedure, the WHA declared smallpox eradicated in 1980.

Fenner and others (1988) have estimated the annual benefits of smallpox eradication to developing and industrial countries (see table 62.1). These aggregate estimates, obtained by

prorating estimates of the benefits of eradication for India and the United States to all developing and industrial countries, respectively, suggest that developing countries benefited more from smallpox eradication than industrial countries. Qualitatively, a consistent picture emerges: smallpox eradication was not only an extraordinary investment for the world; it was also an investment that benefited every country, rich and poor alike.

When the eradication effort began, smallpox was no longer endemic in most industrial countries. Nonetheless, these countries needed to maintain populationwide immunity under the threat of possible imported cases from endemic countries. They would gain from eradication not only through the cessation of vaccination and its associated costs but also by being able to decrease the number of quarantine inspectors at ports of entry and by averting costs of care related to the adverse events from this live vaccine.

The still-endemic countries would also save vaccination costs, although most were vaccinating only a comparatively small proportion of their populations. The greater benefit to them was the avoided cost of disease, including the extraordinary death toll. A number of developing countries had accorded smallpox prevention a high priority, as was evidenced by the number that succeeded in interrupting transmission without international assistance. This list includes China, which was not a member of WHO at the time the eradication effort commenced.

Indeed, and as shown in table 62.1, the still-endemic countries contributed an estimated two-thirds of the US\$298 million cost of eradication. International sources funded the balance. If the latter cost is interpreted as the incremental cost of achieving eradication, the benefit-cost ratio of global smallpox eradication was over 450:1, a singularly high figure. Even including the expenditure by endemic countries, the benefit of eradication exceeded the cost by an unusually large amount.

Brilliant (1985) calculated the annual costs of the smallpox eradication campaign for India to be about US\$17 million per year, including indirect costs (lost productivity caused by adverse reactions to vaccination) and opportunity costs (health workers being diverted from other programs). These costs were only a fraction of the annual benefits of eradication to India, which, by Brilliant's calculations, were US\$150 million. The benefit estimates by Fenner and others (1988) are much larger, and those of Ramaiah (1976) are smaller, but all three studies draw the same (qualitative) conclusion: smallpox eradication was a good investment for India. Basu, Ježek, and Ward (1979, 312) present estimates identical to those in Ramaiah (1976), but without giving attribution.

Originally, India had decided to undertake a smallpox program just one month after the WHA voted to eradicate the disease globally in 1959. The attempt failed, however, largely for administrative reasons (Basu, Ježek, and Ward 1979; Brilliant

Table 62.1 Benefits and Costs of Smallpox Eradication
(Millions of U.S. dollars)

	Annual amount
<i>Beneficiary</i>	
India	722
United States	150
All developing countries	1,070
All industrial countries	350
Total annual benefit	1,420
<i>Expenditure</i>	
Total international, on eradication	98
Total national, by endemic countries	200
Combined total, on eradication	298
<i>Benefit-cost ratio</i>	
International expenditure	483:1
Combined total expenditure	159:1

1985; Fenner and others 1988). Essentially, India had an economic incentive to control smallpox on its own (Brilliant 1985, 33) but lacked organizational capacity and an effective strategy for achieving this goal. Note, however, that India had other health priorities, including family planning. According to Brilliant (1985, 33), “for India’s health planners, occupied then by emergencies and competing political demands on scarce resources, the long-term benefits from disease eradication were not a great motivation. Health planners are sensitive to immediate political realities, and the benefits of smallpox eradication would be realized only at some future time when the \$3 million annual expenditures for smallpox could be applied to other health problems. In the meantime, however, the cost of putting so many scarce resources into one program rather than into many health needs was high.”

Table 62.2 provides estimates of the benefits of smallpox eradication to the United States. The total benefit of eradication to the United States is about the same order of magnitude as India’s, but the breakdown is different. Whereas India benefited mainly from avoided infections, the United States benefited mainly from avoided vaccinations. By the time the eradication program was launched, the United States had already interrupted smallpox transmission, but vaccination was costly, both in economic and human health terms (a small number of people died every year from infections arising from the live vaccine). Defending the nation from imported infections imposed additional costs.

In health terms, smallpox eradication saved millions of lives; in economic terms, it yielded a benefit many times greater than the cost. Identifying another investment that has yielded comparable returns and has benefited every country is difficult. One reason that the economics of smallpox eradication were so favorable is that all countries had strong incentives to join in

the eradication of the disease. A huge organizational effort, but only a relatively small incremental cost, was needed to achieve eradication. The specter of global terrorism has recently caused some countries to prepare themselves for a possible smallpox attack by stockpiling vaccine. Although such actions reduce the benefits of eradication, the economics remain favorable.

Smallpox, however, was a special case. Many attributes of the disease and the vaccine favored eradication. The vaccine was heat stable and required only a single dose to protect a person for a period of at least 5 to 10 years. Vaccination was easily performed and protected immediately on application. Every individual who became infected exhibited a typical, easily recognized rash, thus permitting accurate surveillance without recourse to laboratory diagnosis. The disease spread slowly so that transmission could readily be stopped by isolating the patient and vaccinating contacts within the area.

Poliomyelitis

The polio eradication program, launched by the WHA in 1988, has made substantial progress (CDC 2003a, 2003b, 2003c, 2004a, 2004c, 2004e, 2004g, 2005). The incidence of paralytic poliomyelitis in children fell by more than 99 percent, from an estimated 1,000 cases per day worldwide in 1988 to fewer than 4 cases per day in 2003. The number of poliomyelitis-endemic countries also fell, from 125 in 1988 to just 6 by 2003 (Afghanistan, the Arab Republic of Egypt, India, Niger, Nigeria, and Pakistan). This laudable reduction was the result of repetitive vaccination campaigns with easily administered oral polio vaccine to whole regions, to nations, and to large sub-populations.

During 2004, however, polio immunization activities in northern Nigeria were halted for an extended period for fear of tainted vaccines, and this permitted the development of epidemics extending throughout the country. The disease spread as well to 10 other African countries and to Saudi Arabia, Yemen, and Indonesia. Transmission has again been reestablished in several African countries (Burkina Faso, Central African Republic, Chad, Côte d’Ivoire, and Sudan). Heroic efforts are being made to control these outbreaks by large-scale immunization, but in countries such as these, where health services are stressed and the health, communication, and transportation infrastructures are weak, disease transmission is difficult to interrupt. Meanwhile, other countries throughout the world that appear to be polio free are continuing their vaccination programs but finding it increasingly difficult to maintain a momentum of interest, effort, and financing.

The difficulties of maintaining credible surveillance systems throughout the developing countries were vividly demonstrated by the discovery of polio in Sudan in May 2004, more than three years after the last case had been reported (CDC 2005). In the interim, specimens from 75 to 90 percent of such

Table 62.2 Benefits of Smallpox Eradication to the United States, 1968

cases were processed in the laboratory, and measures of surveillance for acute flaccid paralysis cases were reported to have been entirely satisfactory. At first, the Sudanese cases were considered to have resulted from importations from Nigeria, and, indeed, some cases were. However, from more detailed laboratory studies, it was determined that type 1 wild virus had been circulating undetected for more than three years and type 3 virus for nearly five years.

Clearly, stopping the continuing transmission of wild poliovirus is itself a formidable challenge, the success of which is by no means certain. A problematic discovery since the global eradication program began was the finding that individuals with particular immunologic disorders shed polio vaccine virus for many months to years, thus serving as a reservoir for this virus. The virus, in turn, can revert to a neurovirulent form, which is capable of causing outbreaks of disease (Bellmont and others 1999). Such individuals may be wholly without symptoms and impossible to identify except through fecal cultures. Moreover, no treatment is known to stop them from shedding virus. They pose an all but insurmountable challenge to the current poliomyelitis eradication effort.

The program is further hampered by the tool that has provided so much success—oral poliovirus vaccine (OPV). In resource-poor environments, poliomyelitis is best controlled with the inexpensive, live, and easily administered oral vaccine. The live vaccine is excreted and can infect other susceptible contacts. The ability of OPV to immunize others indirectly makes it an ideal vaccine for achieving high levels of population-based immunity, especially in lower socioeconomic populations that are the most difficult to reach. However, the excreted virus occasionally reverts to a pathologic state, causing not only cases but outbreaks of vaccine-associated paralytic polio, which may not emerge until months or even years after the vaccine has been administered (Kew and others 2004). Unfortunately, the alternative inactivated polio vaccine (IPV) is not immediately an option in many nations, not least because global manufacturing capacity could not begin to meet demand. Other problems include the current cost differential between OPV and IPV, the increased difficulty of administering the vaccine by syringe and needle, and the need to achieve higher coverage rates with IPV because it does not spread from person to person as does OPV.

Tragically, if OPV use were discontinued, in the absence of alternative immunity, polioviruses would likely circulate silently (Eichner and Dietz 1996) and reemerge. Preliminary results from a model presented by WHO indicate a greater than 60 percent chance of an outbreak within two years of the possible global cessation of OPV (WHO 2004) because of continuous circulation of undetected live vaccine viruses that can revert. Outbreaks have already been observed in several regions where decreasing use of live vaccine has left pockets of susceptible persons who eventually have been exposed to vaccine-

derived pathogenic viruses (Kew and others 2002). Such an outbreak could occur with disastrous speed because the polio virus is far more contagious than that of smallpox. In developing countries, virtually all cases of polio occurred among those under five years of age, older persons having been protected by the natural immunity of earlier infection. Within five years after vaccination ceased, therefore, the population immunity level in the developing countries would be no better than it was before vaccination was introduced. With this in mind, it seems questionable as to whether all health ministers could be persuaded to call for a country-wide cessation of poliomyelitis vaccination itself, given the uncertainties of virus detection in so many remote and inaccessible areas of the world.

By definition, eradication implies certifying cessation of virus transmission and the absence of reservoirs so that control interventions can cease. As noted earlier in this chapter, it is only for this reason that eradication yields a dividend. Although the interruption of wild poliomyelitis virus transmission is theoretically feasible, the obstacles to achieving and maintaining this goal are formidable. At this time, it is difficult to foresee a future that does not envisage a continuing vaccination program, perhaps with IPV use in countries that can afford the substantial additional costs entailed and with OPV use in all other countries.

The polio eradication initiative, like that for smallpox, has had to rely primarily on voluntary donations provided both to WHO and bilaterally. Playing an especially important role have been the Rotary International Foundation and the Bill & Melinda Gates Foundation. From 1988 to 2004, more than US\$3 billion was spent on the effort (WHO 2003).

What are the economics of polio eradication? Bart, Foulds, and Patriarca (1996) developed the first global cost-benefit analysis of polio eradication, beginning with the costs incurred since 1986, the year that the Pan American Health Organization launched a regional eradication effort, and extending to 2040. They assumed that eradication would be achieved in 2005, using OPV, and that vaccination would cease after eradication had been certified. Benefits (like costs, discounted at 6 percent) reflect the avoided costs of acute care and avoided vaccination costs after certification. Their analysis showed that the initiative would break even by 2007 and yield a net benefit to the world of more than US\$13 billion by 2040—an encouraging result, but it was based on the assumption that all vaccination would stop abruptly in 2005.

Khan and Ehreth (2003) developed a similar analysis but provided regional detail. They estimated the costs and medical costs avoided of polio immunization and eradication over the period 1970 to 2050, assuming that vaccination could cease after 2010. As table 62.3 shows, Khan and Ehreth estimated that polio immunization and eradication would entail a negative net cost overall, with Europe and the Americas saving the most and with other regions incurring a positive net cost. Compared

Table 62.3 Net Costs of Polio Immunization and Eradication
(Millions of U.S. dollars)

WHO region	Medical care cost savings	Immuni- zation costs	Net costs	Cost/DALY saved
Africa	1,100	3,942	2,842	442
Americas	76,900	25,460	-51,440	-4,983
Eastern Mediterranean	1,930	3,512	1,582	426
Europe	38,250	17,249	-21,001	-2,780
Southeast Asia	1,270	6,519	5,249	1,041
Western Pacific	8,670	10,327	1,657	356
World	128,120	67,009	-61,111	-1,457

Source: Khan and Ehreth 2003.

Note: Cost savings, immunization costs, and net costs are present values for 2000 in millions of U.S. dollars, calculated for the period 1970–2050 and discounted at 5 percent. These estimates assume that immunization by OPV can cease after 2010.

with other health interventions, this cost to developing countries may still be comparatively cost-effective. However, Khan and Ehreth comment that the cost per disability-adjusted life year (DALY) saved is high for developing countries (see table 62.3). As they explain (Khan and Ehreth 2003, 705), “This implies that without the financial support from developed countries of the world many developing countries would not have opted for polio interventions for implementation. From the developed countries’ point of view, providing support for the polio program is not simply helping the poor and the disadvantaged, it actually represents a good economic investment.”

Unfortunately, both of these cost-benefit studies have substantial limitations. First, both show that eradication is economically attractive if one incorporates all costs and benefits from the inception of this program. Because eradication has not yet been achieved, this approach mixes retrospective evaluation and prospective analysis (historical expenditures and benefits are sunk and so are irrelevant to the current situation). Second, benefits and costs are calculated in both studies relative to a world without immunization. A better approach would be to calculate the net benefits of eradication compared with the alternative of an optimal control program. The choice is not between doing nothing and eradication. It is between an optimal level of control and eradication. Finally, both studies assume that vaccination can cease in 2005 or 2010. As explained previously, this possibility is highly unlikely.

A more recent analysis by Sangruee, Cáceres, and Cochi (2004) calculates the costs for 15 years following the goal of certification of eradication in 2005 for three different scenarios: continued use of OPV, OPV cessation with optional use of the killed or inactivated polio vaccine, and OPV cessation with universal IPV. Table 62.4 shows their results.

Table 62.4 Postpolio Eradication Costs
(Millions of U.S. dollars)

	Continue OPV	Stop OPV	Universal IPV
Low-income countries	1,364	487	4,418
Middle-income countries	12,196	12,196	12,196
High-income countries	6,409	6,409	6,409
Subtotal	19,969	19,092	23,023
Global response capacity	1,120	1,320	1,120
Total	21,089	20,412	24,143

Source: Sangruee, Cáceres, and Cochi 2004.

Note: Costs are expressed in present value terms, calculated over the period 2005 to 2020, and discounted at 3 percent.

The respective cost to middle- and high-income countries is the same for all three scenarios, reflecting the assumption that the high-income countries will switch to IPV by 2005 and middle-income countries will do so between 2006 and 2008. The scenarios differ only for the low-income countries. In the first scenario, these countries are expected to continue routine immunization using OPV; in the second, immunization ceases in 2011, followed by a system of surveillance and response. In the third scenario, the low-income countries join the others in switching to IPV between 2008 and 2010. Of these three scenarios, the second comes closest to the 2005 post-eradication strategy now advocated by the polio eradication program leadership.

Unfortunately, this analysis is also deficient. First, interruption of transmission will not occur before 2006, and certification will take an additional three years. Hence, analysis of post-eradication costs should begin in 2009 at the earliest, with the costs of continuing immunization needing to be borne up until that time. Second, the analysis assumes a capacity to supply IPV that exceeds current estimates. It is not obvious that this scenario is feasible or, if it were, if the costs of scaling up production are adequately reflected in the calculations. Third, and most importantly, table 62.4 indicates that only low-income countries would benefit from polio eradication over this 15-year time scale—and yet the table does not include any estimate of the risk these countries would bear of a possible outbreak.

Although this analysis suggests that the discontinued use of OPV promises the greatest return to eradication, this assumes that circulating vaccine-derived polioviruses could be contained if and when they emerged. However, preparing for this possibility would require a far more effective global surveillance system than now exists, maintenance of a laboratory infrastructure, and stockpiles of OPV. In addition, controlling outbreaks with OPV without the risk of viruses reverting to virulence will be exceedingly difficult in the setting of an accelerating proportion of immunologic-naive individuals. The use of OPV in this scenario could very well cause poliomyelitis to

again become endemic. In any case, the estimated cost of any of the strategies exceeds \$20 billion.

The economics of polio eradication are thus not as favorable as concluded by either Bart, Foulds, and Patriarca (1996) or Khan and Ehreth (2003). Both studies assume that vaccination can cease without IPV being used as a substitute anywhere, both exclude the costs of maintaining a response capacity, and neither accounts for the real threat of reemergence. Sangruee, Cáceres, and Cochi (2004) take account of two of these considerations, but their analysis calculates only the costs for 15 years, ignoring both the risk of reemergence and the benefits of eradication. Hence, each study provides only a partial glimpse of the economics of polio eradication and does not adequately address the fundamental difficulty (inability) of stopping vaccination and maintaining eradication.

In conclusion, although the economics of polio eradication may have been thought to be favorable by some (Aylward and others 2003), they are far less favorable than were the economics of smallpox eradication, even assuming that polio vaccination could cease.

Dracunculiasis

Dracunculiasis, or guinea worm disease, is a nematode infection, which is controlled not by vaccination but by education of the affected population, provision of nematode-free water through wells or filtration, and treatment of cases. It is not a global disease but found only in the rural areas of a few very poor tropical countries. This last difference is especially important from an economics perspective. It means that international financing of a guinea worm eradication program needs to rely more heavily on development assistance rather than on the self-interest of donor countries.

Thus far, the eradication program has been successful in reducing the number of cases of guinea worm 99 percent from the 1986 level (Carter Center 2004). The geographic range of the disease has also been reduced from 20 to just 12 countries. Although this achievement is important, eradication remains elusive many years beyond 1995, the year that the WHA set for eradication in 1991 (Cairncross, Muller, and Zagaria 2002, 232).

Only one cost-benefit study of the guinea worm eradication program has been published (Kim, Tandon, and Ruiz-Tiben 1997), and it is unfortunately flawed in a number of respects. First, as indicated previously, eradication costs should be compared with those associated with an alternative optimal control program. Second, the cost-benefit analysis applies to the period 1987 to 1998 and thus is backward looking. The analysis can reveal whether the money spent previously yielded a benefit in excess of the cost (it did), but it cannot reveal whether eradication was worth pursuing at the time that this study was undertaken. Finally, it takes no account of the investment decision of eradication—the main reason for pursuing the eradication goal in the first place.

This last omission is especially relevant to the study's analysis of the eradication program in Sudan. The study projected that, by 1998, infections would cease everywhere except Sudan. (Plainly, this prediction was wrong, although Sudan is the largest problem for the program, mainly because of the ongoing civil war, which has limited accessibility to endemic areas; see Hopkins and others 2002.) It then calculates the net present value of eliminating the disease there. The results are not promising. They show that eradication is attractive only if the disease can be eliminated in Sudan within five years. However, this analysis ignores the dividend that eradication would earn Sudan. It also disregards the most important feature of eradication—that if the disease were certified to have been eliminated from its last stronghold, it would yield a benefit to *all* potentially vulnerable countries. Thus, the economics of eliminating dracunculiasis from Sudan, if that is where the disease makes its last stand, will be much more attractive than suggested by this analysis.

CONCLUSIONS

Of the several attempts to eradicate diseases, all but one has failed. Even the exception, smallpox, barely succeeded despite the many factors favorable to eradication. Whether any eradication effort will ultimately succeed or fail cannot be known with certainty at the time it is launched. Eradication entails risk. Money spent on eradication may not ultimately pay a dividend. Health risks may also exist. If eradication fails and vaccination levels drop after the eradication goal is abandoned, susceptible persons who were previously shielded from infection may become infected at a later age, when the disease can cause greater harm. The risk also exists that, even if eradication succeeds, the disease may be reintroduced by accidental or deliberate release.

The reasons for potential failure of an eradication effort are many. A nonhuman host may not be discovered until the number of infected humans drops to a very low level (as happened with yellow fever). The tools of eradication may be vulnerable to resistance (insecticides and drugs in the case of malaria). Political problems and civil strife may prevent an eradication program from being executed in critical areas where the disease makes its last stand (a problem today for guinea worm). Termination of vaccination may leave populations vulnerable to microbe reintroduction from an unforeseen reservoir or vaccine strain reversion (a risk now facing the poliomyelitis initiative). Another potential reason for failure is the inability to raise the financial resources needed to complete programs that extend beyond expected targets. All eradication programs have experienced serious financial stringencies during the course of their execution.

Most eradication programs to date have been launched as visionary, far-reaching efforts but with vastly incomplete

information. Basic epidemiological information and knowledge of the effectiveness and operational constraints of interventions and costs in different settings are often inadequate, and the required monitoring, evaluation, training, and research components of the program may be absent. If a program's administrators lack a careful, probing analysis of the epidemiology of the various candidate diseases or of the technologies available, and if their comprehension of the potential costs and who would bear them is limited, a program is likely to founder, causing a dispirited staff, confused beneficiaries, and donor fatigue and ambivalence. It is crucial that the eradication methodologies and assumptions in those regions of the world that would be most likely to pose the most significant problems be tested and addressed before launching an eradication program and that evaluation and research continue during the program.

Proposals for disease eradication have seldom been brought to the WHA with specific plans, costs, and uncertainties fully laid out. Nor have the expected sources of fiscal support and needed country support been addressed with specific commitments requested of the members. The WHA has only a limited deliberative capacity, and too much cannot be expected of its members in session. However, designated special committees of the WHA can and should be appointed, consisting of both visionary eradicationists and field-experienced public health and social science personnel. The WHA should take up the question of eradication only after the subject has been thoroughly vetted and sufficiently large-scale pilot programs in the most problematic areas have clarified that an adequate understanding of the epidemiology exists and that the appropriate technologies are available.

In the past, members have not voted for a specific program for which all the uncertainties have been laid out and the benefits and costs associated with different outcomes have also been calculated. Nor, with one exception, have they voted for a resolution imposing responsibilities, including financing obligations, on individual states. The next time a proposal to eradicate a disease is presented to the WHA, it should be comprehensive. It should demonstrate why the effort is worth taking, even if the final outcome is uncertain; it should bind states, morally if not legally, to fulfill the pledges needed to see the program through to its completion; and it should prepare contingencies should the eradication effort fail.

ACKNOWLEDGMENTS

We would like to acknowledge Walter Dowdle and Maria Teresa Valenzuela for their critical review of our manuscript; Joel Breman and Philip Musgrove for providing editorial guidance; John Sentz for his numerous hours devoted to research and editorial assistance; and Cherice Holloway for her preparation of various versions of this manuscript.

Integrated Management of the Sick Child

Cesar G. Victora, Taghreed Adam, Jennifer Bryce,
and David B. Evans

NATURE, CAUSES, AND BURDEN OF CHILD MORTALITY

Every year, over 10 million children under five years of age die. Most of those deaths are due to a small number of causes. In the mid 1990s, it was estimated that 70 percent of all global child deaths were due to five conditions: diarrhea, pneumonia, malaria, measles, and malnutrition (Gove 1997; Tulloch 1999). The World Health Organization (WHO) has since conducted a comprehensive review of under-five deaths using additional data and improved methods (Bryce and others 2005), and now estimates that six causes accounted for 73 percent of these deaths in 2000–2003: pneumonia (19 percent), diarrhea (18 percent), malaria (8 percent), neonatal pneumonia or sepsis (10 percent), preterm delivery (10 percent), and asphyxia at birth (8 percent). Undernutrition is an underlying cause in at least half of all under-five deaths. Few conditions, therefore, account for a large proportion of all deaths.

These deaths are not randomly distributed. They tend to occur in the poorest countries of the world, mostly in Sub-Saharan Africa and South Asia (Black, Morris, and Bryce 2003), and within any country they affect mostly the poorest families (Victora and others 2003). Fortunately, cost-effective interventions are available to prevent most of these deaths. Chapters 19, 21, 24–28, and 56 in this volume, as well as the next section in this chapter, describe these interventions in greater detail. Achieving universal coverage with these interventions would likely prevent 60 percent of those deaths (Jones and others 2003). Yet coverage levels for nearly all of these interventions remain below 50 percent (Bryce and others 2003), and children from the poorest families are least likely to be reached (Victora and others 2003).

In addition, comorbidity is common. Among children who die, a large proportion present with two or more diagnoses (Black, Morris, and Bryce 2003). Comorbidity is also highly prevalent at the community level and among children seeking health care. Nutritional factors—including underweight, micronutrient deficiencies, and inadequate infant feeding practices (see chapter 28)—play a major role in morbidity and mortality, and yet these are often overlooked by practitioners. Also, there are many missed opportunities for preventive interventions during outpatient visits—for example, immunizations and promotion of insecticide-treated mosquito nets.

POLICY SHIFT TO INTEGRATED MANAGEMENT

Until the mid 1990s, actions aimed at improving child health were organized as vertical programs, each addressing a specific disease or providing a given intervention or set of interventions (Claeson and Waldman 2000). Typical examples of these programs are the Expanded Program on Immunizations (EPI), Control of Diarrhoeal Diseases (CDD), acute respiratory infection (ARI) programs, malaria control programs, and nutrition programs that include growth monitoring, breastfeeding promotion and support, and micronutrient supplementation.

The need for an integrated approach to improve child health became evident in the mid 1990s for a number of reasons. From the perspective of epidemiology, a small number of diseases accounted for a high proportion of deaths, and those diseases were often present in the same children and had overlapping clinical signs. Integrated management was expected to increase the probability that children would receive treatment

for all major diseases and to decrease the possibility that children would receive correct treatment for one disease and die from another unrecognized illness. The important role played by nutrition across these major diseases also suggested that an integrated approach to case management was needed to ensure that health workers addressed children's nutritional needs throughout the clinical encounter.

A second set of reasons for the policy shift to an integrated approach was based on the need to promote managerial efficiency. The vertical approach required countries to appoint managers at national, provincial, and district levels to run each program. It also led to separate training activities; for example, health workers might be required to leave their posts on a number of occasions to be trained for the programs. Similar examples of duplication of effort were often found in supervision and provision of essential drugs. There was a strong logical basis for believing that integrating the management structure of child health programs would lead to improved efficiency.

A third group of reasons for the shift to integrated case management related to the need to improve the quality of case management provided by health workers. Vertical programs trained health workers to manage one disease at a time, and decisions about how best to assess and treat those diseases, as well as how to promote nutrition and educate caretakers, were often left to individual health workers. An integrated set of guidelines for managing sick children ensured that health workers, including those with low levels of training, applied the best available knowledge of case management systematically and in correct sequence.

The realization that a few diseases were responsible for most child deaths, that comorbidity was highly prevalent, that effective interventions were available, and that there were many missed opportunities for prevention led to the recognition that an integrated approach was needed. Thus, WHO and United Nations Children's Fund (UNICEF) launched the Integrated Management of Childhood Illness (IMCI) strategy in the mid 1990s (Tulloch 1999). Tanzania and Uganda began implementing IMCI in 1996. By 2003, more than 100 countries had adopted the strategy (<http://www.who.int/child-adolescent-health>).

INTERVENTIONS

A key aspect of IMCI was the integration of effective interventions to improve child health and nutrition into a coordinated strategy. IMCI has three components, each of which was meant to be adapted at the country level according to local epidemiology, health system characteristics, and culture.

Improving Health Worker Performance

The first component of IMCI includes health worker training and the reinforcement of correct performance. Training is based

on a set of adapted algorithms (Gove 1997) that guide health workers through a process of assessing signs and symptoms, classifying the illness according to treatment needs, and providing appropriate treatment and education to the child's caregiver. Figure 63.1 shows a general outline of the approach for children age two months to five years (WHO and UNICEF 2001). Sick children attending a first-level health facility are initially checked for danger signs and for the main symptoms of the key IMCI diseases: diarrhea, malaria, pneumonia, measles, and other severe infections. Next, all children are assessed for malnutrition and anemia, and vaccination status is verified. Children under two years of age, as well as older children presenting low weight for age, receive nutrition counseling. Other health problems related by caretakers are then assessed, and children are classified according to a color code: pink (immediate referral), yellow (management in the outpatient facility), or green (home management). Separate case-management algorithms are available for children under two months of age. IMCI health worker training emphasizes the integration of curative care with preventive measures, including nutrition and vaccinations. A special training module addresses how to communicate effectively with mothers. The training course was originally designed to last 11 days, including a large amount of hands-on experience.

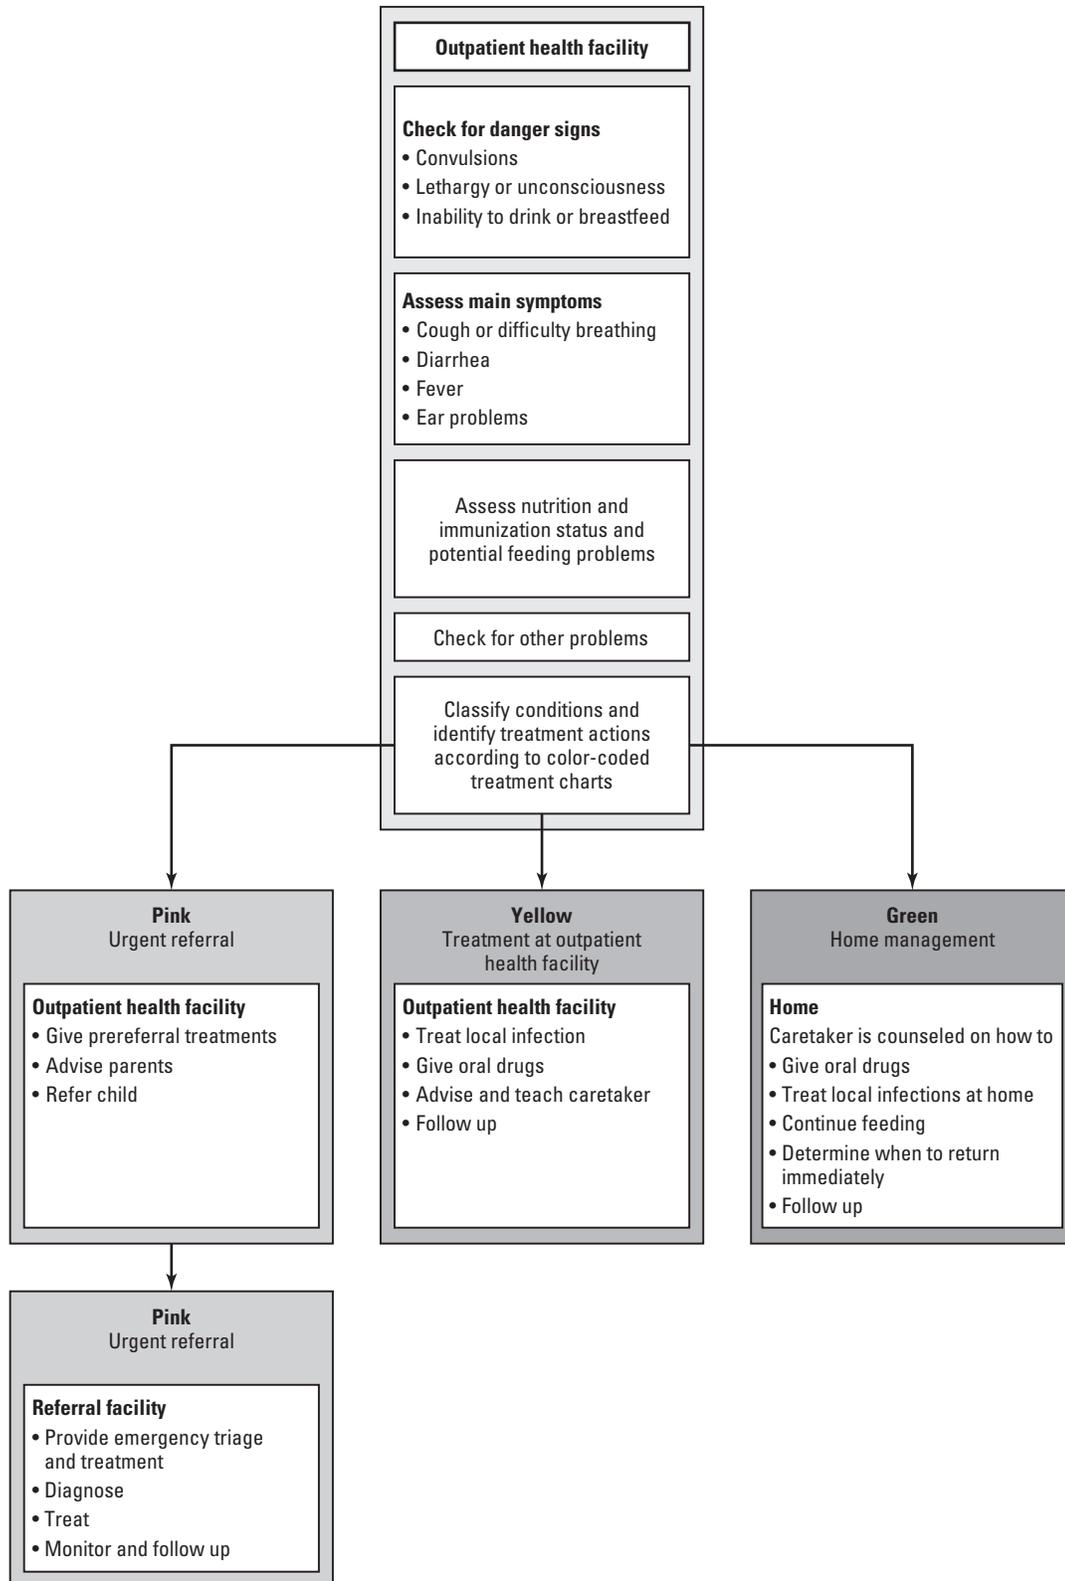

Improving Health Systems

The second component of IMCI is aimed at providing support for child health service delivery, including drug availability, effective supervision, referral services, and health information systems. Tools were developed for implementing specific system-strengthening interventions, including a planning guide for national and district managers, an integrated health facility assessment tool, and a tool for improving referral level care. In particular, several countries—beginning in Latin America through the Pan American Health Organization (PAHO) and more recently in Africa with WHO's Regional Office for Africa—made substantial efforts to improve the management and availability of the specific drugs required for IMCI (A. Bartlett, personal communication).

Improving Family and Community Practices

The third component, known as *community IMCI*, focuses on 12 key family practices relevant to child health and development (see http://www.who.int/child-adolescent-health/PREVENTION/12_key.htm). Community IMCI supports the development and implementation of community- and household-based messages and interventions to increase the proportions of children exposed to these practices. These behaviors address breastfeeding, complementary feeding, micronutrients, personal hygiene, immunizations, insecticide-treated nets, mental and social development, continued feeding

The Integrated Case Management Process

Figure 63.1 Schematic Outline of IMCI Case Management for Children Age Two Months to Five Years

and increased fluids during illness, home treatment of infections, care-seeking practices, compliance with health worker recommendations, and prenatal care.

This chapter addresses issues related to the integrated delivery of these interventions, most of which are covered in greater detail in other chapters in this book. These include case management of ARI (chapter 25), diarrhea (chapter 19), malaria (chapter 21), and malnutrition (chapter 28); community interventions to improve nutrition, including breastfeeding promotion and complementary feeding (chapter 56); insecticide-impregnated bednets (chapter 21); anthelmintic treatment (chapter 24); vaccinations (chapter 20); and micronutrient supplementation (chapter 28).

INTERVENTION COST AND COST-EFFECTIVENESS

One of the rationales for developing the IMCI strategy was the belief that treating the sick child in an integrated manner, by building on interventions that had already been shown to be cost-effective, would result in gains in efficiency. Two types of questions can be asked from an economic perspective. First, is treating children on the basis of the IMCI strategy cost-effective? Second, do the additional health benefits gained by switching from routine practice to IMCI justify the additional costs (if any)?

Only one publication has reported the cost-effectiveness of the IMCI strategy as a whole. Using a modeling exercise, the *World Development Report 1993* identified IMCI as being able to avert 14 percent of the global burden of disease in children under age five in resource-poor countries at a cost of only US\$1.60 per capita per year, with a cost-effectiveness of US\$30 to US\$100 per disability-adjusted life year (DALY) averted. No details of the methods used to derive those estimates are available (World Bank 1993). It is not clear if the costs are the additional costs of moving from current practice to IMCI or the costs of undertaking care for children under age five using IMCI, nor is it clear if the effectiveness is the additional effectiveness of changing current practice or the total effect of the package.

Detailed studies of the cost-effectiveness of some of the components of IMCI are available. For example, oral rehydration therapy for diarrhea, case management for pneumonia, and childhood vaccinations have been shown to be very cost-effective when evaluated as separate interventions (see chapters 19, 25, and 26). It is likely that the combination of different sets of childhood interventions, as proposed by IMCI, would also be cost-effective, although this depends on the relationship between costs and effects when the interventions are undertaken at the same time in the same population.

No published studies of the extent and nature of efficiency gains through integration were found. WHO has recently explored some of these gains for slightly different combina-

tions of childhood interventions in different parts of the world (see <http://www.who.int/evidence/cea>). This research resulted in estimates of the cost-effectiveness of single or combined interventions compared with doing nothing or with incremental intervention or current practice. Because large-scale trials on the effects of joint interventions have not yet been undertaken, the joint effects were modeled using the effectiveness of the individual interventions taken from systematic reviews. The interventions included vitamin A and zinc fortification and supplementation, oral rehydration therapy, case management for pneumonia, and supplementary feeding and growth monitoring. Costs and effects were estimated at various levels of population coverage and in various combinations.

The results showed that a childhood package consisting of vitamin A and zinc supplementation, oral rehydration therapy, and case management of pneumonia was cost-effective compared with doing nothing in most settings but that including supplementary feeding and growth monitoring was not cost-effective. Implementation of this combination at 50 percent coverage was estimated to cost, in 2000 prices, approximately US\$4.10 per child (US\$0.60 per capita) in poor African countries such as Tanzania. The cost-effectiveness was US\$38 per DALY averted. Costs increase faster than the increase in coverage. In Tanzania, it was estimated to cost an additional US\$12.10 per child under age five (US\$1.80 per capita) to reach 95 percent coverage, with a resulting incremental cost-effectiveness ratio of US\$60 per DALY averted.

This study is important because it is one of the few that has specifically explored the cost-effectiveness of undertaking combined interventions in the same population, and the effect of increasing coverage on costs. These absolutely critical questions for policy makers considering different intervention strategies are also critical to IMCI. However, the WHO study did not analyze the same interventions included in the IMCI package, nor did it evaluate the effect of moving from current practice to IMCI-based care.

Some information on the effect of moving from current practice is available from two studies in Kenya and Nigeria. Those studies compared the cost to the provider of traditional prescribing patterns with the costs of pharmaceuticals that would have resulted if the IMCI guidelines had been followed strictly. In Nigeria, the traditional prescribing method was five times more expensive: US\$1.44 per child visit for pharmaceuticals compared with US\$0.29, using 1996 estimates (Wammanda, Ejembi, and Iorliam 2003). In Kenya, also in 1996, the traditional method was almost three times costlier per child visit if the low-cost combination of drugs was assumed (US\$0.44) and similar if the high-cost combination was assumed (US\$0.16) (Boulanger, Lee, and Odhacha 1999). In Bangladesh, it was estimated that strict adherence to the IMCI protocol could result in US\$7 million in savings at the national level simply from more rational use of drugs—almost 3 percent

of the total health budget of the government of Bangladesh (Khan, Ahmed, and Saha 2000; Khan, Saha, and Ahmed 2002).

These estimates were based on models and assumptions, sometimes using evidence from separate systematic reviews addressing the costs and effects of an intervention. It would be valuable if information on relative cost-effectiveness of different combinations of interventions at variable levels of coverage could be derived from field studies rather than developed solely by modeling. Such an approach would allow the use of comparable methods and counterfactuals across the evaluation sites to make the results more useful and generalizable to other settings. In addition to answering questions related to the cost-effectiveness of IMCI, it would clarify gains that can be obtained from delivering interventions at the same time as part of an integrated package rather than delivering them in a vertical manner. This is one of the reasons the Multi-Country Evaluation of IMCI Effectiveness, Cost, and Impact (MCE) was launched (Bryce and others 2004). Five countries are currently participating in in-depth studies—Bangladesh (in 20 catchment areas), Brazil (in 46 municipalities), Peru (in all 24 departments in the country), Tanzania (in 4 districts), and Uganda (in 10 districts). Seven other countries—Bolivia, Cambodia, Kazakhstan, the Kyrgyz Republic, Morocco, Niger, and Zambia—were assessed for the evaluation but could not be included, mostly because of insufficient implementation of IMCI.

The overall objective of the MCE is to evaluate the actual changes associated with IMCI as it is implemented in different settings. All studies measured an identical set of indicators and, with minor exceptions, used identical data collection tools (Bryce and others 2004). The remainder of this section presents the main findings from two MCE countries, Tanzania and Brazil, for which evaluation results are currently available.

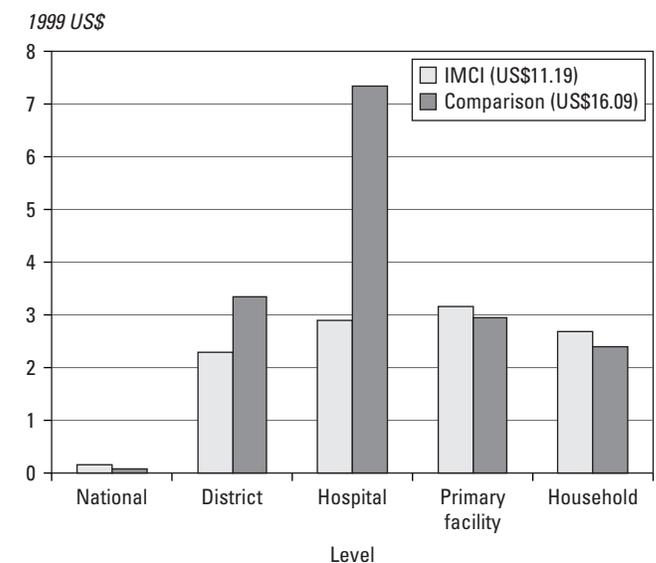

MCE in Tanzania

The MCE in Tanzania uses an observational design to compare two districts where IMCI has been implemented since late 1997 (IMCI districts) with two districts where implementation began in 2002 (comparison districts). The four districts had reasonably well-functioning health services, comparable levels of per capita health expenditure, high utilization rates of government health facilities, and high coverage of selected interventions (for example, EPI). Large numbers of governmental and nongovernmental health actors were also active in the districts, many of which were involved in health worker training and community activities, although their coverage was patchy. The two IMCI districts had engaged in activities designed to strengthen district management skills; the districts also had authority for priority setting and control over their health budgets. These activities of national health sector reform had not started in the comparison districts at the time of the study. In the comparison districts, a high level of coverage of IMCI

training for health workers had been achieved, but there had been no increase in the provision of under-five interventions at the community level, as opposed to the facility level.

Cost data were collected for the start-up period of implementing IMCI (from 1996 to 1997)—defined as the time from the national decision to implement IMCI to the time when IMCI started to be provided in health facilities—and for the maintenance of child health services in both types of districts. Costs were estimated from the societal perspective and were collected from the national, district, hospital, health facility, and household levels. Costs at all these levels were summed to obtain the total cost to the district of providing care for children under age five. So that comparison could be made across districts, cost estimates were standardized to a hypothetical district with a population of 50,000 children under age five. This figure corresponds to a total population of around 300,000, which is roughly the average district population for Tanzania. Estimates of the additional cost to the district of implementing IMCI were based on the difference in cost of under-five care between the IMCI districts and the comparison districts, which, at the time of the study, had not yet implemented IMCI (Adam and others 2004b).

For 1999, the cost per child of caring for children under age five in IMCI districts was US\$11.19, 44 percent lower than in the comparison districts (US\$16.09) (Adam and others 2004b). The lower cost per child in IMCI districts was due to lower hospitalization and administrative costs at the district level. There was no statistically significant difference in costs incurred to treat children at primary care facilities and at the household level (figure 63.2).

Source: Adam and others 2004b.

Note: Standard district with 50,000 children under age five.

Figure 63.2 Cost Components of Under-Five Care per Child in a Standard District

Hospital costs were 2.5 times higher in the comparison districts, not because of differences in the cost per under-five admission, but because more children under age five were hospitalized in those districts relative to IMCI districts (6 percent in IMCI districts compared with 15 percent in comparison districts; t-test: $p < 0.001$). There are two possible explanations: (a) improved quality of care and drug availability for children under age five at IMCI primary facilities reduced the need for referral and subsequent admission to hospitals, or (b) factors other than IMCI, such as differences in quality or geographical access to the hospitals in the different settings, meant that children in non-IMCI districts were more likely to seek care at hospitals. Given that IMCI training had only started one year before data collection of hospital admissions, the second possibility may have played a bigger role in this finding. Even if one takes the most conservative assumption—that all the difference was due to other factors—and excludes the hospital component from the analysis, the total cost per under-five child in IMCI districts was still lower than in comparison districts (6 percent).

The other important difference in costs between both types of districts was found in costs incurred at the district level, which were 50 percent higher in the comparison districts. These costs were mainly linked to more frequent trips for drug distribution and general purpose supervision in comparison districts than in IMCI districts.

Similar costs of training were observed in both types of districts during the study period. This finding was unexpected given the emphasis of IMCI on training, but a wide variety of training courses were performed in comparison districts for preventive, curative, and administrative issues during the study period. These courses included training for immunization, for use of insecticide-treated bednets, and for use of district Health Management Information System forms.

At the facility level, univariate comparison between IMCI and comparison district health facilities showed a 16 percent difference in the average cost per under-five visit (including vaccination visits) at government health centers and dispensaries (US\$1.40 and US\$1.60 in IMCI and comparison districts, respectively; t-test: $p = 0.5$). The average number of visits per child per year was 30 percent higher in the IMCI districts (3.28) compared with comparison districts (2.49). Taken together, the lower cost per visit but higher number of visits per child per year in IMCI facilities resulted in similar overall costs per child under age five for treatment in the two types of districts. Multivariate regression analysis, however, led to a different conclusion. Taking into account differences in other determinants across facilities, in particular the number of visits per facility, the cost per visit was at least 30 percent lower in IMCI facilities (t-test: $p < 0.001$).

Sensitivity analysis showed the importance of hospitalization costs in interpreting total district costs—the difference between IMCI and comparison districts was not sensitive to

variation in the other parameters, only to the assumption about rates of hospitalization. Therefore, if one assumes that hospital admission rates were not related to IMCI, there is no difference in the cost of under-five care in the two types of districts. Otherwise, the costs in IMCI districts are lower than in the comparison districts.

In the IMCI districts, IMCI was implemented concurrently with measures designed to strengthen district management, such as evidence-based planning and expenditure mapping at district level (http://web.idrc.ca/en/ev-3170-201-1-DO_TOPIC.html). In fact, it has been argued that the decision to implement IMCI in the study districts was a result of the introduction of the evidence-based planning. It is not possible to separate the effects of IMCI from district-strengthening measures. The findings of the MCE study in Tanzania, therefore, can be interpreted as the costs of IMCI in the presence of a strong health system with adequate managerial capacity.

The US\$11.20 cost per child of treating children under age five using IMCI in Tanzania translates into a per capita cost of US\$1.70, compared with US\$2.30 for routine care. This finding is similar to previous per capita estimates of the cost of IMCI in resource-poor countries (World Bank 1993). In addition, the Tanzania evaluation had similar findings with respect to savings from drug costs to those expected based on previous studies (Khan, Saha, and Ahmed 2002; Wammanda, Ejembi, and Iorliam 2003; World Bank 1993).

The effects of IMCI can be assessed in terms of changes in intermediate outcomes, such as improved quality of care at health facilities, or in terms of final outcomes, such as changes in under-five mortality or DALYs averted. In the Tanzania evaluation, a health facility survey was carried out in 2000 to compare the quality of case management and health systems support in IMCI and comparison districts. The results indicate that children in IMCI facilities received better care than children in comparison districts. Their health problems were more thoroughly assessed, they were more likely to be diagnosed and treated correctly as determined through a gold-standard reexamination, and the caretakers of the children were more likely to receive appropriate counseling and reported higher levels of knowledge about how to care for their sick children (Tanzania IMCI Multi-Country Evaluation Health Facility Survey Study Group 2004).

Estimating the effectiveness of IMCI training in improving health workers' performance required measuring the proportion of children correctly managed in IMCI and comparison facilities. *Correct management* is defined as the correct drug being provided in the correct formulation (amount, times per day, number of days) and the health worker explaining correctly to the caretaker how the drug should be administered at home. Not prescribing an antibiotic or antidiarrheal drug for a child who did not need one was also considered to be correct performance. In Tanzania, 65 percent of children under age five

Box 63.1

Impact of IMCI on Mortality and Nutrition in Tanzania

Tanzania is the only MCE site where the evaluation has been completed. Its design included a comparison of mortality in four districts—two with and two without IMCI—over the two-year period starting in mid 2000. Demographic surveillance systems were used to compare under-five mortality rates in areas of the IMCI and control districts. Adjustments for age (zero to one and one to four years) and rainfall were made using Poisson regression models. During the IMCI phase-in period (July 1999 to June 2000), under-five mortality levels were almost identical in IMCI and comparison districts, at about 27 deaths

per 1,000 child-years or approximately 120 deaths per 1,000 children between birth and the age of less than five years. The quality of health care provided in the IMCI districts was substantially higher than in the control districts (see box 63.2). Over the following two years, mortality levels became 13 percent lower in IMCI districts than in the comparison areas, corresponding to a rate difference of 3.8 fewer deaths per 1,000 children per year. Stunting rates also became significantly lower in the IMCI districts. Contextual factors, such as mosquito net use, all favored the comparison districts.

Source: Armstrong Schellenberg and others 2004.

presenting to the surveyed IMCI facilities were correctly managed, compared with 16 percent in the comparison facilities. When the information on costs and effectiveness are taken together, the cost per child correctly managed is six times less in IMCI districts (US\$4.02) than in the comparison districts (US\$25.70) (Bryce and others forthcoming).

Some of the differences in costs might be due to factors other than IMCI, so these ratios have to be interpreted with care. What is clear, however, is that treating children using IMCI in Tanzania was no more costly—and probably less costly—than treating children using routine care. At the same time, it resulted in higher quality of care. To the extent that this higher quality of care leads to better health outcomes, IMCI is cost-effective—it costs less (or at least no more) and results in better outcomes (see box 63.1).

MCE in Brazil

Brazil is another MCE site where IMCI is being implemented in the context of an ambitious family health program (FHP), which is supported by the Ministry of Health and the World Bank and based at first-level government facilities. IMCI implementation started in 1996 and is moving ahead in the whole country, particularly in the northeast regions. IMCI training is targeted at FHP team members.

The MCE in Brazil was carried out in four states, all in northeast Brazil, the poorest area of the country. In total, 23 municipalities with both FHP and IMCI were compared with matched municipalities with FHP but without IMCI. Early results from one component of the evaluation—the time and motion study—provide useful insights. After controlling for possible confounding factors using regression analysis, the

evaluation found that IMCI-trained providers spent 1 minute and 26 seconds longer per consultation with under-five children than untrained providers did. The difference was much greater when patient load was low but decreased as the number of patients a provider saw per day increased. This finding suggests that the system's ability to absorb IMCI depends on current capacity utilization. In terms of the assessment of quality of care in the surveyed facilities, IMCI-trained health workers were shown to provide significantly better care than those who had not been trained (Amaral and others 2004; Gouws and others 2004). (See “Lessons about Implementation Success and Failure” later in this chapter for additional results on quality of care.)

These results are important for policy development relating to child health. Where current caseloads are relatively low, providers spend additional time to provide better child health services, using IMCI as the basis of part of their current activities. In this study, the mean number of consultations per provider per day was 34, and 95 percent of the providers had caseloads of fewer than 50 patients per day. If this finding is representative of the rest of Brazil, it would be possible to introduce IMCI relatively easily throughout the country without encountering capacity constraints in terms of provider time. In areas with high patient loads, however, it would be important to explore whether it is possible to maintain high quality of care under IMCI in those areas and what the alternatives should be (Adam and others, forthcoming).

Summary of MCE Results

The available results from the MCE so far show that costs of child health care in Tanzania were comparable or lower in

districts with IMCI than with routine case management. Quality of care was higher, and a 13 percent reduction in mortality was also found in the IMCI districts in the study period. This finding strongly suggests that IMCI is a cost-effective intervention compared with routine care, as it costs less and is more effective in saving children's lives.

In Brazil, the MCE study also showed improved quality of care for children under age five after health workers were trained in IMCI. The results also showed that staff time constraints were unlikely to limit the application of IMCI, because, in settings with low caseloads, health workers could be expected to use the available excess capacity to provide better care for children under age five. Assuming that primary health facilities will experience savings on drug costs similar to those observed in Tanzania and previous modeling studies, one could also argue that IMCI is a good value for money in the Brazilian setting.

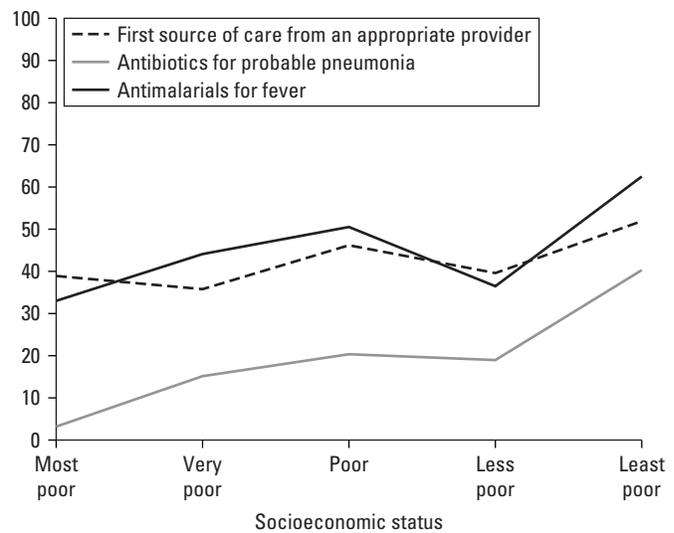

Equity Issues

Some of the equity implications related to care seeking and treatment have also been evaluated in the four rural districts included in the IMCI evaluation in Tanzania (Schellenberg and others 2003; Victora and others 2003). The MCE analysis found no association between sex and any indicator of morbidity, care seeking, case management, or compliance with treatment or follow-up instructions, suggesting that mothers and health workers treat boys and girls similarly (Schellenberg and others 2003). This finding is in accordance with that of Gwatkin and others (2000). Similarly, there were no statistically significant associations between socioeconomic status and reported prevalence of fever, diarrhea, severe diarrhea, or pneumonia. However, hospital admissions were almost half as common in the lowest socioeconomic status quintile as in the highest (t-test: $p = 0.0093$), suggesting that referral care is more readily accessible to the wealthy.

Positive associations were observed between socioeconomic status and care seeking from an appropriate provider (a qualified health worker practicing allopathic medicine) for fever without cough or diarrhea, for care seeking for episodes perceived as severe, and for using an appropriate provider as the first source of care. This finding is illustrated in figure 63.3, which puts households into five wealth categories. The poorest group was at least 25 percent less likely to have sought care than the least poor. Among the children who sought care, antibiotic use for probable pneumonia was less than half as common among the poorest than among the least poor. Also, children in the lowest socioeconomic group were half as likely to have been given antimalarials as those in the highest category (t-test: $p < 0.0001$).

These findings suggest that, although the prevalence of disease (self-reported) does not differ by socioeconomic status, care seeking and the probability of receiving appropriate care

Proportion of children (percent)

Source: Victora and others 2003, based on data taken from Schellenberg and others 2003.

Figure 63.3 Proportions of Children, by Socioeconomic Quintiles, Who Were Brought to an Appropriate Provider and Who Received Correct Care, in Rural Tanzania

vary markedly, even within an apparently homogeneous rural population. This observation agrees with data on mortality and nutritional status inequalities for Tanzania (Schellenberg and others 2003). There is no evidence yet showing whether the introduction of IMCI has reduced or increased this type of inequality.

IMPLEMENTATION OF PROGRAMS: LESSONS OF EXPERIENCE

The IMCI strategy was thoroughly evaluated from its onset. Only two years after the first health worker training course took place, the MCE was launched (Bryce and others 2004). MCE researchers visited 12 countries and carried out in-depth studies in five of those. The MCE and the more recent Analytic Review of IMCI (DFID and others 2003), which included visits to six countries, provide the background for this section.

Institutions and Programs

IMCI introduction was highly successful. As of December 2002, WHO's global monitoring team reported that IMCI had been introduced in 109 countries (see http://www.who.int/child-adolescent-health/overview/child_health/map12_02.jpg). Twelve countries were included in the introduction phase, in which the strategy was officially endorsed, a national IMCI coordination group was appointed, and key ministry of health staff members were trained in the IMCI clinical

guidelines. Another 50 countries were in the early implementation phase, which included development of a national plan, selection of initial districts for implementation, adaptation of the IMCI clinical guidelines and materials, training of course facilitators, and planning at the district level. Finally, 47 countries were in the expansion phase, which included scaling up IMCI activities in districts already covered and expanding to cover additional districts (WHO and UNICEF 1999).

The fact that a country has adopted the IMCI strategy, however, does not mean that a high population coverage has been reached. The best available estimates of IMCI coverage are provided by the percentage of health workers who underwent IMCI training and are managing sick children. For example, the Brazil MCE (Amaral and others 2004) has shown that IMCI is being implemented in all 27 states, but in some of those states only a few health professionals were trained. In the three states selected for the evaluation because of reportedly strong IMCI implementation, there was at least one IMCI-trained health worker in 239 out of 443 municipalities (54.0 percent), but only 23 municipalities (5.2 percent) had at least 50 percent of health workers trained after three years. In Peru, also a leading country in IMCI training, approximately 10 percent of all doctors and nurses providing child care were trained after seven years of IMCI implementation (Huicho and others 2005). Therefore, levels of training coverage in most countries appear to be low.

Lessons about Implementation Success and Failure

Both the MCE (Bryce and others 2004) and the Analytic Review of IMCI that were carried out in 2002–3 (DFID and others 2003) confirm that IMCI has been highly successful in motivating managers and health workers. The training pro-

gram is highly regarded, and trainees are pleased with its logical, consistent approach to child health problems. Innovative clinical skills, such as the use of palmar pallor to diagnose anemia and the use of breathing rate for pneumonia, are often praised. Nutritional counseling, an area in which most health workers receive little formal training in school, is also greatly appreciated. When asked about the limitations of IMCI, health workers often mention the increased time required for a consultation and the difficulty of following the IMCI guidelines when there is a high patient load.

Several studies have shown that health workers trained in IMCI do perform better than those not trained. Health facility surveys carried out in Tanzania (Schellenberg and others 2003), Brazil (Amaral and others 2004), and Uganda show that IMCI training substantially improves health worker performance in assessing and managing sick children, and in counseling their caretakers. Box 63.2 summarizes MCE findings on antibiotic prescribing patterns, a critical area for managing sick children (Gouws and others 2004).

Important constraints to IMCI implementation were also identified through visits to 17 countries by the MCE and Analytic Review teams. Using the framework developed by the Commission on Macroeconomics and Health (Hanson and others 2001), the teams described shortcomings in three areas: community and household issues, health service delivery issues, and issues related to health sector policy and strategic management.

Community and Household Issues. Coverage levels for effective interventions to improve child survival are remarkably low in most developing countries. A review of the 42 countries that account for 90 percent of global child deaths showed that only two out of nine key interventions reached more than half of all children (Bryce and others 2003). This finding agrees with

Box 63.2

Improving the Use of Antimicrobials through IMCI Case-Management: Findings from the MCE

Antimicrobial drugs, including antibiotics and antimalarials, are an essential child survival intervention. Prompt and correct provision of drugs to children under age five who need them can save lives. Ensuring that these drugs are not prescribed unnecessarily and that those who receive them complete the full course can slow the development of antimicrobial resistance. Analysis of data collected through observation-based surveys at randomly selected first-level health facilities in Brazil, Tanzania, and Uganda shows that children receiving care from health workers trained in

IMCI are significantly more likely than those receiving care from workers not yet trained in IMCI to receive correct prescriptions for antimicrobial drugs, to receive the first dose of the drug before leaving the health facility, to have their caregivers advised on how to administer the drug, and to have caregivers who are able to describe correctly how to give the drug at home as they leave the health facility. IMCI training is an effective intervention to improve the rational use of antimicrobial drugs for sick children visiting first-level health facilities in low- and middle-income countries.

those of the MCE, showing that the third component of IMCI—improving family and community practices—was poorly implemented. At the global level, UNICEF was primarily in charge of developing this component (see <http://www.childinfo.org/eddb/imci/practices.htm>), and at the country level, UNICEF often acted through nongovernmental organizations (NGOs). Coverage with these community-based programs tended to be patchy. In Peru (Huicho and others 2005) and Tanzania, the districts that were selected for implementation of the community component were not the same as those prioritized for health worker training, which were chosen by the ministry of health with WHO support. This precluded any possible synergy at the district level between improved quality of care in health facilities and community interventions, including those aimed at improving care seeking and compliance with health workers' advice.

All the countries that were visited, however, have a number of programs and projects that deliver child survival interventions at the community level. Many of these interventions are part of the key IMCI family practices, but they are being delivered in an uncoordinated manner by national, international, and nongovernmental organizations in limited geographical areas. The low population coverage of these projects makes it unlikely that they will ever result in a substantial effect on a larger scale. The notable exceptions are the EPI programs, which, despite some recent evidence of falling coverage (Bryce and others 2003), still reach the vast majority of children in developing countries.

On the basis of the experience obtained in these countries, it appears that those key family practices that are most likely to be synergistic with facility-based IMCI—improved care seeking, home management of disease, and compliance with health worker advice—are among those least likely to be supported by existing programs. Existing programs seem to favor biological interventions such as vaccines, micronutrient supplementation, and insecticide-treated materials.

The present criticism of community IMCI should not be extrapolated to community-level child health interventions in general, which can often be highly successful. These interventions are covered in chapter 56.

Health Service Delivery Issues. Given the difficulties in implementing the community component, IMCI was largely restricted in nearly all countries to training health workers in the improved management of care for young children. Even there, some difficulties were apparent.

In countries such as Peru, Brazil, and Uganda, after an initial sharp increase in the number of health workers who were trained, budgetary and other restrictions led to a decrease in the number of training courses being offered. In Peru, about 10 percent of all eligible health workers in the public sector were trained after seven years of implementation. At the

current rate of training, several decades will be needed before full coverage is reached (Huicho and others 2005). Similar results were observed in Uganda (J. Nsungwa-Sabiti, personal communication).

Staff turnover is also a major problem. In Peru, between 1996 and 2001, 43 percent of IMCI-trained health workers had already been rotated since their training (Huicho and others 2005). In Tanzania, where staffing patterns appear to be quite stable in comparison with the situation in other countries, 23 percent of trained staff had moved within three years of initial training (C. Mbuyia, personal communication). Problems with turnover were also observed in Bolivia, Brazil, and Niger. These health workers did not necessarily leave government employment, but high rotation means that IMCI may not be continually delivered to the same target population over time.

Another relevant issue mentioned in several countries was that of low staff motivation, which was often associated with low salary levels. In Uganda, the performance of health workers fell dramatically in 2001 after the government discontinued cost-sharing schemes that were used to supplement drug supplies and health worker salaries at the facility level (Burnham and others 2004). In Cambodia and Tanzania, salary levels are so low that health workers need other sources of income to maintain their families. Issues related to human resources are addressed in greater detail in chapter 71.

Poor supervision was a major issue in all countries that were visited. IMCI recommends regular supervisory visits that should include systematic observation and feedback on case management. In Peru, the average number of supervisory visits was 0.19 per facility per year (Huicho and others 2005). In Bangladesh, a baseline (pre-IMCI) health facility survey conducted in 2000 found that none of the facilities in the study area had received a supervisory visit, including observation of case management, within the previous six months (S. E. Arifeen, personal communication). Common reasons given by health workers for erratic supervision activities are shortages of vehicles, fuel, and staff members.

Problems with referral were also common. The Urgent Referral category in figure 63.1 requires immediate referral to a hospital. In several countries (Bangladesh, Cambodia, Niger, Uganda, and Tanzania), it was reported that children in this category are often not taken to a hospital because of distance or lack of funds for travel and hospitalization-related expenses. For example, in a Tanzania survey, only 5 of 13 children who had been referred were actually taken to a hospital (Schellenberg and others 2003). Also, in some countries hospital staff members who had not been trained in IMCI were reluctant to admit children with danger signs identified through the IMCI algorithm. This situation highlights the need for reinforcing training of referral-level health workers using IMCI guidelines.

Another important limitation, observed in Bangladesh, Cambodia, Niger, and Uganda, is the low use of public sector health care for a variety of reasons (accessibility, official or under-the-table user fees, perceived poor quality, lack of drugs, and so on). For example, using Ministry of Health documents in Niger, the authors estimated that the average annual number of attendances by children under age five was 0.5. In Bangladesh, only 8 percent of children who were ill were taken to a qualified provider (S. E. Arifeen, personal communication). In the presence of such low utilization rates, it is unlikely that health worker training can have an effect on mortality rates, unless simultaneous community activities improve care-seeking practices.

Although equipment and vaccines that are needed for IMCI delivery were available in most countries visited, availability of drug supplies varied from country to country. Shortages were reported in Cambodia and Zambia, and other countries, such as Peru and Tanzania, reported that essential IMCI drugs were mostly available.

Health Sector Policy and Strategic Management Issues.

Several of the problems described in the preceding section are directly related to health sector issues. In addition, issues related to higher-level policy and management may also represent constraints to successful IMCI implementation.

In some countries, IMCI was not fully institutionalized at national or subnational levels. For example, a national coordinator was not appointed or was appointed on a part-time basis. In Peru, IMCI was implemented side by side with CDD and ARI programs, which it was expected to replace, and in several districts the ARI coordinator's tasks were expanded to also encompass IMCI. In several countries, IMCI activities did not have a separate budget line, or they were not included in district health plans, or neither. A report on the Analytic Review of IMCI (DFID and others 2003, 39) states, "IMCI was generally introduced as a strategy, not as a program. If this was not a barrier in the pilot phase, it seemed to generate problems for rapid scaling up. In five of the six Analytic Review countries, IMCI focal persons did not have the rank or the responsibility of previous disease specific program managers within their Ministry of Health, and IMCI did not have a budget line and a strong management structure." The report also argued that decentralization, as part of health sector reform, reduced managerial capacity at the central level and had, at least in the short term, a negative effect on IMCI implementation.

Conflict between IMCI guidelines and existing policies and regulations was present in some countries, particularly the former Soviet republics of Kazakhstan and the Kyrgyz Republic, where policies for hospital admission—requiring, for example, that all children with diarrhea be hospitalized—were in conflict with IMCI guidelines. Another regrettable example comes from Brazil, where both doctors and nurses were being trained in IMCI until medical associations threatened legal

action to prevent nurses from being trained in using antibiotics for life-threatening conditions. This obstruction succeeded despite an MCE health facility survey that showed that IMCI-trained nurses performed as well as doctors in managing sick children (Amaral and others 2004). In Morocco, IMCI-trained nurses are also unable to prescribe antibiotics because of central regulations.

A particular challenge came to light when the MCE team visited Cambodia and Niger and the Analytic Review team visited Mali. These countries have high levels of under-five mortality and thus the greatest need for IMCI. They also have weak health systems and low utilization rates and are therefore having difficulty implementing IMCI successfully. Just as for individuals, the *inverse care law*—which suggests that those who most need high quality care are the least likely to get it—seems to also apply to countries (Hart 1971).

However, there is a possibility that IMCI (or other approaches to managing sick children) might help strengthen selected health system functions through specific approaches, as the Analytic Review team observed in regard to drug and commodity availability, service management, and health worker motivation through IMCI in the Arab Republic of Egypt (DFID and others 2003).

Implications for Health System Development

The first component of IMCI, which involves training of health care workers, has been implemented in many developing countries and has resulted in important improvements in the quality of care delivered to children in first-level facilities in limited geographic areas. The potential population-level effect of IMCI case-management training has not been realized, however, for three reasons:

- Sufficient resources were not available for full implementation.
- Few health systems in low-income countries are capable of providing the policy, personnel, and managerial support needed to expand and sustain high levels of IMCI training coverage.
- At the time of this writing, not one country had succeeded in mounting a behavior-change program capable of improving care seeking, home management of illness, and nutrition-related practices to coverage levels that will result in population-level changes in service utilization or health status.

One implication for health system development is that support should be continued and expanded for integrated case management in first-level facilities as an essential component of an effective child survival strategy. A second implication, however, is that greatly expanded efforts must be directed

simultaneously to the development of new and innovative approaches to strengthening health systems and to reaching families and communities with known and affordable child survival interventions.

An important distinction can be made between interventions and delivery strategies (Bryce and others 2003). The same intervention (vitamin A capsules, perhaps) can be delivered through different strategies—for example, to children attending health facilities, on National Immunization Days, or directly at the household level through community networks. In spite of its community component—which in most countries has not been operational anyway—IMCI, as implemented to mid 2004, relies on health facilities as its key delivery strategy.

The first component of the IMCI strategy—a focus on improving health worker skills—was innovative to the extent that it provided clear technical guidelines and yet required country-level adaptation. Similar levels of technical clarity and country-level flexibility did not exist for the second and third components of the IMCI strategy, which focused on improving health systems to support IMCI and improving family and community practices. Within these two components, the IMCI strategy has been criticized for attempting to become a uniform global strategy, with guidelines for implementation that do not allow room for country-level modifications, especially the incremental approaches to implementation needed by weak health systems (Bryce and others 2003). The first component of IMCI can serve as a model for the types of development work that must now move forward in the health systems and family practice areas; however, in these areas, key decisions about how best to deliver interventions will need to be made at the country level and below.

One example of progress is that WHO and its partners have now developed a process for assessing country-level opportunities and requirements for achieving population-level behavior change in relation to key family practices and for developing feasible and collaborative work plans for effectively implementing child health activities at the community level (A. Bartlett, personal communication).

As the MCE and Analytic Review have shown, IMCI requires a functional health system with managerial capacity; an ability to train health workers and to keep them on the job; an efficient means of supplying drugs, vaccines, and equipment; and the capacity to maintain regular supervisory activities. It also requires appropriate care-seeking practices, leading to a reasonable level of health services utilization by children under age five. In most countries, appropriate health services utilization is unlikely to be achieved without strong family and household-level interventions such as those promoted by community IMCI.

These problems, however, are not specific to IMCI; they affect every other delivery strategy that relies heavily on health facilities, including the predecessors of IMCI, namely the CDD

and ARI programs. In fact, at least in theory, the efficiency gains represented by the integration promoted by IMCI should make it easier for developing countries to implement as the key child health strategy, so a return to vertical programs is not the answer.

Given these difficulties, however, there may be a temptation to bypass health services altogether in the poorest countries by promoting the delivery of child health interventions directly to families and households. There are successful examples of such community delivery schemes—for example, projects dispensing antimalarials (Pagnoni and others 1997; Kidane and Morrow 2000) and antibiotics for pneumonia (Sazawal and Black 1992). This approach may, in fact, be the most viable short-term solution for countries with weak health services, but it should not be forgotten that most success stories represent small-scale pilot projects with strong managerial backup. In countries with weak systems, the managerial support for implementing and sustaining high-quality, community-based interventions is also likely to be lacking, so it may be naive to assume that such programs will have the effects that health services have failed to deliver. Also, just as first-level health facility care depends on referral services for backup, community delivery schemes will require operational first-level health facilities to handle complications and treatment failures.

There is no substitute for strengthening health systems in the poorest countries. In the long run, strengthening these systems will be the key intervention for reducing child mortality as well as for promoting healthy growth and development. Delivery strategies that reach communities either directly or through other mechanisms are needed in the short term, but the long-term goal of improving health services is paramount.

THE RESEARCH AND DEVELOPMENT AGENDA

This section starts by addressing health systems research issues related to scaling up child health interventions effectively. Key issues on the research agenda are how to make the best possible use of integrated case management in settings where health systems are weak and how to design alternative delivery strategies to improve child survival in such settings.

Specific issues relate to how to counteract the main constraints to scaling up IMCI that were described earlier in “Implementation of Programs: Lessons of Experience.” For example, research is needed in the following areas:

- how to increase utilization in the public sector (and the role of user fees in this respect)
- how to develop viable public sector–private sector partnerships
- how to reduce staff turnover

- how to improve supervision and make it sustainable
- how to institutionalize IMCI case-management training and supervision at the district level.

In addition, research is needed on how to strengthen health systems and improve family and community practices for child survival in ways that take into account and build on features of the country context. These features include the epidemiologic profile and the characteristics of the health system. Country-level assessments and planning and support for longer-term implementation are required to achieve high and equitable coverage and population effect in different epidemiologic, health system, and cultural settings (Bellagio Study Group on Child Survival 2003). Innovative research is needed involving country-level investigators and program staff members, with international partnerships if required, to develop and evaluate different combinations of health facility-based and household-based delivery schemes. In particular, research should address how to go to scale with interventions that have been proven effective in pilot studies. From the costing perspective, research should address the issue of how to estimate the cost of scaling up using different scenarios of resource availability and constraints.

Monitoring and evaluation are key components of the required research. Tools must be developed for use at the district and national levels, and capacity to use them must be strengthened.

CONCLUSIONS: PROMISES AND PITFALLS

IMCI was introduced in the mid 1990s as an ambitious global strategy that held many promises. Cost-effective vertical interventions against the main causes of under-five mortality in the world were integrated into a single, facility-based health worker training program. The program was accompanied by efforts to improve health systems support for child health care and to promote key family practices at the community level. Integration was expected to further improve coverage levels and the cost-effectiveness of child survival interventions relative to their delivery through separate vertical programs.

IMCI case-management training was repeatedly shown to improve the quality of care delivered in first-level health facilities, and the costing data reviewed above suggest that it can do so at similar or lower costs than those of existing health services. IMCI, therefore, is able to deliver better child health care at no increase in costs.

Nevertheless, community IMCI interventions only reached meager population coverage in the countries studied, and even health worker training was never effectively scaled up in most countries as a result of health system constraints. The major effect on child survival that was initially expected as a result of

IMCI implementation has not yet materialized, and country reports of the barriers to achieving and maintaining high coverage levels suggest that effects will not be seen unless IMCI in first-level facilities is buttressed by equally strong or stronger efforts to develop health system capacity and reach families and communities. In fact, progress in child survival in the late 1990s and early 21st century has been slower than in earlier decades (Bellagio Study Group on Child Survival 2003), and current trends suggest that the Millennium Development Goals are unlikely to be achieved for most countries unless major new investments are made very soon.

The Tanzania results suggest that, in a setting where IMCI was implemented in conjunction with health system strengthening and where utilization of health facilities is high, an effect on mortality and nutritional status is likely. However, experience from other countries showed that reaching high and sustained implementation was difficult.

Although IMCI has only partially lived up to initial expectations, it has many positive aspects that must be fostered. A return to isolated vertical programs for child survival will not solve the difficulties faced by scaling up IMCI effectively, and integration should continue to be a key goal of child survival strategies in the future. In fact, much of the frustration associated with reported underperformance of IMCI arises from the fact that sufficient resources—financial, human, and organizational—were not planned for or available to support its full implementation, either at national or at international levels. The meager training coverage levels observed in most of the MCE countries are clear evidence of insufficient implementation, and it is thus not surprising that coverage and effect were also less than expected.

Renewed and expanded efforts to reduce child mortality should build on the proven effectiveness of IMCI case management in first-level facilities, but they also should incorporate new knowledge. Country-specific planning is needed to reach families and communities and to build on the existing health system to achieve and sustain population-level coverage. Countries with weak health systems will require creative approaches to intervention delivery in the short term at the same time that health systems are strengthened as a long-term strategy. The poorest strata of the population are also the neediest in terms of health care and the hardest to reach. The challenge of improving equity is not unique to IMCI or to child survival; it affects virtually every intervention and delivery strategy. Unless equity considerations become a key part of policy making and of monitoring outcomes, interventions may widen instead of narrow inequity gaps (Victora and others 2003).

A continuing challenge is how to raise and sustain the standing of child survival in the international agenda. The more than 10 million annual deaths of children under age five—more than 20 deaths per minute—represent twice the number of

deaths attributable to AIDS, malaria, and tuberculosis combined (Black, Morris, and Bryce 2003). Putting child survival back on the public health and development agenda is an essential developmental step in the process of refining country-level and global child health strategies. Only through taking stock of the lessons learned in early IMCI implementation can a flexible, integrated program be developed that will improve child survival in particular and child health in general.

ACKNOWLEDGMENTS

A substantial portion of this chapter is based on early results from the Multi-Country Evaluation of IMCI Effectiveness, Cost, and Impact. The MCE is funded by the Bill & Melinda Gates Foundation and is supported by technical assistance from the World Health Organization and a technical advisory group representing global expertise in cost-effectiveness analysis, measurement, research design, and child health.

Chapter 64

General Primary Care

Stephen Tollman, Jane Doherty, and Jo-Ann Mulligan

Primary health care has always been a feature of health care systems and—from a modern perspective—involves four inter-related aspects: a set of activities, a level of care, a strategy for organizing health care, and a philosophy that permeates health care provision. At full stretch, then, the “primary health care approach” can affect the configuration and focus of the entire health system and extend to the development of communities (Vuori 1985).

It is not always easy to see how information on the cost-effectiveness of individual interventions—the focus of part 2 of this volume—contributes to the achievement of the wider features of primary health care. Indeed, Starfield (1998) points out that the importance of particular services or interventions is overrated, in part because of limited appreciation of the “essential and unique functions” of primary care. These functions are mutually reinforcing and include first-contact care; continuity in care (in Starfield’s words, “person-focused over time”); comprehensiveness of available services; and coordination with specialized services and other levels of care. The functions point to the centrality of how primary care is organized and delivered, something with which the cost-effectiveness approach has hitherto not been greatly concerned. This chapter attempts to identify some of the common ground between the primary health care approach and the cost-effectiveness approach. We propose that resource constraints simultaneously require (a) the targeting of services toward burdens of disease that are amenable to highly cost-effective interventions and (b) the general strengthening of the health system, particularly at the primary care and district levels.

THE SCOPE OF GENERAL PRIMARY CARE PRACTICE

General primary care can be defined as the immediate—and often continuing—medical and health management of a child, adult, or family when the patient first presents to the formal health system. In low- and middle-income countries, such care is often provided from publicly funded health posts and health centers by nurses or other midlevel health workers, with medical doctors expected to play a support, training, and referral role.

Comprehensive versus Selective Care

The 1978 Alma Ata declaration on primary health care (WHO and UNICEF 1978) was informed by a number of well-described, small-scale health and development efforts in a range of settings (Newell 1975; Tollman 1991). It focused international health care efforts on low-cost, potentially high-impact interventions, both medical and social, at both the primary and community levels. In particular, the declaration emphasized the importance of health promotion and community development through, for example, the supply of water and sanitation and the involvement of communities in decision making.

Before long, the extent of resources and capacities needed to implement such comprehensive activities led to the emergence of the concept of “selective primary health care” (Walsh and Warren 1979). This concept advocated a focus on a limited number of priority conditions, such as children’s health and

particular tropical diseases. Selective interventions, often centrally planned, and managed and operated by a dedicated staff, were intended as entry points into the health care system. Such an approach, when fully operationalized as a “vertical program,” proved especially useful in implementing control and eradication campaigns and in dealing with epidemics following natural disasters (Unger, de Paepe, and Green 2003; World Bank 1994).

The selective approach attracted strong criticism for not acknowledging that primary care practice needs to take account of the range of conditions that present, many of which—by definition—were excluded from the selective agenda (World Bank 1993). In addition, administrators responsible for vertical programs tended to have little contact with local health officers and seldom coordinated well with other vertical efforts, leading to duplication of training, supervision, and logistics management (Briggs, Capdegelle, and Garner 2003). Other inefficiencies resulted from the need for specialized personnel, which led to growing numbers of dedicated staff members as well as excessive demand on service users’ time if they needed multiple services. Verticalization can also lead to competition between programs, favoring of some conditions at the expense of others, weaknesses in continuity of care, disruption of routine health services, and erosion of country-level delivery capacity (Coker, Atun, and McKee 2004).

Concerns about the appropriateness of individual vertical programs were matched at that time by concerns about the continuing misallocation of resources toward expensive, cost-ineffective care, culminating in the publication of *Investing in Health: World Development Report 1993* (World Bank 1993). The report identified highly cost-effective interventions targeted at the major causes of the prevailing burden of disease in low- and middle-income settings. These interventions were grouped into a “minimum package of health services,” which, it was argued, governments and donors should prioritize for funding (World Bank 1993). The delivery vehicle for most of these services was the primary care system.

The definition and costing of intervention packages has evolved over time, and this evolution is reflected in the World Bank’s *Better Health in Africa* (1994), the World Health Organization’s *World Health Report 2000* (WHO 2000), and the report of Working Group 5 of the Commission on Macroeconomics and Health (Jha and Mills 2002). Although some services have been added and others have been described more specifically (partly informed by new research), the essential components of the package have remained remarkably constant. Another World Health Organization (WHO) publication (2002), *World Health Report 2002*, which focused solely on interventions against risk factors, corroborated several of the interventions in the package (Doherty and Govender 2004; see annex 64.A). Thus, a broad consensus appears to exist on the nucleus

of activities that is appropriate at the primary care level (see table 64.1). In many ways, this consensus existed before the publication of *Investing in Health* (World Bank 1993), but economic evaluation has subjected conventional wisdom to empirical validation and considerations of affordability; it has also scrutinized the components of particular interventions (frequency of prenatal health care visits, for example). This evaluation has served the purpose of providing a basis for consensus that is more convincing to key constituencies, such as national treasuries and donors. Consequently, several low- and middle-income countries have delineated minimum or essential packages for their own national contexts.

The notion of such packages is not without controversy, however. Whereas some criticisms relate to methodological issues—and hence to the advisability of generalizing the findings of local studies and using them to establish priority services on a global scale—others relate to the disease-oriented basis of essential packages (Doherty and Govender 2004). The authors of essential packages are not necessarily proponents of verticalization (in some instances, they have argued strongly for the cost-effectiveness that a horizontally well-integrated service can achieve). However, the reality of activity by international agencies, donors, and even governments means that, in many instances, the implementation of narrowly defined programs continues to be favored (with HAART—highly active antiretroviral therapy for the treatment of HIV/AIDS—having the potential to follow suit). Continuing verticalization also reflects the resource constraints faced by countries that are unable to mount a comprehensive set of services and suggests that services in developing countries are chronically underfunded (Jha and Mills 2002).

The disease-based construction of packages may have reinforced this tendency to verticalization, as may have incentives for program managers to monitor program activities in terms of their effect on specific diseases. This factor accounts partly for the suspicion that sometimes greets efforts at cost-effectiveness-based planning, and it signals the need to continually promote the effective integration of activities at the health facility level.

General Primary Care at a Key Interface

Although the primary care level constitutes the first point of patient or family contact, it is also a critical base for extending care to communities and vulnerable groups. These outreach services may focus on individual preventive measures (such as immunization, vitamin A, or oral rehydration therapy) or communitywide health-promoting efforts (such as education on child nutrition or adult diets and exercise; see chapter 56). Increasingly, home-based care for chronic conditions, such as HIV and AIDS and poststroke rehabilitation, can be expected to feature in outreach services. These services depend substantially

Table 64.1 Selected Sets of Interventions Used in the Cost Analysis of the Commission on Macroeconomics and Health, 2002

Disease area	Nature of interventions
Maternity-related interventions	Prenatal care Treatment of complications during pregnancy Skilled birth attendance Emergency obstetric care Postpartum care (including family planning)
Childhood disease–related interventions (immunization)	Vaccinations (Bacillus Calmette-Guérin, oral polio vaccine, diphtheria-pertussis-tetanus, measles, hepatitis B, <i>Haemophilus influenzae</i> type B)
Childhood disease–related interventions (treatment of childhood illnesses)	Treatment of various conditions (acute respiratory infections, diarrhea, causes of fever, malnutrition, anemia), now increasingly combined as integrated management of childhood illness
Malaria prevention	Insecticide-treated nets Residual indoor spraying
Malaria treatment	Treatment for malaria
Tuberculosis treatment	Directly observed short-course treatment for smear-positive patients Directly observed short-course treatment for smear-negative patients
HIV/AIDS prevention	Youth-focused interventions Interventions working with sex workers and clients Condom social marketing and distribution Workplace interventions Strengthening of blood transfusion systems Voluntary counseling and testing Prevention of mother-to-child transmission Mass media campaigns Treatment for sexually transmitted infections
HIV/AIDS care	Palliative care Clinical management of opportunistic illnesses Prevention of opportunistic illnesses Home-based care
HIV/AIDS treatment	Provision of highly active antiretroviral therapy

Note: Smoking cessation interventions, although considered a priority, were not included in this cost analysis because it was assumed that they would be financed by tobacco taxes.

on community support and mechanisms for identifying, training, and supporting village or community health workers.

At the same time, primary care facilities mediate patient access to hospital care, particularly at the district level. General primary care, as a level of care, is thus located at a key interface

that links, on the one hand, ambulatory care with hospital and specialty services and, on the other, individual clinical care with community-wide or population-wide health, nutrition, and family planning programs. Acting as the fulcrum of a comprehensive care and support system, development of general primary care requires that local management teams plan services for their defined catchment communities (Jha and Mills 2002)—recognizing that catchment populations can be more difficult to define in urban (particularly high-density) settings. Delineating the community for which a local health system is responsible—and thereby making explicit the population under the care of providers—makes it feasible to undertake ongoing monitoring and evaluation of the performance of local primary care services (quality of care and extent of coverage, for example) and contributes to the assessment of health systems more broadly.

Given the pivotal position of general primary care, distinguishing sharply the cutoff between activities that occur at this level and those that occur elsewhere is difficult. The balance of services provided at the primary level rather than other health service levels is, in fact, a moving target, affected by an array of factors. For example, diagnostic and technological innovation can influence substantially the level at which interventions are delivered. In many middle-income countries, great potential exists to move elements of surgical, psychiatric, and medical care upstream to the primary care level, provided that the necessary competencies, equipment, and technical or managerial support exist. However, the converse also holds: no matter how appropriate in theory, if service delivery is ineffective, the downstream momentum to district and secondary hospital levels (and into the private sector) is almost unstoppable, with serious implications for the accessibility of care. In practice, therefore, factors such as geographic and financial inaccessibility, limited resources, poor capacity, and erratic drug supply and faulty equipment often mean that the services offered at the primary care level are disappointingly limited in their range, coverage, and effect.

“Fitting” of Interventions to the Health System

Recognition is growing that focusing simply on selecting cost-effective interventions as the basis for services development is inappropriate. Paying close attention to the qualities of the delivery system that are required to support the introduction of these interventions and, in time, provide support to their scale-up is essential. The Multi-Country Evaluation of IMCI Study Group (Bryce and others 2003, 159) highlights the “importance of separating biological or behavioural interventions from the delivery systems required to put them in place, and the need to tailor delivery strategies to the stage of health-system development.”

Thus, seeking and evaluating the goodness of fit between interventions with the potential to be highly cost-effective and the health system responsible for their effective delivery are critical. A major challenge in focusing on the primary care level is to establish the most effective combinations or clusters of interventions that can target multiple conditions and risk factors affecting key community groups (children, women, and older adults, for example) and that are appropriately adapted to local epidemiologic, economic, and sociocultural contexts. Clustering interventions appears to be a pragmatic approach that achieves a degree of comprehensiveness while at the same time acknowledging resource constraints. It also provides opportunities to intensify training, improve the quality of care provided, and assess community health impact (see chapter 63). If clusters, such as integrated management of infant and childhood illness (IMCI) or reproductive health services, can be fully integrated into health service planning, management, and operations, the health system will be provided with some focus while the shortcomings of vertical disease programs can be potentially avoided. Thus, clustering may allow for broader horizontal strengthening of local health system inputs. As stated earlier, persistent efforts to achieve such integration are essential, given that, as expressed by the Bellagio Study Group on Child Survival (2003, 324), “in today’s environment of disease-specific initiatives, cross-disease planning, implementation, and monitoring are hard to establish and maintain.”

However, clustering does not entirely address concerns that interventions based solely on cost-effectiveness assessments, which seldom examine indirect and nonhealth benefits (Doherty and Govender 2004), might deplete some of primary care’s unique features, including responsiveness to the expressed needs of local communities. Indeed, Gilson (2003,) writes that “future analysis and policy development must recognise that health systems are complex socio-political institutions and not merely delivery points for bio-medical interventions.” Community expectations of the services provided at a health center or health post tend to be holistic and may well depart from selected priority intervention categories. The exclusion of services from clusters, or the exclusion of whole clusters, can lead to inequity. Failure to manage this situation adequately can undermine clients’ confidence in the public health system and affect provider behavior negatively. WHO (2000, 59) notes that providers “usually react to this . . . by cross-subsidizing the excluded activities through the budget received to pay for the defined benefit package; or by charging extra for the additional services.”

These considerations need to be taken into account when identifying clusters of interventions to be provided in local contexts. Nonetheless, likely intervention clusters, with potentially high goodness of fit at the primary care level, will generally include IMCI; maternal and reproductive health services; clinic and community-based management of tuberculosis,

HIV and AIDS, and sexually transmitted infections; malaria management; management of hypertension, other cardiovascular risk factors, and—increasingly—stroke and cardiovascular disease; and mental illness and substance abuse. In all cases, a systematic approach must be taken to establish explicit criteria, guidelines, or regulations regarding the appropriate treatment level (primary, secondary, and so on) for key conditions and the interventions suitable for these conditions at different levels of severity, according to a country’s stage of health system development. Broadly categorizing countries according to their income status and the general features of their health system is too blunt an approach to allow the detailed mapping of interventions to the health system capability that is required, and it fails to recognize the wide disparities in health system organization and effectiveness that exist within national boundaries.

THE EFFECTIVENESS OF GENERAL PRIMARY CARE

Whereas it can be argued that highly cost-effective interventions deserve to be implemented, no matter the level for which they are designed, unique reasons exist for giving priority to those based at the primary level. As implied earlier, these reasons relate to the extent of the burden of disease that is potentially avertable through primary-level care (the health effect), the welfare benefits that accrue to households spared the experience of disease (the nonhealth effect), and the potential to provide widely accessible services (an equity effect based on degree of need).

Unfortunately, although many small-scale projects and assessments of single interventions have been able to measure such effects (see part 2 of this volume), the empirical evidence with regard to large-scale and routine primary care programs—whether in industrial or low- and middle-income settings—is scant (Doherty and Govender 2004; Starfield 1998). The key problem is to demonstrate the causal link between provision of general primary care services and positive health outcomes—and especially to disentangle the influences of socioeconomic conditions. This difficulty is compounded by other factors, ranging from the complexity of the study design required to convincingly evaluate routine programs (as opposed to field trials) to the difficulties faced by health ministries in ensuring that monies targeted at primary care are translated into the delivery of quality health services.

Thus, we are able to comment only in broad terms on the positive contributions of general primary care services, recognizing that, although these contributions are potentially enormous, the gains made by such services over the past two decades have been mixed. Importantly, Almeida and others (2001) caution against ascribing the failures of primary care to

inherent weaknesses in the concept. In commenting on analyses of the effectiveness of primary care, they point to “the cataclysmic effect on public health systems in less-developed countries of the global economic recession of the 1980s and the application of policies stressing privatisation and decreased public spending in that decade and the next; [this] resulted in rising poverty and under-funding of health services in many less-developed countries, to the point of near-collapse in the poorest countries” (Almeida and others 2001,).

Health Effects

Investing in Health reported that in countries with moderate to high mortality only a few conditions accounted for the majority of the burden of ill health (World Bank 1993). Thus, in 1990, 55 percent of the global burden of disease was concentrated in children under 15, and 75 percent of this burden was caused by 10 disease conditions or clusters (Bobadilla and others 1994). Except for congenital malformations, all these causes could be aligned with highly cost-effective interventions, many of which are classic components of general primary care (labeled the “clinical services” component of the package). Indeed, almost all of the activities included in the “public health” component of the package also involve some element of individual service delivery in the primary care setting. Together, it was estimated, these interventions could eliminate 21 to 28 percent of the burden of ill health in children.

With respect to adults, the World Bank (1993) found the burden of disease to be less concentrated: here the 10 main causes of disease and injury accounted for some 50 percent of the burden.¹ Most interventions against these problems were found to be quite cost-effective, but their overall estimated effect was moderate because they prevent or treat only part of the problems. Such interventions could thus eliminate 10 to 18 percent of the adult disease burden.

These figures give some sense of the potential effect of interventions at the primary level when they are targeted at common, high-burden conditions in the population. Subsequent work by the World Bank estimated that the primary care level could potentially deal with up to 90 percent of health care demands (World Bank 1994) and that only 10 percent of care needs require the services and skills typically associated with hospitals.

Shifting from estimates to empirical evidence, we find that some studies have been able to demonstrate large-scale success in the sphere of child health. For example, using data from a national survey in Niger, Magnani and others (1996) showed that children living in villages near health dispensaries were 32 percent less likely to die than children without access to modern primary care services (differential access resulted from the phased implementation of services, which produced a natural quasi-experiment). Drawing on earlier work, Ewbank

(1993,) concluded that the results of surveys in Zaire and Liberia “suggest that child survival programmes in Africa can reduce mortality substantially in populations living in different environments at very different initial levels of child mortality. . . . In both countries, it appears that the programme reduced mortality under age 5 by about 20% or more.” More generally, many examples of successful health programs clearly depend on the existence of a strong primary health care system (see chapter 8).

Given the paucity of evidence from developing countries, turning to the experience of high-income countries is useful, although the configuration of primary care services in such settings may be quite different. Following a detailed comparative study of 11 industrial nations (which involved the methodologically complex—and at times controversial—assigning of primary care and health system scores by country and then associating these scores with a range of health status indicators and total health care costs per capita), Starfield (1994,) concluded that “countries with a stronger orientation to primary care indeed are more likely to have better health levels and lower costs.” Shi (1994,) found that, in the United States, availability of primary care was “by far the most significant variable related to better health status, correlating to lower overall mortality, lower death rates due to diseases of the heart and cancer, longer life expectancy, lower neonatal death rate, and less frequent low birth weight.” Although working largely at the level of health output rather than outcome, Blumenthal, Mort, and Edwards (1995), in reviewing a number of studies in the United States, found considerable evidence of the positive effect of primary care services (see box 64.1). They argue that the literature does not adequately address the issue of whether primary care reduces the cost of providing care for underserved populations, but they conclude that “a commitment to primary care should be made for its potential to improve the satisfaction and health status of the American public, not for its potential to save money” (Blumenthal, Mort, and Edwards 1995,).

Nonhealth Effects

Although most of the recent literature on primary care packages places value on primary care services because of their ability to reduce the burden of disease considerably and at low cost, such services potentially bring other benefits to society. Among the most striking may be the welfare benefits that accrue to households as a result of the prevention of illness. Severe disease can limit the ability of patients and caregivers to work, leading to the consumption of household assets in the purchasing of care. Russell (2003) found that such costs amounted to just over 10 percent of household income in three developing countries, a proportion that can have a catastrophic impact on the sustainability of poor households. Through

Box 64.1

Evidence of the Effectiveness of Primary Care Services

The effectiveness of primary care services is illustrated as follows:

1. Community-based interventions improve access to services, reduce the use of emergency and outpatient departments at hospitals, increase the use of noninstitutional ambulatory care, and reduce the use of hospital care (especially with respect to preventable hospitalizations).
2. Primary care is associated with improved control of routine illnesses that have serious consequences if untreated.
3. The availability of primary care services is associated with improvement in patients' self-perceived health status.
4. The longitudinal care afforded by primary care services is independently associated with improved patient satisfaction, reduced use of ancillary and laboratory tests, improved patient compliance, shorter length of stay, and improved recognition of patients' behavioral problems.

Source: Blumenthal, Mort, and Edwards (1995).

prevention and early treatment, geographically accessible and financially affordable primary care services can reduce the negative economic consequences of ill health for households, reduce absenteeism, and enhance children's performance at school.

Serving of Equity Goals

Primary care services have the advantage over hospital care of tending to be more physically, financially, and culturally accessible to local communities. Because of their staffing and organization, they are less costly and more easily able to provide comprehensive, integrated, personalized, and continuous care (World Bank 1993). Because that part of the burden of disease that is addressed by primary care services disproportionately affects the poor, primary care services are theoretically well placed to improve equity in health and health care. Again, few data exist to demonstrate the equity effects of primary care delivered on a large scale in middle- and low-income countries. This gap is compounded by the fact that cost-effectiveness analyses seldom take into account the costs incurred by patients in seeking care (Doherty and Govender 2004).

However, in studies by Shi and Starfield (2000, 2001) examining income inequality and primary care in the United States, a significant association between higher primary physician supply and good health status was established, even in a context of high income inequality: "The finding of a significant association between primary care and self-rated health contributes to the mounting evidence that specific aspects of health services

have an independent [of income levels] effect in improving population health—in particular, the beneficial effects of primary care" (Shi and Starfield 2000,). The authors suggest that, at least within the particular settings studied, strengthening the primary care aspects of health services could mitigate some of the adverse impacts that income inequality has on individuals' health status.

Primary-level services are also potentially responsive to patients' nonhealth needs. These include a need for the range and quality of health services to meet community expectations and a need for services to treat patients in a helpful and dignified manner. In addition, primary-level facilities can act as community resources (providing communal meeting places, for example), and primary care services can contribute support to neighborhood sports and community development activities. All in all, well-functioning primary-level services represent the face of the health system and have the potential to inspire trust in the system as a whole.

Another source of suspicion regarding the cost-effectiveness approach is the fear that efficiency concerns will override these positive features of primary care. Paalman and others (1998,) note that "the fact that the most efficient interventions . . . tend to specifically benefit the poor is more a result of coincidence than of principle." Indeed, the cost-effectiveness approach does not intrinsically protect equity and could, for example, count against the extension of services to populations living in remote areas. Governments will, at times, need to make explicit choices between serving equity goals and responding to efficiency concerns when determining service priorities. This tradeoff is easier to manage in wealthier countries, where resources are less constrained.

Table 64.2 Cost-Effectiveness of the Health Interventions Included in the *Investing in Health* Minimum Package of Health Services for Low- and Middle-Income Countries (2002 US\$, 2001 prices)

Interventions	Cost per DALY	
	Low-income countries	Middle-income countries
<i>Public health</i>		
Expanded program of immunization, including vaccine against hepatitis B and vitamin A supplementation	15–22	32–38
School health program	25–32	48–54
Tobacco and alcohol control program	44–70	57–70
AIDS prevention program	4–6 ^a	16–23 ^a
Other public health interventions (includes information, communication, and education on selected risk factors and health behaviors, plus vector control and disease surveillance)	—	—
Total	18	—
<i>Clinical services</i>		
Chemotherapy against tuberculosis	4–6	6–9
Integrated management of the sick child	38–63	63–127
Family planning	25–38	127–190
Sexually transmitted disease treatment	1–4	13–19
Prenatal and delivery care	38–63	76–139
Limited care (includes treatment of infection and minor trauma; for more complicated condition, includes diagnosis, advice, and pain relief, and treatment as resources permit)	253–380	507–760
Total	—	168

a. Understates cost-effectiveness because the analysis examined the probability of transmission to others in the first year only.

THE COST-EFFECTIVENESS OF PRIMARY CARE INTERVENTIONS

Part 2 of this book details our best understanding of the cost-effectiveness of many of the individual interventions that have been clustered into “essential packages.” According to *Investing in Health*, most of these interventions are highly cost-effective, costing less than US\$100 per disability-adjusted life year (DALY) averted (see table 64.2; World Bank 1993).

Subsequent packages have expanded the *Investing in Health* list somewhat, yet the primary-level interventions put forward in 1993 remain among the most cost-effective available, especially when combined with population-based interventions (Commission on Health Research for Development 1990; Jha and Mills 2002; WHO 2000). It is important to appreciate that, because of the added costs of extending service delivery to people living in more rural and peripheral areas, achieving universal coverage would probably raise marginal costs considerably above the average figures normally quoted. Bobadilla and others (1994,) note that, in these instances, “the relative importance of cost-effectiveness versus equity will then determine whether to modify the package by leaving out some interventions, providing mobile services rather than fixed facilities, concentrating on public health rather than clinical interventions for the high-cost population, or sacrificing some efficiency in order to preserve equity.” The need to redress gender imbalances or respond to cultural preferences and other factors, as well as the choice of interventions, also might affect costs.

SCALING UP

Adequate delivery of services (and health care more broadly) at the primary care level is, we believe, fundamental to effective functioning of health systems. However, for the most part, primary care systems in low- and middle-income countries have yet to receive the sustained attention and resources that their importance warrants. Early efforts at primary care expansion in the late 1970s and early 1980s were overtaken in many parts of the developing world by economic crisis, sharp reductions in public spending, political instability, and emerging disease. Although essential packages based on cost-effectiveness criteria have been criticized for their largely disease-oriented and vertical approach, in most poor countries even these limited versions of general primary care remain incompletely applied and largely unaffordable in relation to current per capita health care expenditure. At the same time, renewed awareness of the centrality of the primary level in responding to the consequences of the HIV/AIDS epidemic or to rapidly rising cardiovascular risk means that increasing demands will be placed on primary care services. This section examines critical elements of any strategy to scale up primary care efforts; a prerequisite, however, is an adequate understanding on the part of policy makers and planners of the position and role of primary care in the national health system (Travis and others 2004).

Committing More Financial Resources

In the mid 1980s, Drummond and Mills (1987) found the best estimate of the cost of effective primary health care (including

Table 64.3 Comparison of Per Capita Total Annual Health Expenditure Required to Provide Minimum Packages (2002 U.S.\$, 2001 prices)

Report	Low-income countries	Middle-income countries
<i>Investing in Health</i> (World Bank 1993)	15	27
<i>Better Health in Africa</i> (World Bank 1994)	16–20	— ^a
Commission on Macroeconomics and Health (Jha and Mills 2002)	Least developed: 40	Lower-middle income: 39
	Other low income: 36	Upper-middle income: 331 ^b

a. Estimate not provided.

b. Higher figure because of range of services provided (beyond minimum package) and higher input costs; applies to a small subgroup of countries.

the recurrent and capital costs of basic and village-level health services but not of water and sanitation) to be 2 percent of the annual per capita gross national product (GNP). This amount, they noted, is considerable, given that many governments in developing countries do not spend even 2 percent of annual per capita GNP on their entire health sector.

More recently, the Commission on Macroeconomics and Health (CMH) estimated that an additional US\$40 billion to US\$52 billion annual expenditure would be required by 2015 to scale up 49 priority health interventions—not all at the primary care level—to reach high levels of coverage in 83 deserving countries (that is, countries with a GNP per capita below US\$1,200, plus all countries of Sub-Saharan Africa) (Jha and Mills 2002). Apart from the recurrent and capital costs of the interventions themselves, this estimate included management costs generated at levels above “close-to-client” services, expenditure to improve absorptive capacity, expenditure on improvements in the quality of care, and 100 percent increases in staff salaries to address the problems of staff recruitment and retention. The inclusion of these costs accounts largely for the greatly increased per capita estimates of the CMH package relative to earlier estimates by the World Bank (see table 64.3), and probably provides a better estimate of what is needed, given the enormous challenges facing primary care service delivery.

The CMH has placed great emphasis on donor funding of services to adequate levels (see chapter 12 for a more extensive discussion of sources of financing). Other avenues of funding include reprioritizing government budgets or recovering costs through health insurance schemes and user fees, although these all remain difficult options within low-income settings. In particular the experience of user fee schemes, which proliferated in the 1990s, suggests that such schemes have negative impacts on equity, especially at the primary care level, and

should be applied with great caution in poor communities (Gilson 1998). Yet the fact remains that an injection of additional resources is clearly one prerequisite for the successful scaling up of general primary care in the 21st century, backed up by political commitment to the centrality of general primary care (and primary health care more broadly) as a fundamental strategy for tackling the highest-burden diseases and their causes.

Developing Human Resources

Although increased financial resources are imperative, Kurowski and others (2003) emphasize that “human resource availability is likely to determine the capacity to absorb additional financial resources and thus the pace of scaling up.” These authors warn that human resource availability is likely to be grossly insufficient to meet the scaling-up needs envisioned by the CMH.

The skills and competencies necessary to deliver and support effective primary care are in some respects similar to those required at other levels of the health system (see chapter 71), but certain competencies warrant special emphasis at the primary care level (see box 64.2). Above all, if local services are to meet community health needs, leaders at the primary care level will have to be freed from the constraints of stifling, rule-bound bureaucracies and encouraged to develop innovative and at times unorthodox responses to the demanding challenges they face. As expressed in the *World Health Report 2000* (WHO 2000, 64), “a key challenge in health service delivery is to balance the need for broad policy oversight with sufficient flexibility so that managers and providers can innovate and adapt policies to local needs and contexts in a dynamic way.”

The creation of dynamic health teams at the primary level is one of the greatest requirements for scaling up effective primary care. The role of community health workers in such teams remains unresolved and bears further investigation. At the same time, one of the most challenging constraints is to overcome the loss of motivation and sense of resignation of the great body of primary care workers who work in understaffed settings; who lack consistent, quality support; and who have grown accustomed to a norm of inadequate service delivery (Narasimhan and others 2004). As Hongoro and Normand assert in chapter 71, the extent to which countries can improve access to good quality primary care will depend in large part on a “better matches of skills to needs . . . and clearer understanding of how improved structures and incentives will work.”

Harnessing Private Sector Resources

Private sector health care provision is widespread and growing. It extends from local supply of drugs and equipment to fee-

Box 64.2

Important Skills and Competencies at the Primary Care Level

The primary care level warrants the following important skills and competencies:

- Ongoing monitoring of use of services with particular reference to patient access and community coverage, and program adjustment as indicated
- Continuous linking of general primary care services with community outreach efforts in order to enhance program effects in the defined catchment community
- Appropriate clinical skills for midlevel workers, especially in the absence of doctors, and practiced judgment regarding timely referral to a hospital
- Responsiveness to community needs—whether or not directly expressed—and heightened sensitivity to cultural norms and local systems of leadership and authority
- Facilitatory and responsive managerial styles by district team leadership that support and encourage frontline health workers.

for-service and insurance-based medical care to the many forms of traditional practice. Although general primary care in most African, Asian, and Latin American settings is a major feature of publicly financed services that are provided by the public sector, private providers clearly play a significant role in many low- and middle-income countries with respect to the provision of primary care services (Berman and Rose 1996; Palmer and others 2003). Governments have thus viewed private sector providers as contributing additional human and related resources that can be deployed in the service of at least a portion of the population (usually those with means, including employees with access to reasonable health insurance coverage). By alleviating the workloads faced by public providers, private sector providers have allowed the public services to focus more directly on poorer communities and patients without means. Out-of-pocket payments, health insurance, and donations (as opposed to government contracts) that fund private sector services thus result in additional financing for the health sector.

Patients often prefer the private sector for a number of reasons. These reasons include geographic accessibility, convenient opening hours, and more favorable staff attitudes, as well as perceived better quality in terms of shorter waiting times, greater privacy, higher standards of diagnosis, better (perceived) treatment, and counseling (Doherty and Govender 2004). Although private providers are generally thought of in relation to curative care, interest is growing in the role they could play in meeting public health objectives, especially with respect to the scaling up of primary care services (Palmer and others 2003).

It is important that the potential contribution of private sector resources be optimized through appropriate use of public-

private partnership mechanisms, public sector contracts, and government regulation. These mechanisms are generally easier for not-for-profit providers to contemplate, because they have often been instrumental in bringing primary care to poor communities. Some nongovernmental organizations (NGOs) are able to offer services that can fill notable gaps, home-based care to HIV and AIDS sufferers being but one example.

The potential of for-profit providers to contribute to the care of the poor is less obvious, especially given the incentives to overservice that are inherent in the fee-for-service reimbursement system. Mills and others (2002) find that consumers of private sector primary care are often unable to assess the technical quality of services, tending to place more weight on aspects of perceived quality, such as interpersonal skills of providers and the comfort of the environment in which treatment occurs, than on technical competence. Mills and others (2002,) argue that the effectiveness of private services is by and large rather low: “poor treatment practices have been reported for diseases such as tuberculosis and sexually transmitted infections, with implications not only for the individuals treated but also for disease transmission and the development of drug resistance.”

Palmer and others (2003, 292) have reviewed a “new model of private primary care provision” that has emerged in South Africa. This innovation involves commercial companies providing “standardized primary care services at relatively low cost” that are targeted at the low-income employed rather than the very poor (Palmer and others 2003,). Regarding the growing popularity of these private clinics, the authors find that they maintain excellent standards with respect to the quality of services. The clinics also run at a cost per visit that is comparable with public sector primary care clinics, demonstrating that the

acceptability of services to users and low-cost service delivery are not incompatible objectives.

Palmer and others (2003, 295) suggest that the increasing popularity of these (affordable) private clinics may provide an opportunity to encourage employed but low-income workers (who historically have used public sector health services at little or no charge) to make use of these clinic networks, which would enable the public sector to better tend to its “role as regulator and providing services to the poorest.” Potentially, this redirection of care could remove some of the burden on the public sector, and the task of regulation might be made easier by the strong hierarchical control exercised within these clinic chains. To some extent, this shift has been the experience in Sri Lanka, where government services have been designed with the explicit assumption that certain forms of care will be provided through the private sector (Rannan-Eliya 2001).

However, Palmer and others (2003) point out that the model has potential drawbacks. The comprehensiveness and continuity of services provided by these private clinics fall short of that available in the public sector. Furthermore, how the behavior of private clinics would change under a system of contractual arrangements with the public sector is not clear. Whereas contracting with the not-for-profit sector tends to accommodate government objectives fairly easily (Gilson and others 1997), the experience of contracting with the for-profit sector has had mixed results. These and other concerns imply that, although the for-profit sector is an important resource, arrangements for the delivery of care through this sector should be developed with caution. It also bears mention that, where public sector systems are weak, private sector services gain ground to the extent of unbalancing the public-private mix, with potentially serious consequences for costs and continuity in patient care and for coverage and equity more generally.

Setting Population Health and Clinical Care Priorities

Along with securing additional resources for primary care delivery, country capacity to generate the information necessary for setting and reviewing public health and clinical care priorities must be strengthened as a fundamental measure (Commission on Health Research for Development 1990). This principle lies at the heart of influential pilot work—at times referred to as *community-oriented primary care*—that emerged in the first half of the 20th century and now underpins the Tanzanian Essential Health Interventions Program (TEHIP), 1997–2004. TEHIP, through a research and development arm tasked with devising practical tools for decentralized health planning, has tested “how and to what extent evidence can guide planning of the health sector at district level . . . [in order to] improve technical and allocative efficiency with regard to local choices for resource allocation and services offered” (de Savigny and others 2002).² A dynamic process of using high-

quality local information, coupled with local problem solving, planning, and ownership, was central to appropriate decision making and consequent implementation.

Because local data on intervention costs and coverage are generally not available to district planners and managers, local cost-effectiveness analysis is difficult to incorporate into decentralized priority setting. With TEHIP, priority setting was driven more by the shares of the burden of disease that known cost-effective interventions could address. New analytic tools were devised that would help focus resource allocations on the major “intervention-addressable” disease burdens; targeted sets of cost-effective interventions were then applied—in place of embarking on a disease-by-disease or detailed cost-effectiveness approach (D. de Savigny, personal communication). Available understanding on cost-effectiveness was used to eliminate interventions known to be grossly cost-ineffective; it was not used to prioritize or rank interventions generally considered to be highly cost-effective.

TEHIP indicates that gross technical and allocative efficiencies are relatively easy to address when incremental funding is available. As described by de Savigny and others (2002), the net effect of decentralized funding, together with a mutually reinforcing series of planning, management, and capacity-development inputs, was a proportional and absolute increase in resources for more efficient delivery of prioritized, cost-effective interventions addressing the largest shares of the preventable local burden of disease; an increase in the use of government health services; and a decrease in mortality in infants, children under five, adolescents, and adults. This effect was achieved with relatively limited resources.

TEHIP and related experience make clear that delivery of effective primary care requires a greatly stepped-up capacity to provide an evidence base that is founded on current and evolving local disease and risk factor burdens, the performance of local health services, client use of public as well as private and traditional services, and (where appropriate) the costs of providing care. Effective use of such information can profoundly enhance the ability of the health system to deliver on its core service functions, target high-risk and vulnerable groups, assess coverage in service provision, and gauge health effects. Moreover, such information is vital to establishing the dimensions of the local disease burden that should be managed at the primary care level (Kahn and others 1999). As cogently stated by the Bellagio Study Group on Child Survival (2003, 324), “the capacity of countries to obtain and use information to support child-health programmes will be a determining factor in reducing child mortality.”

Developing a District Health System

Drawing from theory and experience in other branches of the public sector (Mills and others 1990)—and often as part of

wider public sector developments—the health sector introduced decentralization widely in low- and middle-income countries throughout the 1980s and 1990s (WHO 2000). Positive justification for this method of delivering health care and primary care in particular lay, first, in its intended benefits—for patients and communities—through the provision of context-appropriate services of steadily improving quality. This service delivery was rightly seen as also conferring substantial financial benefit on households. Second, decentralization was expected to lead to the strengthening of local responsibility and accountability, with growing authority of district management teams over local cost centers. Third, it was presumed that the more central management levels would invest in enhanced support systems, including management support, further training, financial management and administration, laboratory services, and drug supply systems (World Bank 1994).

In developing settings, few health systems did not decentralize in some form or another over this period, and most based services development on a so-called district (or subdistrict) health system model. Considerable effort was devoted to achieving a balance between primary care service delivery and referral to the first-level (or district) hospital. Incentives as well as penalties were invoked to encourage first use of primary care facilities.

Notwithstanding the theoretical appeal of health system decentralization, numerous difficulties in implementation were encountered, with the consequence that the performance of decentralized, primary care-oriented systems and national-level support to these systems have fallen way below expectations (Bellagio Study Group on Child Survival 2003). Although various factors can account for this outcome—and although these factors will differ according to local and regional circumstances—common difficulties include inadequate or insufficient primary care skills and competencies, which result in poor-quality care; breakdown in referral systems for emergencies and more complex cases (McCord and Chowdhury 2003; Snow and others 1994); delegation of responsibilities without the concomitant delegation of authority, especially in relation to budgeting; authoritarian or strictly hierarchical managerial styles that are not conducive to local health services support and development; and weak or absent measures to develop workable cost-management systems appropriate to different service levels.

These problems in achieving successful delivery need to be addressed if decentralization is to achieve its intended benefits. Again, greater appreciation of the role of decentralized systems in the broader health care architecture, the support needed to ensure their effectiveness, and the time required to build the necessary capability are all necessary. As Bryce and others (2003, 160) put it, “although research on interventions is plentiful, little is known about the characteristics of delivery strategies capable of achieving and maintaining high coverage for

specific interventions in various epidemiological, health system, and cultural contexts.” From this perspective, a too-narrow preoccupation with the cost-effectiveness of interventions cannot but have shortcomings: “whatever package of services is delivered, the resulting effectiveness and equity will almost certainly depend on how the services are delivered, [in other words] the strategy for organizing the care” (B. Starfield, personal communication,).

Primary care is delivered through a system of facilities, equipment, and personnel; tackling inefficiencies in the system may have major positive benefits for quality of care, program coverage, and cost-effectiveness. In many settings a real opportunity exists to increase the efficiency of general primary care teams by giving attention to working conditions, ensuring functional equipment, and maintaining a stable drug supply. Meaningful step-ups in care, workable referral and communication systems, gatekeeper functions where indicated, and effectively aligned management and support are all needed. Achieving such efficiencies should result in many more patients being assessed and managed properly. Significant cost savings may accrue to the health service (through patients being managed at the primary care level rather than the first or specialist referral level) and to patients, families, and households (through care being delivered more rapidly and nearer to home).

Demanding Services: Relationships with Local Communities

Among poor and vulnerable communities, the need for care is demonstrably high, and the effectiveness of primary care services is likely to substantially influence demand on the public sector. In relation to infectious as well as noncommunicable disease, outreach services have a major role to play in promoting positive health and health-seeking behaviors and in supporting community-level preventive and promotive efforts. More generally, renewed efforts to enhance community relationships with primary care workers and the health system as a whole—and to ensure that community voices actively and appropriately bear on local service development and decision making—can help bring clients and communities into constructive public health care partnerships.

A RESEARCH AND DEVELOPMENT AGENDA FOR GENERAL PRIMARY CARE

Throughout this chapter, we have emphasized the challenges and constraints to the effective delivery of general primary care services. In this section, we single out a few areas that warrant concerted research and development in the effort to establish a high-functioning primary care platform to support the implementation of cost-effective interventions.

Evolving Health Transitions

A critical consequence of fast-changing economic and social conditions is the rapid transition in health profiles in essentially all low- and middle-income settings. This shift has already led or is leading to the coexistence of persisting infectious disease; nutrition and reproductive health problems; emerging noncommunicable disease and related risk factors (such as hypertension, obesity, diabetes, stroke, and cardiovascular disease); and a growing burden from accidents and intentional injury. The challenge this transition poses to primary care systems is considerable. For the most part, these systems are oriented to maternal and child health and the management of acute illness. An accelerating health transition will require extending the reach and capacity of widely established primary acute care systems (oriented to episodic care) to accommodate the need for effective systems of chronic and long-term care (including continuing, medium- to longer-term, patient or client management and monitoring).

Introduction of Antiretroviral Therapy for HIV and AIDS

Many countries, particularly those in southern Africa and East Africa, are moving to the rapid introduction and scale-up of antiretroviral therapies for HIV and AIDS. Substantial and rapidly increasing financial investments are envisaged (indeed are under way); a necessary accompaniment to such scale-up should be improved drug supplies, strengthened laboratory services, clinical training of primary care staff, and reassertion of the importance of health service relationships with local communities. Such measures—which can succeed only with sustained public sector commitment—have the potential to invigorate and motivate all facets of primary care delivery but, equally, could undermine existing services. The challenge is how to realize the positive potential of antiretroviral therapies in meeting the needs of HIV and AIDS sufferers and their communities, while ensuring a major contribution to strengthening primary care provision more generally. In other words, the challenge is to strengthen a particular service (HIV and AIDS treatment and care) and primary care services simultaneously—through building more effective health teams, improving drug supplies, strengthening service monitoring and evaluation, enhancing supervision and support systems, extending service coverage, and so forth. Such systemwide strengthening can be expected to greatly improve the technical efficiency of key elements of the general primary care system.

Effective Support and Networking for Community and Home-Based Care

Along with the reorientation of primary care systems to support chronic and long-term care are needs for “home-based”

care—taking place in rural households, urban residences, or newer community-based facilities such as hospices. Although home-based care of people living with AIDS is most prominent, care and support for clients post-stroke or with other forms of physical or mental disability are as important. Primary care outreach services, working with community health initiatives, NGOs, and communities, are well placed to contribute expertise, training, and resources toward supporting such efforts, which are growing rapidly in importance.

Research to Strengthen General Primary Care in the Public Sector

An abiding need exists for experimental and quasi-experimental evaluation of innovation in general primary care services (whether delivered comprehensively or as clusters of interventions), providing greater insight into the enabling and constraining factors (which may be systemwide) and a more robust understanding of the effects, costs, and cost-effectiveness of modifications to these services in different settings. To maximize the likelihood of success in efforts to scale up effective interventions or system innovations, such initiatives should be carefully designed, implemented, and assessed in partnership with senior health ministry officers (Berwick 2004). Such evaluations are required to assess new forms of organizing primary care services (in particular, balancing persisting acute needs with the growing need for chronic and long-term care, or establishing the skills mix that is most effective in particular settings); similarly, they are necessary when assessing delivery of interventions—such as the cost-effectiveness of multi-disease intervention clusters in different epidemiological and social contexts, or the extent of uptake by vulnerable groups (such as children or the elderly) or marginal populations. Operational research efforts are needed in a range of spheres: to evaluate factors that facilitate or hinder effective performance by service providers or to develop easily managed monitoring systems to assist, for example, in assessments of intervention coverage.

CONCLUSIONS

Clearly, a great many of the most cost-effective interventions detailed in this volume depend on a high-functioning primary care system for their effective implementation. This system comprises the elements of the primary level of care (including facilities, equipment, drugs, personnel, and associated management support); their combination to form a competent delivery capability; and the services that are thereby delivered. Because cost-effectiveness estimates are based on the presumed effective delivery of primary care services, it can be argued that

implicit in the estimates have been overly optimistic assumptions regarding key constituents (staff, drugs, equipment, monitoring and evaluation, and so forth) of the primary care level and their functioning. Great efforts to render such systems as effective as possible, subject to the constraints of particular environments, are therefore justified.

More generally, decisions on the best and most appropriate sites for delivery of interventions are not always straightforward, will benefit from expert discussion, and will often be context specific. Moreover, many interventions can be delivered from multiple sites—although a hierarchy of preference will usually exist, influenced by issues such as cost-effectiveness, ease of service provision, need for monitoring, access, and coverage. Careful review of the extensive range of interventions presented in part 2 of this volume and their likely site of delivery reveals the following:

- The interfaces between (a) community and primary care levels and (b) primary care and district levels are critical sites that profoundly affect the effectiveness of service delivery.
- No substitute exists for a well-functioning district health system comprising community, primary care, and first-

referral (district) hospital levels. This organizational and service unit is fundamental to effective health care provision, and failure to recognize the interrelationship between component levels has had high health costs and resulted in great inefficiency.

The health and development cost of weak or inadequate primary care systems to high-risk or vulnerable groups—and to communities more generally—is demonstrably high. However, effective general primary care that responds to the rapid health transitions under way in all socioeconomic contexts offers the potential for major health and, hence, development gains that provide good value for money and enhance equity. Critical make-or-break points include upscaled financial investments paralleled by major and sustained investment in human resources (principally the strengthening of local staff capacity, the building up of key skill sets—including supportive management—and the encouragement of innovation in services development); far greater attention to improving delivery and service quality, monitoring service coverage, improving access by vulnerable groups and taking account of equity considerations in general; and establishment of a trusting and constructive partnership with local communities.

Annex 64.A Comparison of Proposed Basic Packages of Interventions

Intervention	Alma Ata Declaration (WHO and UNICEF 1978)	Investing in Health (World Bank 1993)	Better Health in Africa (World Bank 1994)	World Health Report 2000 (WHO 2000)	Commission on Macroeconomics and Health Working Group 5 (Jha and Mills 2002)	World Health Report 2002 (WHO 2002) ^a

Annex 64.A Continued

Intervention	Alma Ata Declaration (WHO and UNICEF 1978)	Investing in Health (World Bank 1993)	Better Health in Africa (World Bank 1994)	World Health Report 2000 (WHO 2000)	Commission on Macroeconomics and Health Working Group 5 (Jha and Mills 2002)	World Health Report 2002 (WHO 2002)^a
Tuberculosis treatment	b	+	+	+	+	
Directly observed treatment short course (DOTS) for smear-positive patients				+	+	
DOTS for smear-negative patients					+	
HIV/AIDS prevention		+ (more limited than later packages?)		+	+	+
Youth-focused interventions					+	
Interventions working with sex workers and clients				+	+	
Condom social marketing and distribution					+	
Workplace interventions					+	
Strengthening of blood transfusions systems				+	+	
Voluntary counseling and testing				+	+	
Prevention of mother-to-child transmission					+	
Mass media campaigns				+	+	
Treatment for sexually transmitted infections		+	+	+	+	
HIV/AIDS care					+	
Palliative care		+ (see under limited care)			+	
Clinical management of opportunistic illnesses			+		+	
Prevention of opportunistic illnesses					+	
Home-based care					+	
HIV/AIDS HAART provision						+
Tobacco control program (taxes, legal action, information, nicotine replacement)		+		+	+	
Alcohol control program		+				
Other public health interventions (includes information, education, and communication on selected risk factors and health behaviors, plus vector control and disease surveillance)	+	+	+ (information, education, and communication)			
Limited care (includes treatment of infection and minor trauma; for more complicated conditions includes diagnosis, advice, and pain relief, and treatment as resources permit)	+	+	+			
Noncommunicable diseases and injuries (selected early screening and prevention)				+		+
Populationwide interventions to reduce the risks of cardiovascular disease (salt- and cholesterol-lowering strategies)						+
Water and sanitation	+		+			+ (disinfection at point of use)

Sources: Jha and Mills 2002; WHO 2000, 2002; WHO and UNICEF 1978; World Bank 1993, 1994.

HAART = highly active antiretroviral therapy for the treatment of HIV/AIDS; IMCI = integrated management of infant and childhood illness.

Note: A "+" that appears in a shaded cell but not in the white cells beneath this area means that no details of the exact interventions were provided in the report.

a. Addressed only interventions against risk factors.

b. These and other disease prevention and control initiatives fell under a general item termed *prevention and control of locally endemic diseases* (HIV/AIDS was not an issue at the time).

ACKNOWLEDGMENTS

This chapter draws considerably on the background paper by Doherty and Govender (2004) titled “The Cost-Effectiveness of Primary Care Services in Developing Countries: A Review of the International Literature,” commissioned by the Disease Control Priorities Project. It draws on productive discussions during the workshop “Integrating Interventions and Health Systems” held in July 2004 in Johannesburg; the workshop was supported by the project and convened by the School of Public Health, University of the Witwatersrand, South Africa, and the Health Policy Unit, London School of Hygiene and Tropical Medicine, United Kingdom. The authors acknowledge with pleasure the critique, insights, and support provided by the editors and chapter reviewers.

NOTES

1. Bobadilla and others (1994) comment that separating interventions according to age group is artificial because benefits may accrue in later life, as in the case of hepatitis vaccine, and may improve well-being, such as cognitive abilities. Adult interventions, such as HIV prevention and prenatal care, also benefit children.

2. TEHIP has functioned in a “high mortality” setting. Relevant evidence is related to mortality levels and trends, including cause-specific mortality, as well as to district-level financial allocations and changes over time.

Chapter 65

The District Hospital

Mike English, Claudio F. Lanata, Isaac Ngugi, and Peter C. Smith

Health care comprises a continuum from home-based, self-administered treatment to highly specialized intervention dependent on professionals with many years of training and a heavy capital investment. In principle, the role of the health system planner is to balance the many separate components of the system to optimize the magnitude and distribution of health benefits, subject to a variety of constraints such as budgetary levels, geography, and human resources capacity. While recognizing that other paradigms are possible and valid, we generally adopt this optimization perspective in our discussions because it combines broad social (including user) and political dimensions with systematic economic principles when decisions are made in a competitive, resource-constrained environment. Following such logic, it should be possible to define the place, purpose, and size of the district hospital sector within a balanced system of care for any particular setting.

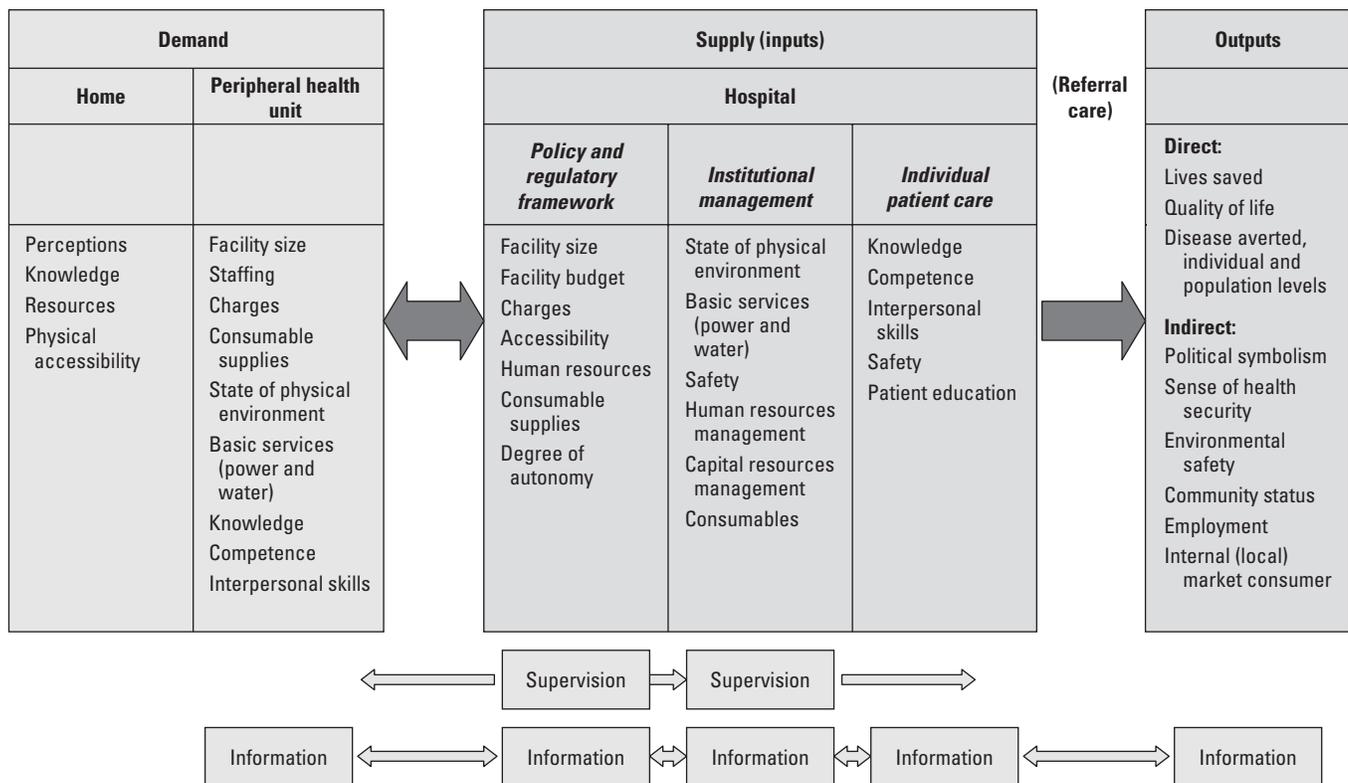

Although this view is theoretically appealing, the world of real health systems that have evolved under different historical and political pressures is somewhat different. This perspective does, nevertheless, suggest some common principles involved in defining the optimum balance of care even within groupings as diverse as “developing countries.” Two further points are worth considering:

- First, although the focus of this chapter is the district hospital, crucial links exist with many other aspects of the health system. Choices made in relation to hospitals are likely to affect the whole health system and vice versa. For example, programs to improve peripheral clinic referrals of women with high-risk pregnancies may result in a paradoxical decline in the quality of care if critical human and other resources are inadequate at the hospital level. Thus, the

picture of public district hospitals as underused, inefficient, and providing poor quality care (Barnum and Kutzin 1993) may reflect deficiencies in the entire health system as well as at the hospital level.

- Second, optimizing the health system configuration is an active, continuing process that must often proceed incrementally, ideally tackling problems in order of priority. An optimal balance is not likely to be achieved naturally through neglect or reliance on market mechanisms.

Hospitals are major consumers of health budgets. However, there is a paucity of good evidence—even in industrial countries—on their effect (McKee and Healy 2002), whereas the body of theory and opinion on their role is wide. This chapter can serve as only an introduction to topics that include, among others, the political and social value of hospitals and their essential role in integrated health systems (Sachs 2001; Van Leberghe, de Bethune, and de Brouwere 1997; WHO 1999; World Bank 1993). The chapter first introduces basic concepts relevant to district hospitals that may affect their role and performance and a description of possible core services (see figure 65.1). For discussions of the evidence justifying inclusion of an intervention or process as a core service at this level of care, the reader is referred to disease- and service-specific chapters. Although recently attempts have been made to refine definitions of *performance* (WHO 2000b), the term is used in a general sense, referring to processes and outcomes that contribute to improved levels and distribution of health. The chapter then summarizes currently available economic data on hospital care, focusing where possible on the district level and acknowledging the difficulty in generalizing findings from one setting to another. An illustration follows of some of

Source: Authors.

Note: Some of the factors that may influence a hospital's performance and its products or outputs, the value of which depends on one's perspective, are illustrated. The intrinsic roles of supervision and information flow are emphasized.

Figure 65.1 Conceptual Framework for Delivery of Health Services at the District Hospital

the factors that threaten district hospitals' performance, indicating the broad range of influences to which they are subject. Finally, possible strategies for improving performance are proposed, focusing on cross-cutting interventions, and highlight areas where current knowledge is inadequate and research is urgently needed.

DEFINITIONS, BASIC CONCEPTS, AND FRAMEWORK

The evolution of a hierarchical system of health care is readily explained if one assumes the perspective of the provider, although less obvious if one's perspective is that of the community using the hospital or a government seeking to create political capital. Concentrating skills and resources in one place for conditions that are often relatively uncommon or that cannot easily be treated closer to the home environment is intuitively attractive. Such concentration also offers the prospect of continued accumulation of experience and, thus, skill and potentially benefits from system resources that may serve a variety of needs.

What Is a District Hospital?

Health systems are often organized in a "hub-and-spoke" arrangement, with a large district hospital (the hub) having more and better-trained personnel and better equipment than more peripheral clinics (the spokes). Although variations frequently occur in practice (for example, a large district may have several relatively similar hospitals), this simple model of service provision is assumed throughout this chapter, with the district hospital supplying first referral-level care for both outpatients and inpatients. District hospitals also, in theory, may serve a gatekeeping role for those patients with less common problems, for whom skills and resources are most effectively concentrated at even higher levels of care provided at a regional or national level. Thus, from the perspective of provider efficiency, economies of scale and economies of scope are important basic concepts in considering district and referral hospital functions.

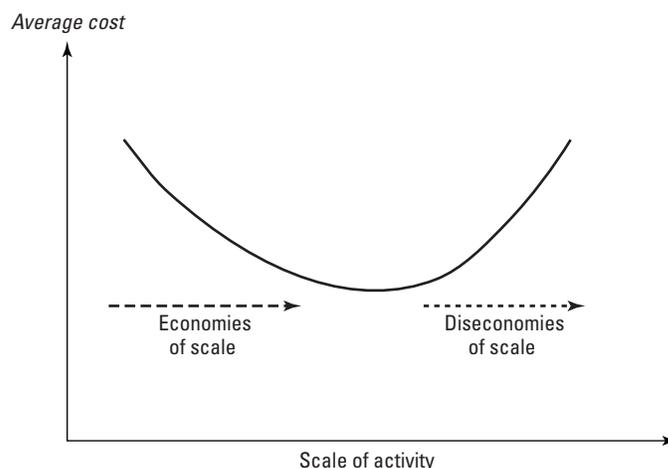

Such hierarchical health systems frequently overlap with wider political and administrative hierarchies that are based on geographically defined units. The district is, therefore, used in this chapter as a generic term for an administrative unit often comprising a population of 100,000 to 1 million people for whom one tier of local government is typically responsible. The

shared administrative boundaries and frequent proximity of district hospitals to district political administrations often result in the district hospital's involvement in the much wider tasks of district health management and public health. The performance of these functions may be critical to the success of the health system as a whole, but this role is easily forgotten.

Efficiency. Allocative efficiency deals with the desire to allocate resources to secure the maximum health benefit from the inputs available (Hensher 2001). Within this paradigm planners search for the balance between community care, primary care, and facility-based care that results in the greatest health benefit at the least cost. At the level of an individual hospital, the issue of allocative efficiency arises when decisions must be made to allocate resources to different services. In theory, cost-effectiveness studies with a global health status outcome measure such as the disability-adjusted life year (DALY) should inform debate on allocative efficiency, because such studies provide a direct means of comparing alternative strategies.

Technical efficiency deals with the extent to which specific institutions are getting the most out of the resources available. For example, is a district hospital deploying its given resources in the most effective manner to achieve the desired output? Technical efficiency is often measured using partial indicators such as cost per procedure. Interpreting such data often requires great care, but most fundamentally it requires some comparator, because a way of knowing the resources needed to produce the desired output rarely exists. Thus, *technical efficiency* is usually a relative term, and performance indicators—carefully interpreted—can be used to identify best current practice. New technology or a change in the availability or price of resources may result in continual improvements in what is achievable, so a process that was technically efficient can become relatively inefficient over time. Data on technical efficiency often provide the basis for benchmarking hospital service providers and may identify poorly performing services for targeted improvement strategies.

Economies of Scale and Scope and Hospital Size. A central policy question is whether it is more efficient to concentrate resources in a small number of large centers, where the planned number of procedures can be high, or to have a greater number of smaller centers. The issue of economies of scale determines the most efficient size hospital. Where the average costs of care can be shown to depend on hospital (or unit) size, economies of scale exist (see figure 65.2). Recent evidence suggests that, at least for industrial countries, large centers may eventually suffer from diseconomies of scale, when the inefficiencies introduced in administering a very large facility begin to outweigh any advantages (Posnett 2002). The potential for diseconomies of scale in developing countries, where the mixture of cases, the costs of inputs (particularly the relative costs

Source: Adapted from Posnett (2002).

Figure 65.2 Theoretical Long-Term Average Cost Curve

of staff salaries and technology), and the pattern of diseases vary widely, has not been examined.

In discussing economies of scale, we must consider two further issues. First, considerable evidence suggests that the ability to specialize and the experience gained with high volumes of patients can lead to better outcomes for physicians practicing in larger hospitals. Second, although reducing the number (and increasing the size) of hospitals may reduce health system costs and improve outcomes, it may shift some costs to patients in the form of increased travel time or even a reduction in the ability to reach the hospital and secure care. Thus, excessive concentration of hospital services may compromise health and equity objectives, particularly in rural areas. The planner may need to balance direct health system costs against the broader population costs of securing access. In many circumstances, this effort may give rise to an intermediate solution, such as medium-sized hospitals, smaller local hospitals equipped to deal with common procedures, or dispersed clinics staffed by peripatetic specialist teams.

The hospital also offers the potential for improving efficiency if different services use some of the same inputs. Although the hospital might not be able to justify paying the salary of a laboratory technician to perform hemoglobin measures and blood cross-matching only for the maternity unit, the fact that such a person also contributes to the work of the surgical, medical, and pediatric services makes that technician's presence more cost-effective. This laboratory service, therefore, offers an economy of scope. The concentration of inputs, both human and technological, evident at the district hospital offers major opportunities for unit-cost reductions and, therefore, economies of scope. Considering the mix of services provided as hospitals are planned or augmented is important to anticipate or account for economies of scope.

Equity. Equity is a fundamental principle guiding most public health systems. It can embrace concepts such as equality of provision or equality of access (for equal need), equality of benefit from health services, or equality of outcome. Although often not defined explicitly, many pro-poor policies, such as the Poverty Reduction Strategy Papers that encompass health, are based on some principle of equity. Loosely speaking, such policies aim to reduce disparities in access or overall health status observed between different sections of a population, most obviously the differences between rich and poor sections of a community.

For health planners, however, equity principles pose some hard challenges. For example, if an urban district has a public hospital with adequate staff and resources providing a range of acute services reasonably efficiently, should not every district hospital provide the same range of services? In practice, ensuring that a hospital in a poor, inaccessible rural district with a highly dispersed, smaller population provides a similar level and breadth of service may be difficult and considerably more expensive. The result can be a hospital with apparently high unit costs of treatment that, because of late presentation or resource constraints, secures poorer outcomes. The central policy question is: To what extent is society prepared to see resources deployed to address such equity concerns at the expense of pure efficiency?

Issues of efficiency, economies of scale and scope, and equity have contributed in part to the development of strategies defining an essential package of services that should be provided for an entire population (Bobadilla and others 1994). These packages are often targeted at the most important causes of mortality and morbidity, so the inefficiencies in providing an equitable service may be reduced. Nevertheless, the unit costs of reaching disadvantaged populations are often likely to be higher than average unit costs, and planners need to recognize this fact when designing packages and set budgets accordingly.

What Essential Services Should a District Hospital Provide?

The World Health Organization (WHO 1992) envisages that a district hospital should be able to offer diagnostic, treatment, care, counseling, and rehabilitation services provided by predominantly generalist practitioners spanning the following disciplines:

- family medicine and primary health care
- medicine
- obstetrics
- mental health
- eye care
- rehabilitation
- surgery (including trauma and orthopedics)
- pediatrics
- geriatrics.

Such hospitals will usually provide 24-hour care and be integrated into the district health system at a wider level to provide or support a range of services:

- districtwide health information
- implementation of peripheral primary health care policies
- administrative and logistics support to primary health care efforts
- communication with the community
- curative and chronic care for patients referred from peripheral units
- district laboratory services
- training and continuing medical education of health workers and students
- links between health and other development agendas
- development of local solutions to local health problems.

This menu of recommended services at the district hospital level does not represent a rigorous attempt to optimize the health system configuration to maximize its cost-effectiveness. Indeed, the logic of the earlier discussion is that the precise mix of services provided should be informed by overall health system design. Rather, the list represents what is perceived to be a fair minimum level of health provision for all, based on accumulated knowledge and experience of the common demands for hospital care (the visible burden), the availability and simplicity of interventions, the perceived effectiveness of interventions, and their acceptability in an environment constrained by limited information and limited availability of human and financial resources (Van Leberghe, de Bethune, and de Brouwere 1997).

An obvious logic supports the inclusion of many of these core functions, sometimes supported by evidence of their value. WHO's Commission on Macroeconomics and Health has attempted to define the services that small hospitals should offer as part of the close-to-client package on the basis of burden and likely cost-effectiveness (Sachs 2001). However, although useful for suggesting service priorities, the report considers primarily infectious diseases and maternal health. In addition, it is not clear whether recommended services were included on the basis of data on condition-specific burden and intervention cost-effectiveness or of the potential effect of the combined package of services considering potential economies of scale and scope. Future studies should perhaps address more clearly the issues of the incremental cost-effectiveness of new or additional interventions at the district hospital level when exploring the appropriateness of services.

Clinical Services

The initial drive to implement primary health care (PHC) left district hospitals sidelined. They were often grouped with

expensive tertiary units; were labeled high cost, inequitable, and relatively ineffective; and were rarely protected by powerful professional groups based in the tertiary centers. Their position as an integral part of PHC was reestablished during the 1980s (Canadian International Development Agency and the Aga Khan Foundation 1981; WHO 1987). Currently the district hospital is envisaged as the apex of the pyramid of primary health care, most obviously in such programs as Safe Motherhood and Integrated Management of Childhood Illness. In programs such as Integrated Management of Childhood Illness, the expected role of district hospital-level care is explicit (WHO 2000a), with priority conditions reflecting burden-of-disease estimates (Black, Morris, and Bryce 2003). Although the effectiveness of this approach has yet to be established, evidence at the hospital level suggests that delivering a basic package of care may, in principle, cover the majority of admitted cases and improve service delivery (Ngoc Anh and Tram 1995). However, without tackling current difficulties at the hospital level, effectiveness cannot be assumed (see “Information and Integration” later in this chapter).

Other basic approaches to delivery of services at the district hospital level, such as triage of new outpatient attendees and a basic package of neonatal care, also show promise (Duke, Willie, and Mgone 2000; Robertson and Molyneux 2001). Interventions such as the provision of basic trauma care can effectively be offered only at this level of the health system (see chapter 68), while in other areas (for example, chapters 26, 31, and 67) hospital inpatient care should be considered together with alternative means of delivering services if cost-effectiveness is to be maximized. These examples all serve to emphasize that close-to-client health services must be tightly integrated with district hospital-level care and demonstrate strong dependency on the referral system. Thus, cases too complex or serious to be managed in the periphery are sent for care where skills and resources are more highly concentrated, in the expectation that health outcomes will be better. This attractively simple idea presupposes that the district hospital is able to provide the care desired; although some evidence supports the likely effectiveness of this approach (Van Leberghe and Pangu 1988), clearly numerous potential obstacles exist along this pathway (discussed in the later section “Factors Influencing District Hospitals’ Performance”).

Additionally, although the focus has often been on district hospitals as recipients of referrals, a much more dynamic relationship has been proposed (WHO 1987): for many PHC activities such as immunization programs the district hospital is both a provider of services and a coordinating center for information and supplies. To permit early discharge, enhance treatment compliance, and make home-based care possible—all of which may improve cost-effectiveness—hospitals need to play an active role in providing outreach services, supervision, and support.

Cross-Cutting Services at the District Hospital

Some medical services provide support to a range of departments or users and are referred to as cross-cutting services. Such services include those aimed at recuperation and rehabilitation (physiotherapy, occupational therapy, and so forth; see chapter XX; laboratory services, and diagnostic imaging. Whether and to what degree these services are provided may be major determinants of the overall range of services that can be offered, the fixed costs of providing care at district hospitals, and their cost-effectiveness. Their provision should, therefore, be planned as part of the portfolio of care to be offered, taking into account expected use and estimates of the value added. This strategy suggests a degree of flexibility that may conflict with historical perspectives about what is important and “one size fits all” national policies. Health information systems are also a critical cross-cutting service; they are discussed in the “Health Information Systems” section of this chapter.

It is worth noting here that the concentration in hospitals of cross-cutting resources used by different activities often gives rise to many accounting complications, such as allocating overhead costs, which bedevil attempts to secure meaningful cost comparisons across hospitals.

Wider Role in the District Health System

District hospitals often house the technical expertise and professional authority essential for local implementation of national policy, making them potentially key players in managing, monitoring, and supervising district health plans. They should also act as advocates for plans that address local health needs. This section examines this wider role of the district hospital, the value of which is often hard to quantify, but which may be critical to the effectiveness of the local health system as a whole.

Integration with Other Local Health-Related Services. A district hospital should, in most cases, be an integral part of a wider district health system. Although not specifically discussed here, part of the broader remit is often to link up with other governmental and nongovernmental actors in health and health-related programs, which may include water and sanitation, education, and social services. (A more specific discussion can be found in WHO 1990.) Those important coordination functions are hard to value in traditional examinations of cost and cost-effectiveness but may be critical in sustaining a coordinated health care approach, especially if greater autonomy is devolved to district administrations.

Training. District hospitals often have a direct role in the primary training of health workers, particularly clinical assistants, nurses, and health aides, as well as an ongoing role in providing continuing medical education. Their role in building human resources capacity among those actively participating in health

care delivery and in ensuring that training and experience reflect the real health needs of the community is potentially of great value. Additionally, as the focal point of outreach for many programs that aim to disseminate knowledge through the cascade mechanism, district hospitals are often relied on to transmit knowledge to more peripheral levels of care.

Supervision. Together with their training function, district hospital staff members are often supposed to provide supervision and support to health workers at more peripheral levels of care and to act as part of the regulatory mechanism, sometimes in both the public and the private sectors. Although this function is likely to be an important means of developing and refining the referral system through two-way exchange of information and of seeing that policy decisions are implemented, the ability of the health staff to fulfill this function is often extremely limited. Because resources are scarce, activities with the least tangible benefit—such as supervision and monitoring—are frequently abandoned, breaking important chains of communication.

Health Information Systems. Many national health information systems rely on district hospitals to coordinate data collection in the district. In theory, for a number of diseases the district hospital may be the only source of information, for example, for severe diseases such as neonatal tetanus, acute flaccid paralysis, or operative deliveries. The district hospital is, thus, a core data source supposedly providing burden-of-disease data at greater resolution than is commonly available and at a meaningful administrative level if action is required. However, in many developing countries health information systems are inadequate and inaccurate; staff members are not equipped with the skills necessary to interpret data (Loevinsohn 1993) and are often unaware of their local value, thus depriving the local staff of essential planning and monitoring tools. Introducing an information culture and the necessary skills and infrastructure to support such a transition, although of potentially enormous value, presents significant challenges even for middle-income countries.

Formulating a Package of Services to Maximize Cost-Effectiveness

Interventions identified as being cost-effective in particular service areas or necessary to preserve the integrity of an effective and equitable health system should be a part of a basic package of services and responsibilities at the district hospital level. However, the way in which these individual components are combined and integrated is also critical. Factors, including economies of scale and scope, whether gains or losses in efficiency result from integration, and the influence of use and resource availability, will all have a profound influence on whether the district hospital itself is as cost-effective as the sum of its parts suggests it should be.

ECONOMICS OF DISTRICT HOSPITALS: A SUMMARY OF REPORTED EXPERIENCE

The previous sections outline the suggested functions and extended role of a district hospital. Although some countries have adopted the principle of essential packages of services and defined detailed norms and standards for care at this level as part of long-term health sector strategies, many countries lack any specific hospital strategy (WHO 1994). Even where a well-articulated strategy exists, decades of different political, social, economic, and historical influences on health system development result in great variability of district hospitals, both between and within developing countries. Thus, some district hospitals of 500 beds have a full complement of specialist consultants and access to a wide range of diagnostic and therapeutic services, while other hospitals of as few as 30 beds, but more often 80 to 150 beds, are run almost entirely by medical assistants and nurses, sometimes lack reliable power or water supplies, and often offer few or no high-quality modern diagnostic services. This variability makes it daunting to extrapolate findings from one setting to another and may seriously undermine the value of attempts to provide useful general descriptions of hospitals. In particular, when interpreting calculated costs of care at a national or individual level, we must remember several critical points:

- Relevant data may often be missing or inadequately defined at a country level.
- Because a number of accepted ways of calculating costs exist, particularly at the level of individual interventions, different methods are likely to lead to different estimates. The particular design used to estimate costs should be considered when interpreting any results.
- In particular, a central feature of the hospital is that many of its resources are used for more than one activity, so unit cost estimates depend crucially on how the costs of these resources are allocated among activities.
- The relative prices of inputs can vary substantially between regions and countries.
- In the majority of cases, only the cost of care is reported without reference to outcomes so that the cost per unit of health benefit (however defined) is unknown.
- Calculated costs usually reflect the care offered; it may not be the same as the care that is necessary, of an acceptable quality, or most effective.
- Cost estimates cannot indicate the extent of unmet need or other sources of inequity.
- The costs of care will depend to some extent on the severity of illness of the patients and, for average costs per bed day, on the variety and relative proportions of different illnesses (the *case mix*). These areas are rarely commented on or adjusted for.

Levels of Provision of Hospital Care

Data on the levels of service provision for many developing countries are crude. In the absence of any more meaningful data, the number of beds is most often used as a (poor) substitute. Bearing this weakness in mind, sources estimate the average number of total hospital beds to be 1.3 per 1,000 population in developing countries (World Bank 2002), a figure probably declining in many developing countries (Hensher and others 1999), with varying estimates of the average number of doctors from 0.5 per 1,000 population in low-income countries generally (World Bank 2002) to 0.09 doctors per 1,000 population in Sub-Saharan Africa (Peters and others 2000). These estimates are considerably lower than the averages for beds and doctors of 7.2 per 1,000 and 2.9 per 1,000, respectively, in high-income countries (World Bank 2002). Although these estimates provide some indication of the major disparities in service provision between rich and poor countries, their value is limited. Lack of information on the relative distribution of beds and staff by geographic zone, or between district and higher referral levels of care in a single country, and the fact that bed and staff numbers are probably a poor reflection of activity make these figures a poor substitute for data on patient throughput and outcomes, statistics rarely available for district hospitals. Furthermore, with the concentration on provision of service, the demand for services may often be ignored. It is still true in many countries that most deaths, presumably many preventable, occur at home and that many chronic diseases are inadequately treated. The need for hospital care is largely undetermined, but some have argued that the lack of provision of district hospital care, in Sub-Saharan Africa at least, is a significant impediment to improving overall health status (Van Leberghe, de Bethune, and de Brouwere 1997).

What Do District Hospitals Cost at a National Level?

Although it has been argued for some time that hospitals consume too much of health sector budgets, thereby depriving primary care of adequate resources, it is surprisingly difficult to identify how much hospitals cost in low- and middle-income countries. Even where data exist on health expenditure, such data are often at a highly aggregated national level and the functions that are included (clean water and sanitation, for example) are not always clear (World Bank 2002). Furthermore, whether private or nongovernmental expenditure, capital expenditure, or the value of noncash inputs—such as donations of equipment or volunteers' time—are included is rarely apparent. Add to this ambiguity the nearly impossible problem of separating what is spent at different levels of the health or hospital system—for example, to distinguish between district and referral hospitals—and it should be clear that we currently have only a crude understanding of the costs of district hospitals as a unit of service provision (Mills 1990a).

If just government health expenditure is considered, the available data suggest that hospitals at every level taken together consume 50 to 60 percent of recurrent national health budgets, with the proportion appearing to increase as countries become richer (Barnum and Kutzin 1993). If private expenditure on health care (insurance and out of pocket) is included, the proportion of total health expenditure consumed by all hospitals falls to 30 to 50 percent of the total in developing countries (excluding South America) (Mills 1990a). Whereas these figures reflect total hospital sector expenditure, the limited data available suggest that district hospitals may receive less than 50 percent of this total in many countries, consuming fewer resources than secondary and tertiary referral facilities (Mills 1990a).

The Nongovernmental and Private Sectors

In many countries (especially in Africa) nongovernmental institutions, often religious organizations, are major health service providers, and private physicians are often as numerous as those in the public sector. In Kenya, for instance, the number of private and nongovernmental hospitals is equal to the number of public hospitals (Government of Kenya 2001), while in Indonesia, 32 percent of hospital beds are private (Gani 1996). This potentially important contribution to the hospital sector may also be underrecognized, particularly in urban settings, where multiple, small facilities may operate without registration, resulting in inaccurate local, regional, and national data on levels of overall service provision. Although few data exist on the effectiveness and quality of these hospitals, the belief is widespread that they may be more efficient than public sector hospitals. This belief is not necessarily borne out by the limited data available (Bitran 1996), and concerns exist about the quality of care provided by private as well as public providers (Brugha and Zwi 1998).

District Hospital Efficiency

Data on hospital efficiency in developing countries are scant. Considerable variability has been observed in the technical efficiency with which surgical services were provided in a small number of Indian hospitals, with differences in total salary costs being the main explanatory variable (Purohit and Rai 1992). Also in India, some evidence has been provided that nongovernmental hospitals may be more efficient, on average, than public hospitals, although considerable variability existed within both groups (Bhat, Verma, and Reuben 2001). In Kenya, public hospitals were found to have an average inefficiency level of 30 percent (that is, the same resources could have achieved a 30 percent increase in output) with significant contributing factors including shortage of appropriate professional staff members, poor combinations of inputs (resources), nonfunctioning theaters and laboratories, lack of transportation, irregular distribution of drugs and supplies,

and frequent breakdowns in medical equipment (Owino and Korir 1997). All these data highlight the critical role of human resources, often a hospital's principal recurrent input cost (see the next section). Underinvestment in or absence of staff or inadequate flexibility in reallocating roles between different health worker groups may prevent hospitals from functioning efficiently (Hensher 2001).

What Are the Costs of Providing Care in District Hospitals?

In a detailed review of actual hospital expenditure, Mills (1990b) identified two input categories that together accounted for two-thirds or more of recurrent expenditure in almost all settings. Salaries varied between 20 and 80 percent and medical supplies between 15 and 58 percent of reported hospital expenditure. These and other data also suggest that, in many countries, costs of referral hospital care are often more than double the cost of equivalent care at district hospitals, although without knowledge on case mix or illness severity such data are hard to interpret (Barnum and Kutzin 1993; Mills 1990b). More recent data collected from seven church-supported hospitals in Tanzania also demonstrate considerable variability in the proportion of costs attributable to salaries and supplies even within a single organization in the same country (Flessa 1998). The strong dependence of hospital costs on salaries particularly cautions against generalizations across countries.

In the following analysis, all original U.S. dollar costs have been adjusted to represent the U.S. dollar cost in 2004. The

Tanzanian nongovernmental hospital data indicate that the average cost per inpatient day derived from 1995 reports (including expenditure on maintenance and expatriate salaries) would equate now to approximately US\$3.60 (range US\$2.60 to US\$6.00) in district hospitals (Flessa 1998). However, if care had actually been provided according to the standards defined by the provider (including recommended staffing levels, building maintenance, and equipment), the estimated cost per day would have risen to the equivalent of US\$11.60 (range US\$9.20 to US\$15.90) (Flessa 1998). This cost compares with costs reported in Kenya in 1993–94 (Kirigia, Fox-Rushby, and Mills 1998), adjusted to 2004 prices of actual inpatient costs per day from two district hospitals of US\$8.30 to US\$10.10, and adjusted 1995 data from a district hospital in Bangladesh of US\$15.90 (McCord and Chowdury 2003). In a middle-income country, South Africa, the cost per inpatient day calculated between 1996 and 1998 and adjusted to 2004 prices in five district hospitals ranged from US\$37.80 to US\$96.30 (Daviaud and others 2000). These data do not necessarily reflect the cost of optimal care, and the Tanzanian study demonstrates that even in externally supported hospitals actual expenditure may be insufficient to provide good-quality care and cover essential maintenance, resulting in steady deterioration of capital stock and worsening efficiency in the long term.

Data describing costs of treating some specific conditions in district hospitals are summarized in table 65.1. Given the difficulties in extrapolating data across contexts and the potentially significant effect of exchange rate fluctuations, great caution

Table 65.1 Costs of Delivering Care at the District Hospital Level

Country and year	Item costed	Cost (original data adjusted to 2004 US\$)	Comment
Kenya, 1993–94, two district hospitals, research study	Treatment of inpatient severe malaria in children	US\$41.50 to US\$132.00 per case treated	Step-down approach to allocate all costs, including capital costs
Zimbabwe, 1994–95, three district hospitals, ^a research study	Medical inpatient stay; HIV/AIDS care	Non-HIV: US\$49.20 to US\$110.00 HIV: US\$133.00 to US\$217.00 per inpatient stay	Bottom-up and step-down approaches used, including capital costs
Zimbabwe, 1999, six provincial hospitals, research study	Severe malaria inpatient care; Pulmonary tuberculosis inpatient care ^b	Severe malaria, mean costs per case US\$26.60 to US\$49.90; tuberculosis, median costs per case US\$22.20 to US\$61.00	Overhead costs purposefully omitted; 1999 exchange rates
Uganda, modeling based on 1997–99 data factoring in program expansion	Aspects of safe motherhood delivered at hospital ^c ; actual and recommended practices	Eclampsia: actual US\$63.40; recommended US\$127.00 Cesarean: actual US\$53.20; recommended US\$57.80 Prenatal care: actual US\$2.90; recommended US\$8.30	Attempt to estimate current program costs and costs if program implemented as recommended; excludes facility costs

Note: Shaded rows provide data from studies that did not include overhead or facility costs.

a. Only data from district hospitals are shown.

b. All hospitals had a median length of stay for tuberculosis cases of 10 days or less.

c. Only selected items are shown.

Table 65.2 Estimate of the Effectiveness of a Kenyan District Hospital in Preventing Childhood Deaths in a Rural Community with Good Access to the Hospital

Study site and population: Kenyan rural community with access to basic primary health care services provided by five clinics, three private	Population 51,183; 52 percent younger than age 15
Surveillance period	1991–93
Service provider	Kenyan Ministry of Health district hospital supplemented by research unit
Mortality rates:	
Neonatal	31.5 per 1,000 live births
Infant	58.3 per 1,000 live births
Child	12.4 per 1,000 children ages one to four years
Observed number of admissions	2,223
Admission rate	45 per 1,000 children ages 1 to 59 months per year
Proportion of deaths occurring in the hospital:	
Neonatal	28 percent
Ages 1 to 59 months	30 percent
Observed number of deaths	134
Expected number of deaths without inpatient care based on expert estimates for case fatality rates	349
Lives saved	215
Estimated cost per life saved ^a	US\$104.40

Source: Snow and others 1994.

a. 2004 US\$ equivalent, using admission cost data from Kirigia and others 1998. The estimated cost of the admissions in 2004 US\$ would be $2,223 \times 10.1 = \text{US}\$22,452.30$. This expenditure prevented 215 deaths; average cost of life saved therefore = $22,452.30/215 = \text{US}\104.40 .

should be used in interpreting these data, which, it should be noted, derive in all cases from specific research rather than routine sources.

Measuring the Effect and Cost-Effectiveness of District Hospitals

In the previous section, some limited data on the costs associated with provision of care at the district hospital were presented. What of a hospital's cost-effectiveness? Ideally we would like to know the aggregate health output of a hospital in terms of improved health compared with a situation in which there is no hospital. Such data do not exist, even from industrial countries, where the hospital has been the subject of intense academic study.

However, some attempts have been made to estimate the effect of a hospital by comparing the observed outcome of illness treated with hospital care to consensus expert opinion on the likely outcome of illness in the absence of hospital care. Using this approach in Kenya, Snow and others (1994) estimated that a well-functioning rural district hospital might reduce all-cause child mortality by 44 percent in a population with reasonable access to the hospital (see table 65.2). Extending this approach, researchers in a small rural hospital in Bangladesh calculated the benefit of hospital admission for patients of all ages suffering from life-threatening conditions

using a slightly modified DALY (McCord and Chowdury 2003). Over a three-month period, the total costs (including all staff, capital, and hotel costs) of running the hospital were calculated and divided by the estimated total number of DALYs gained attributable to inpatient care over the same three months. The authors report an average cost per DALY of approximately US\$11.00 in 1995, or US\$13.30 in 2004 dollars (McCord and Chowdury 2003; see table 65.3). This figure compares favorably with costs per DALY of many primary care interventions regarded as highly cost-effective (World Bank 1993). To what extent these results depend on the quality of primary care, the referral system, the inpatient care, the hospital administration, and the commitment of health personnel working for a small independent nongovernmental organization will remain uncertain until more such data become available.

FACTORS INFLUENCING DISTRICT HOSPITALS' PERFORMANCE

The overall macroeconomic policy framework, as illustrated here with reference to financing mechanisms, may often be overlooked as a considerable influence on hospital performance. For the sake of simplicity, other factors (not exhaustively described and illustrated in figure 65.1) are discussed as primarily affecting the demand for hospital services or their supply and may

Table 65.3 Estimate of the Cost-Effectiveness of a Nongovernmental District Hospital in Rural Bangladesh

Study site and population: Rural Bangladesh, with community served by four peripheral clinics	Population 160,000
Surveillance period	July through October 1995
Service provider	Independent nongovernmental organization
Major causes of death	74 percent under-five mortality attributable to perinatal deaths; maternal mortality ratio high
Admissions analyzed	541 (33 percent obstetric/gynecological problems)
DALYs gained by hospital services:	
Adult medical	177.0 life years; 6.5 disability years
Surgical	459.4 life years; 236.3 disability years
Pediatric	371.5 life years; 10.8 disability years
Obstetric/gynecological	897.5 life years; 125.4 disability years
Newborn (resulting from ob/gyn interventions)	1,024.3 life years
Total DALYs gained	3,308.7
Cost per DALY	US\$10.93 in 1995 (\$13.30 in 2004 US\$)

Source: McCord and Chowdury 2003.

operate at both national and local levels. The way some of these diverse factors affect people's daily lives is illustrated in box 65.1. What is clear is that failure to tackle these many challenges all too often results in facilities that fail their communities.

Central Financing Mechanisms

Three broad methods of government financing of public district hospitals are generally used: prospective with a fixed budget, prospective with revenue depending on activity, and retrospective in proportion to actual costs. The fixed budget is widely used, often based on historical spending levels, with a (frequently inadequate) provision for price changes. Such a system clearly can secure good expenditure control and is administratively undemanding. However, it can often perpetuate historical inequities and fail to respond to new demands and priorities. Moreover, fixed budgets offer few incentives to maximize the effectiveness, quality, or quantity of care offered by hospitals (Barnum, Kutzin, and Saxenian 1995).

Indeed, many budget systems continue to finance hospitals through line-item budgets directly from the ministry of health or finance. Such mechanisms allow central bureaucracies to exert the maximum level of control over peripheral spending with little or no capacity at peripheral levels for flexible use of funds in response to local needs. Thus, centralized budget systems can contribute to technical inefficiency by preventing local managers from optimizing the deployment of inputs. In contrast, global fixed budgets provide for central control of total spending but may permit increased independence when allocating funds at a local level. Fixed budgets based on capitation payments can be more sensitive to local needs than incremental budgeting and can contribute toward equity objectives.

However, they demand technical skill and accurate data at the central level, especially if capitation payments are adjusted for differences in population health status or other needs.

Financing based on activity levels (such as the diagnosis-related group methods in widespread use in high-income countries) are similarly demanding of central-level capacity and also require considerable competence and probity at more peripheral levels of the administration. However, such financing might be an essential prerequisite of insurance-based mechanisms. In contrast to fixed budgets, it has the potential for encouraging supplier-induced demand—the greater the hospital's income, the more services it provides. It produces some incentive to reduce unit costs. Expenditure control may be difficult unless a cap is put on the aggregate hospital sector budget.

Retrospective reimbursement of actual costs is a discredited system of financing hospitals because it offers no incentive to control costs or manage demand. In its favor, it may stimulate higher-quality care. In practice, many health systems use a mixture of all three payment mechanisms, with broadly fixed budgets, sometimes adjusted for changes in demand, and some element of retrospective reimbursement for unplanned activity. In general, no one strategy is perfect. However, the considerable demands on management for some schemes imply that a global budget, ideally based on population needs, in conjunction with some form of quality-monitoring system may be the most appropriate way forward for many developing countries (Barnum, Kutzin, and Saxenian 1995).

Mechanisms permitting local income generation (cost recovery, cost sharing, facility improvement funds, and local taxes) may be superimposed on any of these schemes. Such devices can help countries shift toward a local, more needs-based allocation of financing and help promote accountability

Box 65.1

Hospital Performance: Perspectives from a Sub-Saharan African Country

Caretaker (C) and health worker (HW) experiences of hospital care:

“When the doctor realized my child was breathless he quickly called us into the office even though I was at the back in the queue.” (C)

“The [nursing] sister came and talked to me and asked if I had a problem, and I felt good and cared for.” (C)

“Things here have greatly improved; the ward is clean and the treatment prompt. We are happy and hope that this will continue.” (C)

“I admitted a patient in very poor condition with malaria and anemia and I managed to remove blood for cross-match and fix a line, start on oxygen, and get the doctor. Blood was started quickly, and the child rapidly improved.” (HW)

“I resuscitated a baby with severe asphyxia, and it successfully came up. The success was because I had attended a course in basic life support skills for neonates.” (HW)

Caretaker and healthworker descriptions of referral to hospital:

“If you do not have the money, you have to look for it first. Sometimes you may even have to spend a day or two looking for the money for the treatment. If you have coffee,

then you sell it before you go.” (C) (Peterson and others 2004).

“I spent a long time in MCH [Maternal and Child Health]; the doctor wanted money before he would see me, and I did not have any.” (C)

“There is a lot of suffering when it comes to drugs because they are usually not enough and most of the time the mothers do not have money.” (C)

“I want to know everything about the illness; I asked the nurses, but they refused to explain, so I got disheartened from asking anyone.” (C)

“I had a patient with anemia and mild marasmus, and the mother waited for three hours in the lab for an Hb only to be turned away as she had no money. Then I went to get the child some milk, and I was turned away as the storeman said it was too late. The child had to wait until the next day.” (HW)

“A child with severe LRTI [lower respiratory tract infection] was very dyspneic on admission. Only one cylinder of oxygen was available, but we started giving it to the child, and the condition improved. The condition became worse when the oxygen ran out, and there was none left; he started gasping and died.” (HW)

Source: English and others 2004a, unless otherwise noted.

by focusing local attention on the efficiency and quality of local services. This flexibility presupposes that those empowered with authority have the skills and freedom to make and execute plans. The experience of such a decentralized policy on district hospital or district health system performance is mixed, with a lack of real transfer of authority reducing effectiveness in some areas (Blas and Limbambala 2001), while more balanced and carefully implemented mechanisms of decentralization may be productive (Bossert and others 2003).

The specific effects of requiring out-of-pocket payments to access health care are a matter of fierce debate. Although some data suggest an improvement in allocative or technical efficiency, other data do not (Arhin-Tenkorang 2000; Van der Geest and others 2000). It has been suggested that an improved quality of service may overcome the cost barrier to access (Van der Geest and others 2000). However, the likelihood that the poor will be excluded from hospital care is a major concern. There is also an increasing tendency to encourage district hospitals to provide some beds with an enhanced level of professional

attention and hotel services (sometimes referred to as *amenity beds*) as a means of generating profit; reports indicate that the fees levied may not even cover the cost of the enhanced service, let alone generate extra revenue with which to cross-subsidize services for the poor (Flessa 1998; Suwandono and others 2001).

Demand for Services

Patients' demand for services may be influenced by a wide variety of factors, many of which have little to do with the hospitals themselves. Patients' perceptions of the severity of their illness, cultural beliefs, physical accessibility, and financial and opportunity costs together with the performance of the peripheral health unit screening process all potentially limit the effectiveness of the referral mechanism and thus the hospital (Font and others 2002; Siddiqui and others 2001). Recent data highlighting the inability of many families to meet the financial costs of hospital referral (Peterson and others 2004) and the

potentially catastrophic consequences of severe illness (Xu and others 2003) underscore the importance of financial barriers, especially for the poor. Not only are there obvious implications for health generally, but underusing service capacity also reduces efficiency and increases the costs per case of hospital care. Improving the efficiency and effect of a hospital may, therefore, be best achieved by tackling factors that influence demand—for example, providing emergency transport and limiting out-of-pocket expenses. However, often a concern exists that the provision of free high-quality services may itself promote unnecessary demand—the so-called moral hazard. In addition, the relative importance of demand factors may vary considerably in different settings, for example, in urban and rural areas, making universal rules unhelpful.

In the context of PHC, it is suggested that high demand for services provided by hospitals rather than peripheral clinics, driven by a perception that hospitals provide higher-quality service and resulting in bypassing of the PHC level of care, is inefficient. It has been proposed that hospitals be specifically prevented from delivering PHC services (WHO 1990). However, the view that patients who bypass PHC increase the costs to the provider may not always be true (Siddiqui and others 2001). Patients may also choose to bypass the district hospital and proceed directly to referral hospitals, often increasing the costs of care if the condition could have been treated in the lower-level facility. The perceived quality of care at the district level may be a major determinant of this behavior, with some data suggesting that improved district services increase use rates (Barnum and Kutzin 1993), potentially making district hospitals more cost-effective but more costly.

The Supply of Services

A fundamental role of policy makers is to determine the geographical distribution of hospitals and the functions they should undertake. These decisions are often severely circumscribed by topography, historical accident, and political imperatives, as well as by the level and quality of resources that are available. Often, changes can be made only incrementally, building on an existing structure of administration and capital that may not be in any sense optimal.

Nevertheless, many of the factors determining the quality of supply are theoretically under the influence of local management personnel, who are in a potentially powerful position to significantly affect a hospital's function. Lack of resources, low morale, inability to attract staff members to hardship areas, poor training, and inadequate supervision among many other factors may all conspire to prevent health workers from executing their duties effectively or even at all. Those factors may, in turn, result in less demand for services from consumers, who opt to avoid the hospital or go elsewhere for treatment. The paradox resulting from this decline is that the hospital may

continue to operate within a fixed budget, thereby satisfying finance ministries but having little or no effect on health. Long-term underinvestment in facilities and skilled, motivated staff may then condemn a health system to many years of underperformance, given the time necessary to address these issues. This is the fundamental reason for seeking to measure system outputs and quality as well as costs.

On a regional or national scale, the actual distribution of hospitals and personnel may work for or against effective service delivery. For political reasons (to reward a community or to honor a powerful politician, for instance), hospitals may be situated in areas that would not be chosen if purely rational plans had been followed. Nongovernmental providers or philanthropists may build or alter hospitals without regard to the overall function of a health system or achieving either equity or efficiency. Public, private, and nongovernmental hospitals may compete for patients, potentially reducing efficiency in some or all sectors. The crisis of inadequate personnel in low-income countries, which limits the range, quality, and quantity of services that can be offered, has been described (Narasimhan and others 2004). However, imbalances in the within-country distribution of staff members are less well publicized and equally damaging. All the factors mentioned and others are commonly encountered in health systems of developing countries and are major barriers to implementing potentially valuable interventions at an operational level (Oliveira-Cruz, Hanson, and Mills 2001). New interventions must therefore often be considered in the light of existing (rather than optimal) levels of service provision and performance. Little literature is available on these public choice features of decision making.

EFFECTING CHANGE WITH CROSS-CUTTING INTERVENTIONS

So far this chapter has outlined concepts fundamental to understanding the position, functions, and performance of the district hospital and has presented some of the existing (though limited) data on costs and cost-effectiveness. Operating at the interface between primary care—aimed often at the poor—and the more Western biotechnological model of care at secondary and tertiary levels—often more accessible to the better off—district hospitals are easy to ignore because they lack any advocates for their role. However, optimizing their role to maximize health benefits and promote equity does demand the following:

- explicit policy decisions about the services that should be offered at this level and about the balance between primary care, district hospital care, and higher-level care services provided

- national strategies on the distribution of services that encompass all providers
- commitment to provision and equitable distribution of essential human resources and supplies
- systems for monitoring hospital performance in terms of efficiency and quality and for intervention when performance is poor.

When a framework defining the district hospital is available, interventions that might improve performance can be considered. The focus here is on cross-cutting interventions rather than condition-specific or service area-specific interventions described elsewhere. Cross-cutting interventions seem to be rarely prioritized but have the ability to add value in many areas and are perhaps critical when thinking of developing an improved health system.

Human Resources

Key issues that affect district hospitals are the quantity and quality of personnel and their range of skills. Staff members should be appropriate to the tasks they are asked to perform. This approach may mean continuing to use nursing or auxiliary staff members with more limited training in district hospitals because they may be more cost-effective, running against the tide of rising academic requirements often demanded by professional associations (AED 2003). Similarly, devolving some tasks to lower cadres of staff may be practical and much more efficient—for example, training and licensing clinical assistants to perform emergency surgery including cesarean section. Such initiatives, too, may face opposition from powerful professional vested interests. Although some tasks may be transferred downward, a problem often faced by district hospitals is an absence of high-quality senior staff members or leaders. Traditionally, running a district hospital has commanded less respect and remuneration than work at a secondary or tertiary facility and has been regarded as a stage to be moved through as rapidly as possible. Arguably, the challenges to a district hospital professional are at least as great as those of a tertiary consultant specialist, and the development of appropriate skills-training programs, and parity of postgraduate qualifications and pay, might help foster the development of a professional group that improves performance and fills a much needed advocacy role.

Improving Clinical Management

For more than a decade, industrial countries have increasingly promoted the use of the best evidence in clinical management. Clinical guidelines, means to implement them, feedback on their use and value, clinical audit, and performance review are all now the subject of considerable research, with some

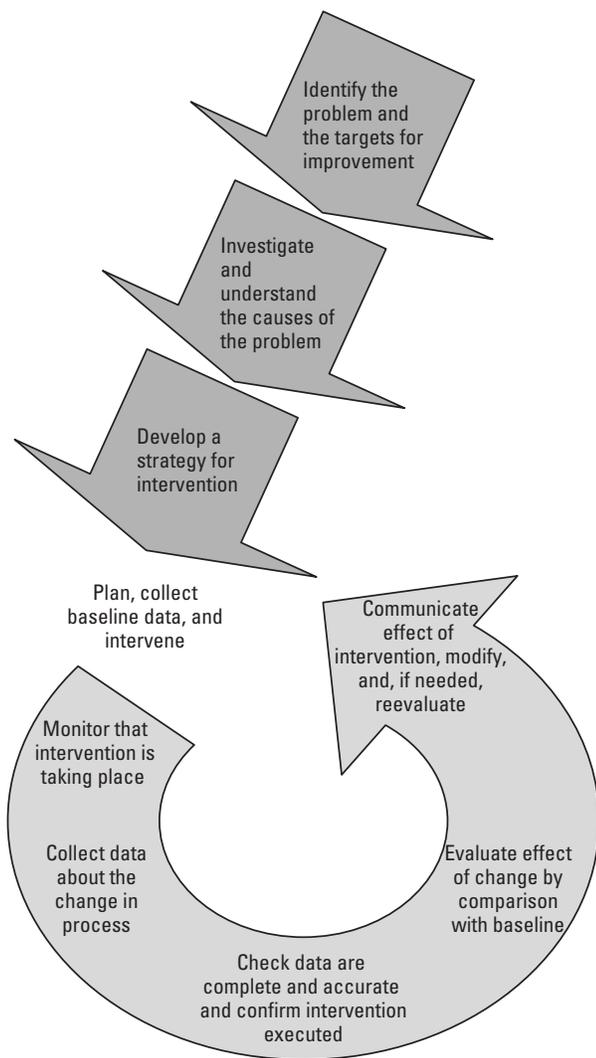

evidence of benefit particularly when part of a broadly based approach (Grol and Grimshaw 2003). District hospitals in developing countries have largely missed out on this revolution, which may be of particular value in settings where care by nonspecialists with little or no access to recent information is the norm.

Information and Integration

Although much focus is given to technological development in the fields of diagnosis, treatment, and imaging, relatively little attention is paid to the potential for technology to change the collection and use of information, despite the possibly major effect on improving administrative and clinical management. As at the primary care level, where many of the interventions are currently available to achieve significant reductions in mortality (Claesen and others 2003), many of the tools that could be used to improve health are well known at the district hospital level. Making better use of these tools through more reliable provision, better training, improved information collection, on-the-spot analysis of data, and real-time use of the results for service planning might be both possible and of considerable benefit (Cibulskis and Hiawalyer 2002). Clearly, how a hospital is performing as part of an integrated primary care system is also vital. Local information on population health, on use and referral patterns, and on success and the reasons underlying successes and failures is invaluable if the hospital is to respond to the particular needs of its locality.

Quality Improvement and Accreditation

Quality improvement is a generic technique adapted from industry that involves a rolling approach to identifying problems, solving them, and assessing the results of change (see figure 65.3) and that has been institutionalized in hospital care in many developed countries (DiPrete-Brown and others 1993). An essential first step is defining standards for service provision, which can span all areas, including the technical content of care, the physical environment in which care takes place, and interpersonal relations between patients and health workers. This approach is often linked to formal systems for external assessment of hospitals' performance and accreditation. Accreditation may serve as a goal for participating hospitals, a means of promoting positive competition, and a means of identifying poorly performing institutions. Potential advantages of such initiatives are empowerment of local service providers to solve problems they feel are important and the overall aim of working toward a systemwide standard of care. However, although an obvious need exists for quality improvement in hospitals in developing countries (English and others 2004b; Nolan and others 2000), few examples exist of hospital-level interventions in industrial or developing countries that

Source: Adapted from Massoud and others (2001).

Figure 65.3 Quality Improvement Process

provide evidence of effect on major outcomes. One exception is a broadly based quality improvement intervention targeting maternal and child health in Peru that focused on the entire system of care. This project was associated with a 25 percent decrease in maternal deaths in program areas (see box 65.2 for details). However, the relatively poor progress of an operational-level quality improvement and accreditation program in Zambia's hospitals highlights the significant problems of intervening in countries with poorly functioning health systems that are severely constrained by lack of resources (Bukonda and others 2002).

Hospital-Acquired Disease

Probably the most important infection in developing countries that can be acquired as a result of hospital care is HIV, espe-

cially in Sub-Saharan Africa. Reuse of needles and blood transfusion are the main sources of infection and also carry the risk of hepatitis B and C and other viral infections important in their own right. It has been estimated that effective measures to improve blood safety in particular are a highly cost-effective intervention at approximately US\$8 or less per DALY (Creese and others 2002).

Nosocomial infection, another major adverse consequence of admission to hospital, is common in some settings in industrial countries, contributing significantly to hospital costs. Historically, relatively simple approaches to prevention have proven reasonably effective with additional effect from dedicated prevention services (Ayliffe and English 2003). The potential effect of intervention in district hospitals in developing countries is largely unknown, although in China nosocomial infection rates of between 8 and 13 percent have been reported (Barnum and Kutzin 1993). Because overcrowding and lack of basic resources, even water, are common in some districts, the potential for simple cost-effective interventions to prevent such infections seems high.

Other Managerial Initiatives

In high-income countries, numerous other initiatives are being tested to promote improved efficiency and quality. They often rely heavily on having in place appropriate institutional arrangements, managerial capacity, and information systems, so their feasibility for local implementation is highly dependent on local circumstances. One of the most widely tested arrangements within public national health systems has been the experiment with internal markets, in which a range of public hospitals compete for contracts from separate public service purchasers, such as local governments. The split of purchaser and provider of public services is recognized as a potentially powerful instrument for securing efficiency improvements but can be demanding in terms of managerial skills (Le Grand, Mays, and Mulligan 1998).

A less direct way of introducing some form of competition into the hospital market is to require hospitals to publish performance reports that allow direct comparisons to be made between hospitals.

An alternative to relying on indirect methods of influencing behavior is to give physicians incentives or instructions to deliver care in line with guidelines reflecting best practice. In the United States, numerous experiments have been carried out under the general banner of managed care (Glied 2000), and other systems have attempted analogous approaches to hospital regulation. At one extreme is the centralized U.K. system of performance management, under which hospitals are given challenging and immediate targets and are rated according to measured outcomes (Smee 2002). At the other extreme is the system of guided self-regulation practiced in the Netherlands, under

Box 65.2

Prevention of Maternal and Child Deaths from Improvements in the Quality of Health Services: An Example from Peru

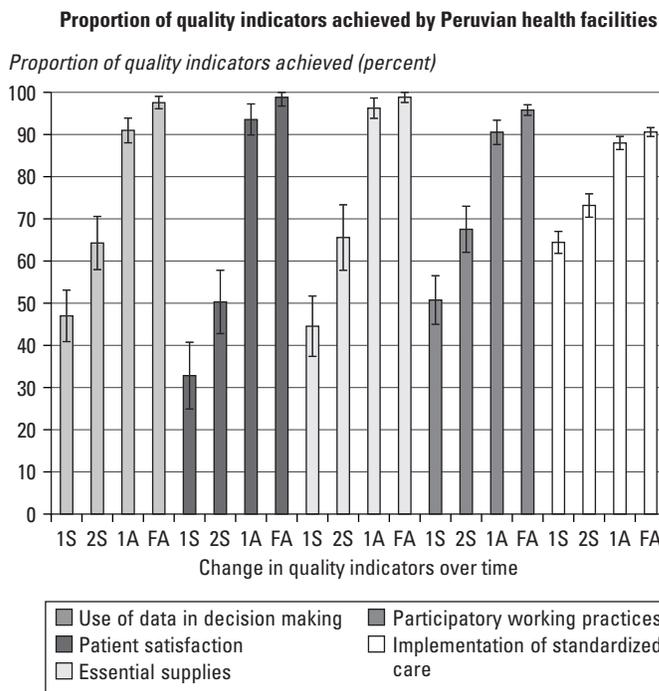

Recognizing the failure of previous training attempts to improve the quality of health services, the Ministry of Health, with support from the U.S. Agency for International Development and the participation of local institutions, developed an innovative program in Peru. Aiming to reduce maternal and perinatal deaths, the program expected to increase use of health services by improving quality and by strengthening links between the health services and their communities by working with midwives and community health workers. Multidisciplinary teams implemented a quality improvement program in approximately 2,500 health facilities, focusing on

- standardizing care
- ensuring the availability at all times of essential supplies and equipment
- making use of existing information systems and doing small operational studies to generate data at the local level to facilitate decision making
- promoting the participation of all personnel in a concerted and agreed-on plan of action
- measuring patients' satisfaction over time and addressing the causes of complaint.

Training activity mainly involved use of a participatory problem-solving technique. In parallel, health networks in each health region participated in a program to work with 1,143 midwives and 2,549 community health workers, under the coordination of a health facility member who was part of the multidisciplinary team.

Supervision and evaluation at each facility occurred three and six months after training and before accreditation visits. A tiered accreditation system was developed to promote participation and provide an incentive for improving quality. Results of each evaluation were presented to the Ministry of Health, which made accreditation decisions through an independent institution to generate political support. Quality in five areas (corresponding to the program aims) was assessed. Significant improvements were observed in the proportion of indicators achieved in all five aspects of quality evaluated (box figure). An evaluation one year after the end of the program found that performance had declined but remained at 60 to 80 percent of the levels achieved at accreditation.

Sources: Lanata, Butron, and Espino 2002; Ministerio de Salud, Peru 2001.

Note: Proportion of quality indicators (with 95 percent Confidence Index) measured in the five domains achieved by health facilities at first supervision visit (1S), second supervision visit (2S), first accreditation visit (1A), and final accreditation visit (FA).

By the end of the three-year program (1996–99), demand for health services had increased considerably, the success itself creating managerial problems in many instances. Motivation and satisfaction of patients and health workers had also increased, and revenue collected (through fee-for-service payment) at the facilities rose. Maternal mortality in the regions included in the program was 60 percent higher than in other regions at the start of the intervention period and fell 25 percent after the intervention, while no change was observed in the other health regions. The inequitable distribution of maternal mortality was narrowed to a 20 percent excess in intervention areas. A national demographic and health survey examining Peru between 1995 and 2000 found a significant overall reduction of maternal mortality, increases in prenatal care coverage, and a higher proportion of deliveries in health facilities or attended by health professionals.

which hospitals are required to engage in quality improvement but are given no prescription as to what format that effort might take (Klazinga, Delnoij, and Kulu-Glasgow 2002).

THE FUTURE: RESEARCH AND INFORMATION NEEDS

A few fundamental and urgent needs must be met as a prerequisite to improving understanding of district hospitals in low- and middle-income countries, although tackling these issues may be far from simple:

- developing and accepting meaningful performance indicators in conjunction with developing appropriate standards of care
- collecting higher-quality routine data from district hospitals
- improving understanding of the costs and health consequences of different, evidence-based, service provision portfolios proposed for district hospitals and improving understanding of the marginal benefits of incremental additions and their implications for planning infrastructure and estimating human resources and technology needs.

A solution to the first issue would perhaps pave the way for and enhance the value of further focused research in a number of areas.

Implications of a Changing Disease Spectrum

In many middle-income and some low-income countries, the demographic transition to noncommunicable diseases—notably cardiovascular, smoking-related, and malignant diseases—will have considerable implications for the hospital sector. Thus, hospital costs likely will rise as older patients with chronic diseases become an increasing proportion of inpatients (Barnum and Kutzin 1993). In some cases, the relative cost-effectiveness of hospital care will improve compared with further expansion of primary or preventive services that incur increasing marginal costs (Barnum and Kutzin 1993).

More immediately, in low-income countries in Africa, the massive impact of the HIV pandemic is most easily seen in the continent's hospitals. Bed occupancy is rising, and hospital stays appear to be lengthening, as an increasing proportion of hospital admissions, now over 50 percent in some countries' medical wards, have HIV-related disease (Mpundu 2000). Those diseases associated with HIV infection, notably tuberculosis, and changing demands for care, such as the need for palliation, may change not only the workload but also the nature of the demands placed on the service. The advent of antiretroviral therapy, which might ameliorate some of these problems, will itself place great demands on the hospital service provision mechanisms. With or without new drugs, HIV will continue to tax both planners, who have to

respond to a rapid change in needs, and health care financing. Research that permits hospitals to tackle these new challenges and develop efficient and cost-effective strategies to provide care for HIV-related disease while preventing a decline in care standards for HIV-uninfected patients is a high priority.

Accounting for Case Mix and Case Severity When Measuring Hospital Performance

Overall inpatient-fatality rates and case-fatality rates of different common diseases are often included in district hospital performance measures. These are crude measures unless some adjustment is made for case mix when describing inpatient fatality and for severity of illness when describing case fatality. Alternatively, hospital outcomes should perhaps be replaced as key indicators of performance by carefully chosen process indicators, which are likely to be more generalizable tools of performance monitoring that offer the advantage of specifically identifying areas that require improvement (Lilford and others 2004).

Implications of Emerging and Existing Technologies

Technology has had an enormous effect on the amount of information available to clinicians and managers in industrial countries, from new rapid diagnostic tests to automated stock-checking and ordering procedures. A particularly exciting potential in developing countries may be the ability to undertake and interpret many diagnostic tests remotely, thereby enabling district hospitals to operate without a skilled diagnostic staff on site. It also seems probable that appropriately targeted technology could have a major effect, not least in the generation, communication, and analysis of hospital use, cost, and outcome data, without which the health system cannot identify and respond to needs.

Interventions That Improve Performance

Interventions aimed at improving hospital administration and clinical management at the district hospital level warrant investigation. For clinical management, interventions such as clinical guidelines, supervision, and feedback; audit and continuing professional development; quality improvement strategies and accreditation; and improvements in referral and integration with PHC may improve district hospital performance and be relatively cost-effective. Such interventions deserve attention, along with more traditional research aimed at optimizing treatment of specific diseases.

Chapter 66

Referral Hospitals

Martin Hensher, Max Price, and Sarah Adomakoh

The appropriate allocation of resources to referral hospitals within a national health system has long been a controversial issue in health system planning in developing countries. Consensus appears to be widespread that referral hospitals consume an excessive share of health budgets and that their contribution to improving health and welfare is low relative to the expenditure on these facilities, but the literature does not indicate what percentage of budgets should ideally be allocated to referral hospitals. Presumably, except in the poorest countries, some referral facility is needed, but how much is required, and how should the proportion allocated to referral facilities vary with increasing levels of health expenditure and health system sophistication?

One approach would be to review how much countries at different levels of gross domestic product (GDP) currently spend on referral hospitals. However, as explained later, the definition of *referral hospital* varies widely; therefore, analyses of national health accounts and studies of expenditure are rarely comparable. Thus, although the chapter summarizes the literature on expenditure on referral hospitals, this evidence cannot provide guidelines for policy makers.

A second approach might be to undertake a detailed analysis of the role of referral hospitals in treating disease to derive their contribution to total disability-adjusted life years (DALYs). A simple analysis of the cost-effectiveness of specific interventions offered by referral hospitals might allow the selection of those interventions that are justified given their marginal cost per DALY gained. Those interventions, multiplied by expected demand, would then be aggregated to give a total optimal allocation for referral hospital services. This approach is precisely the one used for evaluating and prioritizing disease-specific interventions throughout this volume. However, when this kind

of “pure” cost-effectiveness analysis is used to determine an appropriate or optimal resource allocation for referral hospital services, several problems arise. To begin with, hospitals have complex economies of scope and scale. At the point when hospitals offer a range of cost-effective interventions, the marginal cost-effectiveness of additional interventions may be much greater than would be the case if these other interventions were evaluated in isolation. Yet a standard disease-specific analysis of interventions would rarely be able to calculate the marginal costs of referral hospital-based interventions. Similarly, important and complex interdependencies exist between services and specialties within referral hospitals that may be almost impossible to capture adequately using a cost-effectiveness analysis.

A further limitation to a cost per DALY approach arises because referral hospitals produce multiple outputs, many of which contribute so indirectly to DALYs that they cannot be compared directly to individual health interventions, but which are critical to the functioning of the health system. For example, referral hospitals are arguably essential to the training of doctors, particularly specialists. If a country can justify training its own doctors, then it must have a referral hospital. Yet the value of this output in terms of DALYs probably cannot be calculated. Indeed, many of the functions of a referral hospital occur outside the hospital itself and involve enabling and facilitating the effective functioning of lower-level health services. Although the referral hospital’s contribution may constitute only a small fraction of the total cost of an intervention provided at a lower level of care (which may perhaps be viewed as a fixed cost of the health system), the referral hospital’s role may nevertheless be essential, thereby justifying a considerable premium on its valuation above and beyond the cost per DALY of the care directly provided within the hospital’s own walls.

Finally, strong arguments can be made that cost-effectiveness analysis fails to capture important dimensions of the individual utility—and thus the social welfare—that accrues from the provision of health services, especially those relating to high-cost and low-frequency conditions.

We are, therefore, highly skeptical about the feasibility of proposing a formulaic and purely quantitative response to the question of how to achieve an appropriate allocation of resources to the referral hospital level. Although perhaps unsatisfying for some readers, this chapter attempts instead to provide an overview of the critical features of and challenges relating to referral hospital care in developing countries and a guide to the many issues that decision makers face in setting policy for this level of care. We suggest that planners need to adopt a far more qualitative and intuitive approach to deciding on the appropriate allocation of resources for referral hospitals than for other health care interventions. Such an approach is informed by a more extensive listing of the roles of referral hospitals and their direct and indirect benefits and costs to society. We acknowledge that analysis of the value of referral hospitals is bedeviled by the fact that, when judged empirically, they do not work as they are supposed to. The chapter, therefore, considers the key problems faced in the real environment in which referral hospitals operate in poor countries before reviewing what needs to be done to improve their functioning, drawing in particular on the authors' knowledge of South Africa and the Caribbean.

DEFINITION AND CHARACTERISTICS

Any hospital, including a district hospital, will receive referrals from lower levels of care. Indeed, *referral* can be defined as any process in which health care providers at lower levels of the health system, who lack the skills, the facilities, or both to manage a given clinical condition, seek the assistance of providers

who are better equipped or specially trained to guide them in managing or to take over responsibility for a particular episode of a clinical condition in a patient (Al-Mazrou, Al-Shehri, and Rao 1990). Furthermore, higher-level hospitals in developing countries do not treat only referred patients; tertiary hospitals are frequently the first point of contact with health services for many patients.

Differentiating referral hospitals from district hospitals, therefore, requires consideration of the different resources used by different levels of hospital. Such a differentiation will tend to revolve around three features—the availability of increasingly specialized personnel, of more sophisticated diagnostic technologies, and of more advanced therapeutic technologies—that permit the diagnosis and treatment of increasingly complex conditions.

This volume, including this chapter, uses a standard definition of hospital levels (Mulligan and others 2003). Table 66.1 presents some of the commonly used alternative terminology for different levels of hospitals. Note that this chapter deals only with general—that is, multispecialty—secondary and tertiary hospitals. Specialized hospitals, such as psychiatric, substance abuse, tuberculosis, infectious diseases, and rehabilitation hospitals, clearly have important roles to play in a well-functioning referral system. However, they are attended by specific features and challenges, account for a relatively small share of overall resources, and operate in a significantly different manner than general hospitals do.

FUNCTIONS AND BENEFITS

The functions of referral hospitals may broadly be categorized into (a) the direct clinical services provided to individual patients within the hospital and the community and (b) a set of broader functions only indirectly related to patient care.

Table 66.1 Definitions and Terms for Different Levels of Hospital

Disease Control Priorities Project: terminology and definitions	Alternative terms commonly found in the literature
<i>Primary-level hospital</i> : few specialties—mainly internal medicine, obstetrics and gynecology, pediatrics, and general surgery, or just general practice; limited laboratory services available for general but not specialized pathological analysis	District hospital Rural hospital Community hospital General hospital
<i>Secondary-level hospital</i> : highly differentiated by function with 5 to 10 clinical specialties; size ranges from 200 to 800 beds; often referred to as a <i>provincial hospital</i>	Regional hospital Provincial hospital (or equivalent administrative area such as county) General hospital
<i>Tertiary-level hospital</i> : highly specialized staff and technical equipment—for example, cardiology, intensive care unit, and specialized imaging units; clinical services highly differentiated by function; could have teaching activities; size ranges from 300 to 1,500 beds	National hospital Central hospital Academic or teaching or university hospital

Source: Definitions from Mulligan and others 2003, 59.

Range of Clinical Services Provided

The primary function of the referral hospital is to provide complex clinical care to patients referred from lower levels; however, no agreed international definition exists of which specific services should be provided in secondary or tertiary hospitals in developing countries. The exact range of services offered tends to vary substantially, even between tertiary hospitals within the same country, as much because of historical accident as deliberate design.

In South Africa, the National Department of Health is attempting to improve the quality and accessibility of referral hospital services through development plans that will try to ensure that hospitals at each level move toward providing a comprehensive set of clinical services (National Department of Health, South Africa 2003). The department has developed a target template of services (table 66.2) for regional (secondary) hospitals, tertiary hospitals, and so-called national referral services (which will be offered at only a small number of the

Table 66.2 Target Service Configurations by Level of Referral Hospital, South Africa

Specialist services available on site	Components explicitly included	Specialist services available on site	Components explicitly included
<i>Regional (secondary) hospitals</i>			
Anesthetics	—	Mental health (psychiatry and psychology)	Acute inpatient and outpatient treatment
Diagnostic radiology	X-ray, CT scan, ultrasound, fluoroscopy		Child and adolescent psychiatry
General medicine	Echocardiography, stress electrocardiogram Specialist immunology nurse Regional intensive care unit Diabetes, endocrine clinic Gastroenterology, including endoscopy, proctoscopy, sigmoidoscopy, colonoscopy (with general surgery) Geriatric care Genetic nurse and counseling Oncology palliation and basic care Neurology basic care Spirometry and oximetry Basic rheumatology	Obstetrics and gynecology	Electroconvulsive therapy Liaison psychiatry Satellite clinics Emergency obstetrics and gynecology Ultrasound, prenatal diagnosis Kangaroo mother care Basic urogynecology
General surgery	Regional burns service 24-hour trauma service, accident and emergency	Orthopedic surgery	General orthopedic surgery 24-hour trauma service, accident and emergency
		Pediatrics	Neonatal low and high care General pediatric medicine service General pediatric surgery (general surgeon)
		Rehabilitation center	Physiotherapy, occupational therapy, orthotics and prosthetics, speech therapy, dietetics, podiatry Acute rehabilitation team
<i>Tertiary hospitals</i>			
Anesthetics	—	General medicine	As regional plus: Angiography Coronary care
Burns unit	Specialized burns intensive care unit and operating theater		Echocardiography, stress electrocardiogram Endoscopy, proctoscopy, sigmoidoscopy, colonoscopy (with general surgery) Genetic nurse and counseling Oncology palliation and basic care
Clinical pharmacology specialist	—		Complex and high-acuity care
Critical care and intensive care unit	Full intensive care unit service	General surgery	—
Dermatology	Inpatient and ambulatory treatment	Infectious diseases	
Diagnostic radiology	X-ray, multislice CT scan, ultrasound, fluoroscopy, mammography, color Doppler ultrasound	Mental health (psychiatry and psychology)	Child and adolescent psychiatry, old-age psychiatry, forensic psychiatry, substance abuse treatment, liaison psychiatry, treatment for eating disorders, inpatient psychotherapy, social psychiatry, acute psychotic (complicated) care, acute nonpsychotic (complicated) care
Ear, nose, and throat surgery	—		
Gastroenterology	—

largest tertiary hospitals). Although certainly not directly applicable to all developing countries, the template does give a helpful picture of how services “build up” from one level of care to another, and it can be used as a starting point for considering the situation in different countries.

Clinical Services within the Community

Referral hospitals may perform a number of functions that provide population-level health benefits through direct involvement in public health interventions. Responding to the HIV/AIDS epidemic in Latin America and the Caribbean has

heightened awareness about the important role of the hospital in reducing incidence and preventing disease outbreaks. For example, hospitals scaled up services to prevent mother-to-child transmission and initiated follow-up clinics for mothers and babies. In Barbados, the main hospital scaled up voluntary counseling and testing services to address the prevention of horizontal transmission from mothers to their partners, with positive outcomes. The program also served to increase access to obstetric services at the primary health care level because of the screening campaign initiated through the hospital’s prevention of mother-to-child transmission program (Adomakoh, St. John, and Kumar 2002).

Referral hospitals often prove to be a highly effective focal point for disease-specific health promotion and education activities. Bermuda's diabetes education program serves all levels of care and provides a strong link between the primary, secondary, and tertiary health care levels. The program is centered in the main referral hospital and serves not only diagnosed patients but also families at risk. Overall, hospitals in the Caribbean are recognizing that central coordination of public health programs within hospitals can provide benefits by strengthening coordination with other services.

Valuing the Benefit of Clinical Services

Measuring the improvement in an individual's health status produced by the combined activities of a referral hospital, whether for patient care in the hospital or for population-based programs, would theoretically be possible, although practically and methodologically demanding. To our knowledge, such an effort has not been attempted at the referral hospital level, though two studies have attempted to proxy the effect of hospital interventions on health outcomes for small district hospitals, focusing on survival only (McCord and Chowdhury 2003; Snow and others 1994). Both studies indicate that district hospitals appear to have a significant positive effect on health outcomes.

Large numbers of patients receive care in referral hospitals, and most survive with their suffering alleviated, having gained substantial benefit from the care they receive. Therefore, the aggregate direct personal health benefits from referral hospital care will almost certainly be high. The question of whether referral hospital care is cost-effective relative to other interventions delivered at lower levels of care is less easy to answer in aggregate. By its nature, appropriate care in a referral hospital will tend to require more complex input mixes and higher skill levels and, hence, will be relatively expensive. Analysis of the costs and cost-effectiveness of individual interventions offered at different levels is tackled directly by the disease-specific chapters in this volume.

Wider Activities and Functions

Aside from direct patient care, referral hospitals serve other functions within the health system, some of which are offered within the facility, such as teaching and research, while others reach out to the lower levels of the health services, such as technical support and quality assurance.

Advice and Support to Lower Levels. The referral process does not simply entail transferring a patient from a lower to a higher level of care, nor does it end when a patient is discharged from a referral hospital. An effective referral system requires good communication and coordination between levels of care and support from higher to lower levels to help

manage patients at the lowest level of care possible. Too often, personnel in referral hospitals adopt an insular and inward-looking perspective, focusing exclusively on the patients directly under their care. However, referral hospitals should offer significant support to personnel in lower-level facilities, and specialist staff members should ideally spend a significant portion of their time providing advice and support beyond the walls of their own hospital, either in person or through various modes of telecommunication. Even in poor countries, a steady improvement in communications infrastructure means that such support functions should become easier to provide over time. Key dimensions of this support function include the following:

- availability by telephone or e-mail to advise referring practitioners on whether referral is required
- specialist advice to the patient's local practitioner on post-discharge care
- specialist advice on the long-term management of chronic conditions
- specialist attendance at lower-level facilities to provide regular outreach clinics
- provision of expert diagnosis or consultation through telemedicine
- coordination of discharge planning between levels of care
- coordination of the development of and training in the use of shared care protocols and referral protocols
- provision of technology support by skilled technicians and scientists.

Quality Assurance and Quality Improvement. Referral hospitals can and do play a pivotal role in quality assurance and improvement. The most important mechanism for quality assurance and improvement is through the training that referral hospitals provide. The other key mechanism is through the setting of standards for treatment. For example, experts at referral hospitals should review evidence of effectiveness and cost-effectiveness applicable to the local context, determine the formularies to be used at each level of the health system, and develop and amend treatment protocols. Referral hospitals can improve the quality of peripheral services by giving advice, offering on-site training, providing clinical services alongside local practitioners, and monitoring the quality of the referrals they receive.

Education and Training. Many tertiary referral hospitals in developing countries are associated with universities and medical schools and may, therefore, also be regarded as teaching hospitals. Any country wishing to train its own doctors will need one or more teaching hospitals. The number of doctors a country needs will be influenced by its level of development, resources, and personnel structure. Many will aim for a ratio of at least

Box 66.1

How Many Medical Students Should Be Trained Per 1 Million Population?

In a steady state (that is, the number of doctors being produced is equal to the number retiring from practice), and if we assume that doctors practice, on average, for 40 years after qualifying, the total number practicing will equal the number graduating in 1 year multiplied by 40 years. If a population of 1 million needs 1,000 doctors,

Source: Authors.

the number needing to be trained is $1,000/40 = 25$ per year. If 30 percent of doctors leave the country or leave medical practice within 8 years of qualifying, then each graduate, on average, contributes 30 years of service, and 1,000 practicing doctors $(1,000/30) = 33$ must qualify each year.

2 per 1,000 population, though most developing countries have 0.05 to 1.0 per 1,000 (Puzin 1996; WHOSIS 2004). If we assume a 40-year working life and loss through brain drain or other attrition of 25 percent, the number of doctors that must be produced each year is between 16 and 67 per 1 million population, resulting in 0.5 to 2.0 doctors per 1,000 population (box 66.1). A population of 40 million would, thus, need medical schools able to graduate between 640 and 2,680 doctors per year. Medical schools possess economies of scale, and although some extremely small schools train 50 or so students a year, agreement is widespread that a class size of about 150 to 200 is optimal (see, for example, Harden and Davis 1998). A country with fewer than 3 million population would really need to consider whether training doctors locally is justified on economic and other grounds, but for larger countries, the arguments for training doctors locally are strong, and a teaching hospital would, therefore, be required.

Basic generalist doctors should be trained in a range of facilities across all levels of care, reflecting the facilities in which they will work after graduation. Traditional approaches toward medical education have been widely criticized by educationalists and health planners for being dominated by training in tertiary settings by specialists. Not only is this setting inappropriate, but typical content and clinical experience do not reflect what the doctors will be doing or what they will need to know after qualification. Nevertheless, the university teaching hospital cannot be omitted from the basic training of doctors. If students and faculty were involved only in district-based services, they would miss many important advances in biomedical science and the care of complex problems (Husain 1996). Moreover, doctors need to know enough about what the various tertiary specialties do to be able to refer patients appropriately and to make personal career choices.

The training of specialists, of course, depends far more on the existence and proper functioning of referral hospitals. Again, a particular country will need to decide how many specialists it needs in which specialties and whether it should send its doctors abroad to specialize or train them internally. In

developed countries, 60 to 90 percent of doctors are specialists, whereas in developing countries the range is wider (for example, 76 percent of Indian doctors are specialists, 45 percent are specialists in Tanzania, and 31 percent are specialists in Morocco). A World Health Organization expert workshop agreed on a figure of 50 percent (Puzin 1996). Therefore, a country of 40 million would aim to train approximately 300 to 1,300 specialists per year. On average, such training lasts four years. Thus, at any time the academic referral hospital system would need to supply 1,200 to 5,200 residents. A guideline many countries use requires a ratio of postgraduate specialist supervision of not more than two residents per qualified specialist. This ratio can be used to get some idea of the referral hospital capacity required to train specialists.

Although basic doctors could spend most of their training time in primary care and district hospital facilities, with limited exposure to tertiary care hospitals, the training of specialists—as well as of other specialized allied staff members such as nurses for intensive care or specialized psychiatry, physiotherapists specializing in back injuries or burns, and pharmacists specializing in oncology—can take place only in referral hospitals.

In recent years, continuing medical education has grown in importance as the need for professionals to continually update their knowledge and acquire new skills has been more clearly appreciated. The coordination and provision of appropriate continuing medical education depends heavily on the specialists and academics associated with referral and academic hospitals.

Management and Administration. Referral hospitals in many developing countries play important roles in providing managerial and administrative support to other elements of the health system. These roles may include managing laboratory services on behalf of the whole health system; serving as the location for drug and medical supply depots and distribution systems and managing procurement systems; hosting and managing health information systems, often including epidemiological surveillance systems; managing centralized transport fleets; and, on occasion, providing financial management, payroll, and human

resource management services to other health units. Our intent is not to consider whether such arrangements are “right” or “wrong”—complex factors would have to be taken into account in every individual circumstance—but to note that making changes to the functioning of referral hospitals may have unintended consequences. For example, moving referral hospitals from funding based on a global budget to reimbursement systems based on patient activity may unintentionally cause hospitals to cease to provide these wider support functions if explicit alternative funding mechanisms are not established.

Research and Innovation. Referral hospitals tend to be where most health research is undertaken. Whereas in developed countries they may often be associated with the development of new technologies, in developing countries they are more often the site of research for the initial piloting and introduction of new technologies developed elsewhere and for the evaluation of their local suitability and field efficacy. Referral hospitals are also the vehicle for disseminating such technologies through the exposure of staff during training as well as through the role that referral hospitals frequently play in continuing professional education.

Research activities are vital in attracting and retaining specialist staff members who are required not just for the treatment of complex patients, but also for the training of new specialists. Research that is responsive to local conditions—that is, local disease burdens and technology constraints—fills a critical gap because researchers in developed countries and pharmaceutical companies do not generally pursue such research questions if they do not foresee sufficient returns to their investments.

Valuing the Indirect Contribution to the Health System. From the enumeration of the many roles of referral hospitals and their indirect effect on health through their contribution to the health system by way of supervision, administration, training, research, and quality improvement, it is immediately evident that these benefits cannot readily be translated into DALYs or any other metric to be used in a relative cost-benefit analysis.

Externalities and Intangible Benefits

The previous sections reviewed the various functions of referral hospitals within the health system, all of which contributed directly or indirectly to the health status of individuals. This section addresses other ways in which referral hospitals contribute to welfare and well-being, and comments on how they complicate the issue of valuing the contribution of referral hospitals in society.

Referral hospitals have a broader effect on overall societal welfare than can be captured by measures of health outcomes.

Utility, or welfare, includes health as one of many important outcomes, such as financial security, risk alleviation, and psychological reassurance. However, as Hammer and Berman (1995) note, health policy is typically conducted as if it has a unidimensional objective—namely the maximization of health (DALY) outcomes. Determining the appropriate resource allocation to referral hospitals purely on the basis of the cost of generating health (DALYs) may, therefore, seriously underestimate the optimum level of resources, because such measures will fail to capture the full welfare gains from the availability of higher-level health services. An example will highlight the difference between valuing hospitals on the basis of their contribution to health status alone compared with including wider concepts of welfare in the valuation.

Renal failure leading to the need for dialysis is relatively rare, and certainly rare in comparison to many other infectious and chronic diseases in lower- or middle-income countries. Treatment is lifesaving, but must continue indefinitely (involving visits two or three times every week) and is, therefore, extremely expensive. In many cases, dialysis can be justified only if it is linked to a renal transplant program, which terminates the need for dialysis and frees the equipment for someone else. The proportion of the total population who will benefit from such a referral hospital program is small; therefore, the DALYs generated are low, and the program would not rank high among the priorities given a limited budget. However, every member of the population is at risk of renal failure and, if affected, would find that, in the absence of a publicly funded program, he or she would either die or face extremely high costs to secure treatment in the private sector or abroad.

Even in poor countries, patients’ price elasticity of demand is low when faced with life-threatening illnesses, particularly when treatment can change the outcome. Studies on poverty have shown that a significant proportion of households that have become poor did so as a result of serious illness, which resulted in their liquidating assets to pay for health care (see, for example, Liu, Rao, and Hsiao 2003). Thus, people seek the peace of mind of knowing that they can obtain lifesaving treatment should they need it without the risk of incurring catastrophic costs of care. This additional welfare derives both from the financial security of not having to spend more than people can afford to save their lives and from the direct health benefits of treatment itself. The utility from the former (financial security) increases with the cost of the intervention required, whereas the utility derived from the latter (direct health benefits) is unrelated to the cost of the intervention. Paradoxically, one could, therefore, argue that the rarer a particular illness is—and the more costly the intervention required—the greater will be the welfare gain from public spending on that intervention.

This argument, of course, is likely to stand in direct contrast to the conclusions drawn from prioritization based on cost-effectiveness. For most individuals, willingness to pay is far less

than the costs of the procedure to them; however, because the whole population benefits from the security of knowing that each individual would be entitled to referral hospital care should he or she need it, in the aggregate the welfare value generated by public provision or funding may be many times greater than the value of the DALYs generated directly for those few patients who do receive treatment. This literature review did not find evidence of studies on national willingness to pay for referral hospital care in developing countries, but this area could be of interest for future research.

In practice, too, the public—particularly an urban, middle-income public—expects the government to provide care of last resort for complex trauma or diseases, especially for natural and man-made disasters. Thus, even though referral hospitals may provide care to a small number of people, often with limited health benefits, politicians and the public alike may value and prioritize them simply because they meet the public's expectations for what the government must provide. In addition, politicians and the public often regard a country's ability to provide the kind of complex, high-tech care offered in a referral hospital as a measure of that country's level of development and sophistication, and it is a source of national pride. Whether economically rational or not, this nonhealth benefit appears to drive public choices to some extent.

Negative Impacts

The “negative” impact of referral hospitals is largely attributable to their potential to exert distortionary effects on the health system by diverting resources from peripheral areas and from lower levels of care (Fiedler, Schmidt, and Wight 1998; Filmer, Hammer, and Pritchett 1997) for the following reasons:

- Tertiary hospitals and specialists have a high political and public profile.
- Urban and political elites are more likely to use referral hospitals than rural primary care facilities or district hospitals.
- Harmful competition with lower levels of care may result from the maintenance of higher-level referral hospitals in many poor countries, lowering use of the former.
- Referral hospitals can be entry points for the introduction into the health system of inappropriate and unaffordable technologies.
- Skilled personnel frequently find referral hospitals far more attractive to work at than rural and district hospitals for such reasons as preferences for a metropolitan location, better hospital resources allowing for a more rewarding professional experience, and better opportunities for private practice (official or unofficial). However, given the huge problem of global migration of health workers from poor to rich countries (Bundred and Levitt 2000), one could argue that well-functioning referral hospitals might

provide local health professionals with a good incentive to remain at home, whereas the absence of referral hospitals would increase the propensity of local professionals to emigrate.

DETERMINANTS OF AN APPROPRIATE BALANCE OF REFERRAL-LEVEL CARE

When one considers the ideal level of resources to be provided for referral hospital care and the appropriate balance between resources for referral hospitals and for other levels of the health care system, no simple formula is available that can be applied to different countries and contexts. However, certain key factors have an important influence on the need and demand for referral-level care, the resources that may be available to the health sector, and the ability of the health sector to provide adequate and effective care in different settings.

General Determinants

Arguably the most important determinant of demand for and ability to pay for referral hospital care is a society's level of economic development and wealth, captured (albeit imprecisely) by measures of GDP per capita. Extensive international evidence indicates that national health expenditure displays an unambiguously positive income elasticity both across countries and over time; that is, as a country gets richer, it spends relatively more on health (see, for example, Getzen 2000; Schieber 1990). Studies in developed countries indicate that in the United States, every 1 percent long-run increase in GDP leads to a 1.6 percent increase in health expenditure, and in other countries the increase is between 1.2 and 1.4 percent (Getzen 2000). Therefore, expecting developing countries to spend a higher proportion of their GDP on health care as they become wealthier seems to be reasonable. If the poorest countries were to focus their limited resources on highly cost-effective interventions in primary health care, somewhat better-off countries might be expected to spend progressively more on the referral hospital level as resources became available.

An overlapping set of demographic and geographical factors also plays an important role in determining the balance of referral care—namely, population size, population density, terrain, distances between main urban centers, and access. Populations of some millions are required to justify a major tertiary hospital with a full range of tertiary services. Small countries with populations of less than 1 million will certainly not be able to provide a full range of tertiary hospital services because of the need to achieve minimum volumes to ensure service viability and to attract a critical mass of specialized personnel. Countries with fewer than 100,000 inhabitants (generally island states) may find even secondary hospital services

beyond their means and capabilities. Supranational referral, reliance on larger neighbors, or regional collaboration may be unavoidable for smaller countries, especially for tertiary care provision, with the Caribbean and southern Africa providing clear examples of many smaller states relying on referral facilities in larger or wealthier neighbors. Within larger countries, population density can complicate the planning of referral services. Compact countries or regions with dense populations can typically provide high levels of access to referral care at a relatively small number of sites, whereas countries or regions with more dispersed populations face more complex tradeoffs regarding number of sites, volume thresholds, and transportation systems.

The other main influence on the appropriate balance of referral services for a given country is its particular pattern and burden of disease. Although referral-level services will always be needed, as a society passes through epidemiologic and demographic transitions, it is likely to require more of those services typically found at referral hospitals. For example, rapidly increasing rates of heart disease and cancers are typically encountered in industrializing nations and aging populations, and these are diseases whose effective management requires access to the interventions, skills, and equipment that will typically be concentrated at the referral hospital level.

Health System Determinants

A number of factors specific to the particular context of a country's health system will also influence the appropriate balance between referral hospitals and lower levels of care. These factors are especially important in considering the appropriateness of plans to change the balance of care between levels. Broadly, they can be summarized as follows:

- capabilities of lower levels
- availability of specialized personnel
- training capacity, organization, and needs
- cultural issues, political issues, and traditions.

The first three factors are closely interrelated. If primary health care and district hospital services are weak, cutting resources for referral hospitals without destabilizing the system will be more difficult. In such circumstances, rapid rebalancing of resources is unlikely to be possible because careful efforts will be required to develop lower-level services first, while still maintaining the referral service. Where lower-level services are strong, devoting relatively fewer resources to referral hospitals may well be possible. However, even though an effective district health system will be able to treat a large proportion of patients at lower levels of care, it will also be better able to identify patients who require referral for more complex care and, thus, may generate a greater appropriate demand for referral hospital care.

Referral hospital services require a specialized staff to fulfill their mission. If specialized personnel are not available in a country, then attempting to develop referral hospitals on a large scale will clearly be infeasible. However, many countries arguably have too many specialized staff persons and too few well-trained generalists. Where large numbers of specialists exist, their presence will likely tend to draw resources disproportionately toward the referral level and away from district health systems. Wherever such imbalances exist, positive changes will require a substantial training or retraining agenda. The feasibility of such efforts is closely linked to the professional and social status of different professional groups and subgroups—for example, whether medical specialists are viewed as having a higher status than general practitioners—and to the premium a society places on having access to “advanced” medical care.

CURRENT BALANCE OF CARE IN PRACTICE

In this section, we summarize data on the current balance between referral and lower levels of care. We first look at the share of total health expenditure going to these different levels, but given that referral care normally has much higher unit costs, we recognize that the balance also needs to be viewed in terms of volume of cases and access and equity.

Share of Health Expenditure

Different health systems categorize hospitals and services rendered differently. Methodologies in national health accounts in developing countries during the 1990s and early 2000s have tended to use a simple, catch-all category of “hospitals” or “acute hospitals” (for example, WHO 2002). Even high-income countries following the Organisation for Economic Co-operation and Development's system of health accounts provider classification (OECD 2000, 136) distinguish only between “general” hospitals and “mental health and substance abuse” and other “specialty” hospitals in their national health accounts. Consequently, making valid cross-country comparisons of spending by levels of hospital care remains extremely difficult.

Mills (1990a) reviews published data on hospital expenditure patterns in developing countries, and Barnum and Kutzin (1993) provide a comprehensive survey of expenditure on hospital services in a number of developing countries, drawing their information largely from World Bank sector reviews. These analyses remain the most authoritative assessment of the proportion of public health expenditure absorbed by secondary and tertiary hospitals, even though their data represent only a handful of countries at different points in time.

Overall, Mills (1990a) finds that hospitals in developing countries appear to absorb from 30 to 50 percent of total

health expenditure. Public hospitals of all types absorb some 50 to 60 percent of public health expenditure, and secondary and tertiary hospitals absorb about 60 to 80 percent of public hospital expenditure, with the remainder going to district hospitals. Her results are broadly similar to those of Barnum and Kutzin (1993, 26–33), who find that public hospitals at all levels absorb a mean of approximately 60 percent of recurrent public health expenditures. Across five countries (Belize, Indonesia, Kenya, Zambia, and Zimbabwe), they find that tertiary hospitals account for between 45 and 69 percent of total public expenditure on hospitals. In South Africa, Thomas and Muirhead (2000) find that tertiary hospitals account for 28 percent of hospital expenditure and 17 percent of total public health expenditure, but when taken together with regional referral hospitals, constitute 59 percent of hospital expenditure.

Unit Costs of Care

One of the explanations for the high share of expenditure that flows through higher-level referral hospitals is, of course, that the unit costs of a referral hospital are necessarily higher than the unit costs of a district hospital. This difference results from the more complex case mix they treat, their more expensive inputs, and the additional costs of their teaching functions (Barnum and Kutzin 1993, 26). Mills (1990b) reports that her analysis of available data indicated that secondary-level hospitals were typically twice as expensive per bed day as district hospitals and that tertiary hospitals were typically between twice and five times as expensive per bed day as district hospitals. Barnum and Kutzin (1993) find similar relationships between unit costs by level of hospital in a variety of different countries. This upward gradient in unit costs has also been found in econometric studies of hospital costs (Adam, Evans, and Murray 2003) and has been explicitly incorporated into the regression-based unit cost estimates used in other chapters in this volume.

Table 66.3 shows data on unit costs by level of care from Mauritius and highlights a commonly encountered contradiction of the preceding paragraph—namely, that costs appear

Table 66.3 Cost Per Bed Day in a Medical Ward by Level of Hospital, Mauritius, 1995
(2001 U.S. dollars)

Level of hospital	Cost
District	17
Regional	21
Tertiary	20

Source: Murray and others 1996.

Table 66.4 Cost Per Bed Day for Selected Specialties, Tertiary Hospitals, Mauritius, 1995
(2001 U.S. dollars)

Specialty	Minimum	Maximum
Medicine	16	20
Orthopedics	18	23
Pediatrics	29	43
Cardiothoracic surgery	36	39
Burns	37	37
Intensive care unit	106	120

Source: Murray and others 1996.

similar at all levels. This phenomenon is explained by average bed occupancy in Mauritian district hospitals of around 45 percent in 1995, compared with average bed occupancies of 90 percent or more in tertiary hospitals. Thus, the high cost of district hospital care in this case reflects not inputs, which are much less extensive than in a tertiary hospital, but the effect of low levels of utilization. Such a difference in utilization between levels of hospital tends to be the norm in many developing countries (Barnum and Kutzin 1993, 91–96). Note that the regression-based unit costs of district hospitals used in the cost analysis for this volume reflect an “optimized” bed occupancy of 80 percent (Mulligan and others 2003, 29). This assumption is entirely defensible from a long-run perspective, assuming cost-minimizing behavior is necessary and appropriate. It does, however, reflect quite a substantial shift from the levels of utilization and productivity commonly seen in rural district hospitals in most developing countries.

The use of a simple unit cost hides important cost differences between services and specialties within the same hospital, as demonstrated by the breakdown for Mauritian tertiary hospitals in table 66.4. Differences in length of stay for different specialties and conditions also obviously contribute to radically different costs per admission or patient; however, these differences should be captured by the condition and procedure costs used in the disease chapters in this volume.

Appropriateness of Utilization of Referral Hospitals

Perhaps the most frequent theme in the research literature on referral hospitals in developing countries is the inappropriate utilization of higher-level facilities and the apparent failure of most referral systems in developing countries to function as intended. Broadly speaking, hospitals of all levels, up to and including national tertiary centers—especially in their outpatients departments—are overwhelmed by patients who could have been treated successfully at lower-level facilities, many of

whom have self-referred, bypassing primary health care or district hospitals in the process (Holdsworth, Garner, and Harpham 1993; London and Bachmann 1997; Omaha and others 1998; Sanders and others 2001).

Atkinson and others (1999) describe an extreme manifestation of this phenomenon, whereby the University Teaching Hospital is actually the only public hospital in Lusaka. Combined with the bypassing of primary health clinics in the city, this situation results in the University Teaching Hospital's functioning primarily as a glorified health center and first-contact provider for most of Lusaka's population. The problem of bypassing typically seems to be driven by a number of factors, including patients' perception of superior quality of care and resource availability at referral hospitals, which often may be entirely well founded and rational (see, for example, London and Bachmann 1997; Nolan and others 2001); the desire to avoid delays in care if referral to a higher-level facility proves to be necessary; and the fact that for many urban populations a referral hospital may simply be the closest health facility. Grodos and Tonglet (2002) argue that many countries' failure to develop an adequate urban equivalent of the district health concept greatly exacerbates inappropriate utilization of hospitals. The urban phenomenon of widespread bypassing and self-referral is frequently accompanied by low rates of formal referral from rural and outlying facilities (see, for example, Nordberg, Holmberg, and Kiugu 1996; Omaha and others 1998).

These problems have a number of negative impacts and consequences. Simple conditions are unnecessarily treated in a high-cost environment; outpatient departments are congested by patients requiring primary care, thus causing long waiting times; scarce staff time is diverted from specialized areas and into inappropriate care; and more complex cases requiring specialized care are crowded out by more urgent but less technically demanding cases that could be cared for at lower levels. The latter has been a particular concern in those countries with more serious HIV/AIDS epidemics. As the number of patients falling sick with AIDS increases rapidly, they start to occupy a significant proportion of beds in hospitals at all levels (Gilks and others 1998), inevitably crowding out patients requiring other forms of care. Although AIDS cases may well require hospitalization, only a small proportion of cases require specialized or tertiary care. Gilks and others (1998) find that this crowding-out effect may fall over time as the health system adjusts to the pressures of AIDS, but countries facing impending AIDS epidemics should be prepared for its initial appearance.

Taken together, this complex of problems undermines the effective delivery of both specialized care and appropriate primary health care. Specialized care is pushed to the background by the human wave of demand for primary care, while hospitals unwittingly further undermine the credibility of the primary health care system through one-sided competition

(Stefanini 1994), which reinforces the cycle and ensures that primary health care facilities remain underused and inefficient.

Access and Equity

By their nature, referral hospitals must be limited in number and will inevitably be sited in major towns and cities. As a result, a significant portion of the population, especially people living in rural areas, will tend to live at some distance from the nearest referral hospital. Studies of the accessibility of referral hospital care in countries such as Ethiopia (Kloos 1990) and Nigeria (Lyun 1983; Okafor 1983) have repeatedly confirmed the existence of a steep distance-decay function, indicating that—other things being equal—individuals with a given need for a clinical service will be less likely to access that service the farther away from the referral center they live.

Compounding the impact of distance, investigators find that problems relating to the availability, regularity, and cost of transportation to referral centers also affect service utilization (Kloos 1990; Martey and others 1998). The same authors indicate that prohibitive hospital fees are often a significant barrier to utilization, especially among poorer patients. Other important barriers included perceived lack of drugs and essential supplies, even at referral centers; negative staff attitudes; and cultural and linguistic differences (for example, where the staff at a referral center does not speak the language of a patient from a remote area). As noted earlier, peripheral district hospitals also tend to have low rates of referral. These barriers, which all disproportionately affect rural patients, must be contrasted with the phenomenon noted earlier of excessive and inappropriate use of referral hospitals for primary care by urban residents.

In addition to finding that public hospitals favor urban residents over rural dwellers, a number of studies have indicated that public hospitals in many poor countries disproportionately benefit the better off, leading their authors to argue that diverting public funds from hospitals and toward primary health care would be pro-poor (see, for instance, Castro-Leal and others 2000; Filmer, Hammer, and Pritchett 1997; Mahal and others 2002). Other studies find this tendency in some countries but not in others (Makinen and others 2000). By contrast, in Latin American countries, Barnum and Kutzin (1993) find strong evidence that public hospitals are pro-poor in their distributional effect. Even if referral hospital services are not currently pro-poor, policy makers face two contradictory alternatives: either to retarget public funds toward primary health care for the poor, hence greatly reducing or abandoning public funding for referral hospitals, or to attempt to remove the barriers that prevent the poor from using higher-level services, which would probably require increased spending on all levels of care.

GETTING BETTER VALUE FOR MONEY FROM THE HOSPITAL SYSTEM

Although prescribing how resources should be allocated across levels of care is hard, at least they should be efficiently used, wherever they are spent within the hospital system. The preceding analysis has highlighted how deficiencies at the lower levels of the hospital system render referral hospitals less efficient and how factors that affect access lead to skewed benefits and inequity. Here we look more specifically at three areas for improving the efficiency of the hospital system: interventions within the referral hospital, the use of public-private partnerships, and strengthening of the referral chain.

Improving the Efficiency of Referral Hospitals

Although space does not permit a lengthy discussion of approaches to improve efficiency in the context of referral hospitals, this aspect is nonetheless important in planning and system strengthening (for a more detailed discussion see Barnum and Kutzin 1993; Hensher 2001; Walford and Grant 1998). In summary, the key areas on which planners and managers should focus are as follows:

- reducing inappropriate outpatient and inpatient use of referral
- improving systems to allow early discharge from the hospital
- ensuring that bed occupancy rates can be maintained as close as possible to optimal rates—namely, 85 percent for referral hospitals
- developing systems for booked outpatient appointments, admissions, and procedures to permit better planning of activity and staffing
- undertaking as much activity as possible on an ambulatory rather than an inpatient basis, supported by the use of “step-down” beds and patient hotels
- evaluating the staff skill mix and the potential for skill substitution, as well as efficient remuneration strategies, on a continuous basis
- evaluating and improving processes and systems, including cost-effective clinical guidelines for patient treatment, on a continuous basis
- ensuring that new or replacement referral hospitals conform as much as possible to available evidence on economies of scale—that is, that hospitals with fewer than 200 beds are likely to be scale inefficient and that diseconomies of scale are likely to become increasingly evident in hospitals with more than 600 beds
- adopting intelligent procurement processes and engaging in effective negotiations with suppliers in relation to prices and service levels

- ensuring effective ordering, stock control, and distribution systems to minimize theft and wastage of key supplies
- undertaking planned preventive maintenance and programmed replacement of equipment and buildings.

Can Public-Private Interactions Improve Efficiency?

In the context of this discussion, privately owned hospitals that provide subsidized care to public patients, such as nongovernmental organization and mission hospitals, are regarded as public hospitals. *Private* refers to for-profit hospitals that are generally funded by paying patients and are minimally subsidized. Few studies have been undertaken of how private hospitals operate in developing countries (see, for example, Muraleedharan 1999). Although the exact balance of and relationship between the public and private health sectors varies greatly from country to country at all levels of the health system, a common theme in almost all low- and middle-income countries is that private hospitals do not follow the pyramidal referral form that public hospital systems have adopted almost universally. Most private health sectors do not clearly delineate district, secondary, or tertiary hospitals. Different private hospitals may offer different services and facilities on a more or less idiosyncratic basis, with independent medical specialists practicing and admitting patients at various different hospitals.

In most systems, scope exists for both positive collaboration and competition between public and private hospitals, especially for secondary and tertiary services. Competition between public and private sectors obviously has the potential to be beneficial by driving quality up and costs down, but it may also have negative effects by encouraging a duplication of services and resulting in the underutilization of fixed capital by creating perverse incentives for physicians and patients and by competing with the public sector for scarce human resources. In some settings, the private sector may be able to offer services that the public purse cannot afford to provide, thus allowing patients who could not afford private care some chance of accessing sophisticated treatments through the government’s paying private providers or by some pro bono provision of treatment for poor patients.

In many countries, government hospitals are establishing private wards as a vehicle for income generation. The fees for such units are lower than those at private hospitals, offering access to private facilities to patients who may not be able to afford private hospitals. The link with academic medicine often adds to the appeal of such facilities. However, as is the case in South Africa, effectively only tertiary hospitals and a handful of secondary hospitals are felt to be attractive enough to private patients to offer genuine opportunities as preferred providers. The mass of district and regional hospitals are unlikely to be attractive to private patients; therefore, the positive spinoffs of these initiatives may be limited in their scale and reach.

Contracting out services to private providers, particularly high-cost, low-volume services, may be an efficient way to offer such services to public patients. For example, the government of Barbados contracts out surplus demand for dialysis to a private facility on the island. In some provinces of South Africa, expensive imaging such as MRI has been contracted out to private radiology practices. South Africa is also experimenting with contracting out the management of some academic referral hospitals to a private hospital group that is assumed to have greater management expertise and is free from certain public sector constraints, such as salary scales for senior managers. It is too early to judge the success of this arrangement, but in all cases it is imperative that contracts be carefully regulated, monitored, and enforced. For a comprehensive review of contracting, see Bennet, McPake, and Mills (1997).

Particular problems may arise where the same doctors provide care in both public and private hospitals. Under fee-for-service arrangements, physicians may focus on their more lucrative private patients to the disadvantage of public hospital patients, refer patients with adequate insurance to their private practices and private hospitals, and transfer patients with expensive diseases or inadequate insurance to public hospitals.

Improving the Functionality of Referral Systems

An ideal referral system would ensure that patients can receive appropriate, high-quality care for their condition in the lowest-cost and closest facility possible, given the resources available to the health system, with seamless transfer of information and responsibility as that patient is required to move up or down the referral chain. Although few referral systems anywhere in the world live up to this ideal fully, it does provide a target in relation to improving the current situation. Improving the effective functioning of referral systems broadly requires progress in three areas: referral system design, facilitation of the smooth transfer of patients and information between levels, and what Walford and Grant (1998, 38) refer to as effective “referral discipline.”

Improving referral system design must start with a detailed attempt to assess which services should be provided at which level of care, encompassing community- and home-based care, primary health care, district hospitals, secondary hospitals, tertiary hospitals, and specialized hospitals. Such an assessment must take local circumstances into account, requires a significant analytical and consultative effort by planners and clinicians if it is to be credible, and must explicitly be open to revision in light of practical experience. After such an exercise has identified which services can appropriately be provided at each level of care, adequate resources must be dedicated to strengthening lower levels of care to make them attractive and credible in the eyes of patients. This effort will require significant

investment and funding to ensure the availability of appropriate staff members and supervision, to ensure continuous drug supplies, and to provide basic laboratory tests (Walford and Grant 1998, 38). Given the pervasiveness of inappropriate use of referral hospitals for primary health care problems by urban residents, both urban and rural primary health care and district health systems must be adequately strengthened. Financing strategies that redistribute funds from urban to rural regions may unwittingly hamper such strengthening of the referral system by failing to allow for the development of appropriate lower-level facilities for urban residents. This risk is especially high when a country is pursuing a redistributive agenda against a background of limited or zero overall growth in expenditure.

From a physical planning perspective, planners should consider providing primary health care and district hospital walk-in ambulatory services (emergency and general outpatients) in a physically distinct facility sited immediately next to the referral hospital. This arrangement not only enables triage and filtering of less severe cases (while proximity ensures that severe emergency cases can be transferred rapidly) but also enables rigorous enforcement of a referral-only policy within the referral hospital.

The development of effective patient transportation arrangements is also critical, not only to ensure that patients from remote areas have a fair chance of being successfully referred to a center of excellence (bearing in mind that most referral systems will almost certainly need to increase referral rates from rural areas), but also to ensure that patients can be discharged in a timely and well-planned fashion.

Perhaps more challenging is the concurrent need to align the incentives of referral hospitals, district hospitals, and primary health care services. This goal may or may not be achievable by means of an integrated management structure, but it certainly requires a good deal of communication, collaborative planning, and collaborative development of shared care protocols, and senior personnel need to be given responsibility for coordination and liaison across key interfaces of the referral network. A single, global budget controlled by an authority that is concerned with optimizing the cost-effectiveness of health care delivery would seem to be a necessary condition to achieve alignment across service levels; however, a consideration of financing mechanisms is beyond the scope of this chapter.

At the patient level, a number of mechanisms to improve referral discipline can be considered. In situations in which eliminating nonreferred patients entirely from the referral hospital is impossible, queuing systems should be redesigned to separate referred patients from nonreferred patients so that referrals can be fast-tracked. Explaining to nonreferred patients why other patients are being fast-tracked past them is important to encourage them to seek referral in future. Ideally, they should be diverted to an on-site primary health care facility where they can be treated more quickly than in the referral

hospital. Another possibility may be to institute bypass fees for nonreferred patients, charging them a penalty fee for failing to use the referral system. Such a decision requires careful consideration and planning. Credible lower-level care must be readily available, and substantial efforts to communicate the new policy to the public will be required if this approach is to be seen as fair. More broadly, intensive public communication and education will be essential to inform the public how, where, and when they should seek health care at different levels and to build their confidence that lower-level facilities really will be able to offer acceptable quality care when they need it.

CONCLUDING COMMENTS

This review of the available evidence indicates that referral hospitals frequently do command a large share of health sector resources and expenditure, yet no simple way exists of assessing what an appropriate share would be. Strong referral hospitals can distort priorities and undermine basic services, but they also provide important health benefits to large numbers of patients whom they treat successfully. Referral hospitals provide essential support to lower levels of the system, which cannot function effectively without access to upward referral, and they are frequently the most functional component of the health system, paying greatest attention to quality of care.

Overall, we have argued that both national and international policy makers should be cautious before demanding the reallocation of resources away from referral hospitals and should be still more cautious in allowing themselves to believe that such a reallocation is likely to be achievable in practice. In particular, this chapter has made the case that a unidimensional focus on cost-effectiveness analysis and cost per DALY gained will fail to capture the importance of referral hospital services adequately. In reality, in most developing countries, the scope for reallocation of resources from referral hospitals to lower levels of care is limited, and the managerial demands of achieving a successful reallocation are great. Lower levels of care certainly require strengthening, but this need is more likely to reflect inadequate financing of the entire public health system than a grossly excessive allocation to referral hospitals. Instead, referral hospitals should perhaps be seen as the capstone of the referral pyramid: they should not be too heavy, but if they are too light, the levels below them will lose cohesion. A restructuring of referral hospital services is certainly called for to improve appropriate referral and utilization, especially by remote and rural populations; to transform the inappropriate use of referral hospitals as primary health care providers; to improve efficiency; and to provide much better outreach and support to lower levels of care.

This restructuring should not be confused with wholesale demolition. Undermining referral services will be far more

likely to undermine and destabilize the entire health system than to liberate resources for primary health care. Clearly, countries must critically evaluate their health priorities and their balance of care and resources between levels, but they should do so carefully and thoroughly, with a clear understanding of the analytical effort required to draw meaningful conclusions, of the planning and managerial capacity that they will require to bring about successful change, and of the long time frames required to develop and implement robust plans for major system changes.

Chapter 67 Surgery

Haile T. Debas, Richard Gosselin, Colin McCord,
and Amardeep Thind

Countries with developing economies have not considered surgical care to be a public health priority, yet surgically treatable conditions—such as cataracts (Javitt 1993); obstructed labor (Neilson and others 2003); symptomatic hernias (Olumide, Adedeji, and Adesola 1976; Rahman and Mungadi 2000); osteomyelitis (Bickler and Rode 2002; Hilton 2003); otitis media (Smith and Hatcher 1992; Whitney and Pickering 2002); and a variety of inflammatory conditions—add a chronic burden of ill health to populations. These acute and chronic conditions take a serious human and economic toll and at times lead to acute, life-threatening complications.

Inadequacies in the initial care of injured patients (Hyder and Peden 2003; Jat and others 2004; Mock 2003; Mock and others 1995); of women with obstructed labor; and of children with treatable congenital anomalies, such as clubfoot (Ponseti 1999; Turco 1994) lead to preventable deaths or to chronic disabilities that make productive employment impossible and impose dependency on family members and society.

The role of surgery as a preventive strategy in public health needs to be studied and measured far more extensively than is currently the case. Another key reason for this study is that virtually all countries are developing their economies, and as a result, developing nations are increasingly facing a double burden—that is, the infectious diseases that have historically been so relevant and the conditions that emerge with economic development (for example, trauma from motorcycle, truck, and car accidents). The inclusion of a surgery chapter in this book recognizes that surgical services may have a cost-effective role in population-based health care. Recent studies (for instance, McCord and Chowdhury 2003) show that basic hospital service, which requires no sophisticated care, can be cost-

effective, with a cost per disability-adjusted life year (DALY) that is much lower than might have been expected, and can be on a par with other well-accepted preventive procedures, such as immunization for measles and tetanus and home care for lower respiratory infections (Armandola 2003; Dayan and others 2004; Moalosi and others 2003; Ruff 1999).

We have identified four types of surgically significant interventions with a potential public health dimension: (a) the provision of competent, initial surgical care to injury victims, not only to reduce preventable deaths but also to decrease the number of survivable injuries that result in personal dysfunction and impose a significant burden on families and communities; (b) the handling of obstetrical complications (obstructed labor, hemorrhage); (c) the timely and competent surgical management of a variety of abdominal and extra-abdominal emergent and life-threatening conditions; and (d) the elective care of simple surgical conditions such as hernias, clubfoot, cataract, hydroceles, and otitis media.

NATURE, CAUSES, AND BURDEN OF SURGICAL CONDITIONS

Surgery is at the end of the spectrum of the classic curative medical model and, as such, has not been routinely considered as part of the traditional public health model. However, no matter how successful prevention strategies are, surgical conditions will always account for a significant portion of a population's disease burden, particularly in developing countries where conservative treatment is not readily available, where the incidence of trauma and obstetrical complications is high, and

where there is a huge backlog of untreated surgical diseases (Murray and Lopez 1996). Some surgical procedures can certainly be perceived as forms of secondary or tertiary prevention. Since the publication of the first edition of this book, which did not have a chapter on surgery, the health care community has recognized that the surgical management of some common conditions can indeed be a cost-effective intervention (Javitt 1993; McCord and Chowdhury 2003). The purpose of this chapter is to explore this hypothesis in more depth.

Methods for Determining Burden of Surgical Disease

We have arbitrarily decided to define a *surgical condition* as any condition that requires suture, incision, excision, manipulation, or other invasive procedure that usually, but not always, requires local, regional, or general anesthesia. We prefer this definition for two main reasons, to one that would define *surgery* as procedures performed by trained surgeons. First, surgery does not have to be performed by qualified surgeons. Indeed, in developing countries with few doctors, nondoctors can be trained to perform several types of operations satisfactorily. Second, we believe that the concept of surgery should include minor surgical procedures that nurses or general practitioners could perform along with nonoperative management of surgical diseases (for example, certain types of abdominal, thoracic, or head trauma and burns and infections). Any definition of surgery will have limitations, as has ours, and those limitations must be kept in mind when making interpretations, extrapolations, or estimates. Our broad definition is compatible with the concept of regionalized, coordinated, and interdependent services provided at the community clinic level and at the district and tertiary hospital levels. The most difficult task we then face is trying to determine the burden of surgical conditions as measured in DALYs. To our knowledge, this measurement has never been attempted. What we provide here is a starting point, with the understanding that the calculations will change as data are developed.

Our methodology was based on data from the *World Health Report 2002: Reducing Risks, Promoting Healthy Life* (WHO 2002) and the global burden of disease study (Murray and Lopez 1996). We began by listing all the conditions for which surgery might be indicated into three groups, with group I being communicable diseases, group II being noncommunicable diseases, and group III being injuries. We then undertook a comprehensive literature review for each condition to determine the proportion of the total burden of disease attributable to it and the proportion of the burden that could be prevented or treated by surgery. Essentially, we found no data of value except maybe for cataracts (group II-F), for which a single intervention (intraocular lens removal with or without implant) is or should ultimately be indicated for nearly 100 percent of patients (Dandona and others 1999; Javitt 1993).

The *World Health Report 2002* attributes 8,269, of a total 1,467,257,000 DALYs, to cataracts (0.56 percent), and all those DALYs are considered potentially surgical. Maternal conditions (group I-C), perinatal conditions (group I-D), diabetes (group II-C), intentional injuries (group III-B), and unintentional injuries (group III-A), to name a few, are much broader categories of conditions for which the demarcation between the surgical and nonsurgical burden is not as clear as for cataracts.

Faced with a near total lack of pertinent data, we decided that the next best approach was to try to obtain consensus on a “best educated guess” for the surgical burden of each condition. We developed a survey instrument that listed all the possible surgical conditions (all potential surgical DALYs representing the maximum imaginable DALYs that could conceivably be surgical). We sent the questionnaire to 32 surgeons in various parts of the world, asking them what was, in their opinion, the proportion of each condition that would require surgery, which we have referred to as *estimated surgical DALYs* or the *conservative minimum*. For each of the 18 completed questionnaires, we discarded the two lowest and two highest values for each condition, leaving a sample of 14 surveys. The lowest value of this sample was consistently chosen so as to err systematically on the conservative side. Note that more than 90 percent of all retained values were within 10 percent of the chosen value. We then applied this value to the DALY numbers provided by the *World Health Report 2002* for each category of potentially surgical conditions.

Findings

Table 67.1 presents our estimates of the actual surgical burden for each category of potential surgical conditions for the world as a whole and by region. The table indicates that conditions requiring surgery account for a significant proportion of DALYs. Developing more refined, region-specific information to help policy makers will require more detailed data on the burden of surgical diseases (diseases requiring surgical treatment) and on the cost-effectiveness of surgical therapy. To this end, an extremely helpful step would be for international surgical associations to regularly monitor the disease burden attributable to surgical conditions throughout the world.

A few salient points about the burden of surgical diseases can be made from data provided in table 67.1. We estimate very conservatively that 11 percent of the world’s DALYs are from conditions that are very likely to require surgery. Our estimated figures are as high as 15 percent for Europe and as low as 7 percent for Africa. Estimated surgical DALYs for the world are 27 per 1,000 population. The estimated figure is about twice as much for Africa (38 per 1,000) as for the Americas (21 per 1,000).

Table 67.2 summarizes the burden of common surgical conditions based on *World Health Report 2002* data. A more

a. *Estimated surgical DALYs* refers to our conservative estimate of DALYs averted by surgical treatment in the most likely diseases for the most likely indications.

detailed look at these data allows us to make the following observations:

- Injuries account for 63 million DALYs, or about 4 percent of all DALYs and 38 percent of the world's estimated surgical DALYs.
- Surgical infections, including infected wounds, superficial and deep abscesses, septic arthritis, and osteomyelitis, undoubtedly account for a significant portion of surgical DALYs, but the available data do not permit quantification.
- Surgical DALYs pertaining to acute abdominal conditions, including appendicitis, intestinal obstruction, gastrointestinal bleeding, hernias, and blunt or penetrating injuries also cannot be calculated because of the lack of data.
- Approximately one-third of maternal conditions, including hemorrhage, obstructed labor, and obstetrical fistulas, are surgical, and these represent 10 million DALYs, or 0.7 percent of all DALYs.

- *Congenital anomalies* refer to an ill-defined grouping of disparate pathologies that includes congenital malformations such as cleft lip and palate, hernias, anorectal malformations, and clubfoot. We estimate that some 50 percent of congenital anomalies are surgical, representing about 14 million DALYs, or 1 percent of all DALYs.
- Malignancies account for 31 million surgical DALYs, or slightly more than 2 percent of all DALYs.

Table 67.3 breaks down the burden of common surgical conditions by region, also showing rates per 1,000 population. The absolute burden of injuries is highest in Southeast Asia, followed by the Western Pacific and Africa. In terms of population rates, whereas injuries account for 10 DALYs per 1,000 population for the world, the estimated figure is almost twice as much for Africa (15 per 1,000) as for Europe (8 per 1,000). Similarly, rates of obstetrical complications are far higher in Africa than elsewhere, at 6 DALYs per 1,000 population. In

Table 67.3 Estimated Surgical DALYs by Condition and Region
(DALYs in millions followed by DALYs per 1,000 population in parentheses)

Condition	Africa	Americas	Eastern Mediterranean	Europe	Southeast Asia	Western Pacific
Injuries	10 (15)	7 (8)	6 (12)	7 (8)	20 (13)	13 (8)
Obstetrical complications	4 (6)	1 (1)	1 (2)	(<0.5)	3 (2)	1 (1)
Cataracts and glaucoma	1 (2)	(<0.5)	1 (2)	1 (1)	3 (2)	2 (1)
Malignancies	2 (3)	4 (5)	1 (2)	8 (9)	6 (4)	10 (6)
Perinatal conditions	2 (3)	1 (1)	1 (2)	(<0.5)	3 (2)	1 (1)
Congenital anomalies	2 (3)	2 (2)	2 (4)	1 (1)	4 (3)	3 (2)
Other	4 (6)	3 (4)	3 (6)	5 (6)	9 (6)	7 (4)

Source: WHO 2002 and authors' estimates.

contrast, Europe has the highest rate of surgical DALYS related to malignancies—9 per 1,000 population.

All these estimates are debatable. Work is needed to obtain more valid, accurate, and reliable data, but in the meantime, we believe that our results represent a conservative and acceptable baseline estimate of the burden of surgical conditions against which prospectively gathered data for given interventions can be compared in order to assess the extent to which they address the burden. In addition, the burden needs to be monitored over time. Evidence suggests that the burden of intentional and unintentional injuries is rising, particularly in Sub-Saharan Africa and the Middle East. Some of the important contributing risk factors include (a) aging populations; (b) increased access to and use of mechanized vehicles and tools without commensurate improvements in roads, traffic control systems, or capacity for trauma care; and (c) persistent armed conflicts (Kaya and others 1999; Krug, Sharma, and Lozano 2000; Meyer 1998; Mock and others 1995, 1999; Nantulya and Reich 2002; Peden and Hyder 2002).

INTERVENTIONS

Both population-based strategies and personal services provided in community clinic, district, and tertiary hospitals are considered in this section.

Population-Based Strategies

Population-based approaches to the prevention of unintentional and intentional injuries are discussed in the chapters on

those topics. A population-based approach to injury should not, however, be limited to injury prevention. Patients may survive their primary injuries only to become chronically disabled and a burden to their families and to society (Krug, Sharma, and Lozano 2000; Mock and others 1999; Nantulya and Reich 2002; Peden and Hyder 2002). The incidence and severity of the complications of survivable injury may be significantly lessened by the provision of adequate surgical care during pre-hospital care and initial hospitalization. No published data from developing countries are available, however, either to prove this plausible contention or to quantify the benefits of adequate initial surgical treatment. A strategy to prevent chronic disability arising from survivable injury requires well-coordinated services for resuscitation, evacuation, and early and expert operative management of the initial injury.

Many other surgical conditions that can be treated electively, such as hernias, hydroceles, and otitis media, are treated when they present with complications requiring emergency surgery. Thus, a pertinent question is whether treating such conditions electively would be more cost-effective, but no reliable data are available to answer this question positively or negatively.

Population-based strategies could also be applied to prevent or treat some musculoskeletal conditions. For example, the incidence of clubfoot is estimated at 1 or 2 per 1,000 live births, but in developing countries these children are typically brought in for orthopedic care when it is too late for effective nonsurgical conservative management (Ponseti 1999; Turco 1994). Because we have no baseline data for the burden of clubfoot and other musculoskeletal conditions, we are unable to

quantify the DALYs that could be averted by comprehensive surgical care.

The following sections describe the organization of surgical services that we think would begin to provide coordinated surgical care in developing countries. The provision of surgical services in developing countries requires organizational structure and capacity at the level of community-based clinics, district hospitals, and tertiary care hospitals. Our concept of minimally adequate modules of surgical care is informed by our personal experiences, the experiences of others, and a recent World Health Organization report (WHO 2003). We recognize that to accommodate local needs and reality on the ground, any proposed plan to develop surgical services must be flexible. Table 67.4 presents our estimates of the needs for infrastructure, equipment and supplies, and workforce for the three levels of surgical care: community clinic, district hospital, and tertiary hospital.

Community Clinics

Table 67.4 shows resource and workforce requirements and types of surgical services a community clinic could provide for a population of around 20,000. We assume that surgical services in community clinics would be provided at no cost to patients. A cost-recovery system would be unlikely to succeed everywhere but, if implemented, should be equitable, with payments adjusted to patients' ability to pay. A mechanism for accountability and monitoring should be established to avoid the misuse of drugs and supplies. Simple patient records should be maintained, including outcomes of treatment and use of supplies. Even though the community clinic described here is what we think it should be as opposed to what we know it to be, our model may serve the needs of rural areas in developing countries and could provide a starting point for estimating costs.

District Hospitals

The next level of organization of surgical services is the district hospital, which in addition to providing primary care for the local population would also provide secondary-level surgical services and serve as a referral center for a number of community clinics in a defined region. In turn, the district hospital would ideally refer patients requiring complex surgical care to a tertiary-level hospital, but we recognize that such referral cannot always be achieved in practice because of transportation limitations, economic constraints, and prevalent social and cultural contexts. District hospitals vary in size from as small as 10 to 20 beds to as large as 200 to 300 beds and vary in their degree of sophistication in relation to diagnostic and therapeutic capabilities. For this discussion, we have arbitrarily chosen to focus on district hospitals with 100 beds or fewer.

Table 67.4 shows the infrastructure requirements for this type of hospital. Patients requiring more complex imaging studies and laboratory tests would be referred to the tertiary hospital.

To the extent possible, all equipment and supplies (table 67.4) should be standardized, and an efficient and reliable system for maintenance and replacement should be ensured. Operating room instruments and supplies should be available to enable the performance of laparotomy, thoracotomy, obstetrical and gynecological procedures, treatment of extremity fractures, skin grafting, and emergency burr hole of the skull. These instruments should be available at least in duplicate. Table 67.4 also shows workforce needs and the types of surgical procedures that may be performed in a district hospital.

The district hospital is assumed not only to serve as the referral hospital for community clinics, but also to coordinate the community clinics in its own region as a single operating unit, assuming responsibility for wireless communication, training the workforce, providing continuing medical education, and monitoring the quality and outcome of care. It would also provide primary care to its contiguous population.

Tertiary Hospitals

The tertiary hospital would function as the referral center for all complex surgical care in a region, country, or group of countries. Ideally, but depending on the country's resource constraints, it would provide the full range of care shown in table 67.4. The tertiary hospital would also provide primary surgical care for its local population and could take on the role of a teaching hospital for doctors, nurses, and other health care workers.

In the proposed organizational structure, the tertiary hospital is viewed as the top of a pyramid of surgical services, with several district hospitals referring patients requiring complex surgical care to the tertiary hospital. As such, it should also take the primary responsibility for coordinating and collaborating with all the district hospitals and community clinics in its area of responsibility to ensure that surgical care is available throughout the region and that well-functioning wireless communication and ambulance systems are available. If a regionalized system of separate ambulance services is not available, the tertiary hospital can provide the ambulance services required. Specialists in the tertiary hospital should provide telephone and electronic consultation for doctors and nurses in district hospitals. The tertiary hospital should also coordinate and monitor the quality of care in the region that serves as its referral base, undertake clinical outcome studies, and provide continuing medical education. In addition, it should be the main teaching hospital for medical students, nurses, and technicians, with the district hospitals and even the community clinics serving as clinical rotation sites for trainees. This organizational

Table 67.4 Resource Requirements for Surgical Services and Surgical Procedures by Level of Care

Category of requirement	Community clinic	100-bed district hospital	Tertiary hospital
Infrastructure	Weatherproof building (100 square meters) Storage space Clean water supply Power supply	Inpatient facility of 100 beds including several wards and an isolation ward Outpatient facility including an emergency room Operating rooms (at least two: one clean, one contaminated) Labor and delivery rooms Recovery room or intensive care unit Blood bank Pharmacy Clinical laboratory Radiology and ultrasonography suite	A major facility providing: <ul style="list-style-type: none"> • Full emergency services with advanced diagnostic services; • Inpatient wards for complex general medical and surgical care • Various types of specialty services • Several delivery rooms and operating rooms • One or more recovery rooms and intensive care units • Rehabilitation and occupational therapy facilities
Equipment and supplies	Furniture Refrigerator Blood pressure machine Minor surgical trays Sterile and burn dressings Autoclave Intravenous sets and solutions Bandages and splints Drugs: local anesthetics, nonsteroidal anti-inflammatory drugs, antibiotics, tetanus toxoid, silver nitrate ointment, oxytocin, magnesium sulfate Wireless communication equipment Materials for recordkeeping	Anesthetic machines and inhalation gases Monitors (electrocardiogram, blood pressure, pulse oximetry) Fully equipped operating room Fully equipped delivery room Fully equipped recovery room or intensive care unit Respirators and oxygen supply Blood products and intravenous fluids Basic microbiology equipment Pharmaceuticals (anesthetics, analgesics, antibiotics) Surgical materials (drapes, gowns, dressings, gloves) and other consumables (disposable equipment and devices)	All required equipment and supplies to undertake the range of routine and complex services provided
Human resources ^a	Nurse or nurse equivalent Skilled birth attendant Orderly	Nurses (20) Midwives (2–3) Anesthetists (2–3) Anesthesiologist (1) ^b Primary care physicians (4) ^c Obstetrician/gynecologist (1–2) General surgeons (2) Pharmacy assistants (2) Pharmacist (1) ^b Radiology technician (1) Radiologist (1) Physiotherapist (1)	Nurses (50) Midwives (5) Anesthetists (5) Anesthesiologists (3) Primary care physicians (10) Obstetricians/gynecologists (5) General surgeons (5) Orthopedic surgeon (1) Pharmacy assistants (2) Pharmacist (1) Radiology technicians (5) Radiologists (2) Physiotherapists (5) Neurosurgeon (1) ^b Cardiac surgeon ^b Reconstructive surgeon ^b

Category of requirement	Community clinic	100-bed district hospital	Tertiary hospital
Services provided	Simple suturing and dressing of wounds Incision and drainage of abscesses Care of simple burns Control of hemorrhage Splinting Deliveries Vacuum extraction and manual vacuum aspiration	Emergency abdominal, thoracic, head injury Uncomplicated general surgical operations for hernias, anorectal conditions, and biliary tract disease Surgical infection treatment and control Obstetrical (including surgery for complications) Simple orthopedic care: extremity fractures, dislocations, and amputations Burn care Physiotherapy and occupational therapy Education and training	Full emergency service Management of all complex general surgery Full range of services in orthopedics, trauma, urology, otolaryngology, ophthalmology, and obstetrics and gynecology Basic (and, if resources permit, advanced) neurosurgery and cardiovascular surgery Intensive care services Major burn service Radiology services including CT and MRI imaging and angiography Full service clinical laboratory Physiotherapy Occupational therapy Training of doctors, nurses, and midwives

Source: Authors.

a. Because of the variability in size and the complexity of services provided by tertiary hospitals, it is difficult to describe a standard tertiary hospital; the human resource needs given in the table represent what we think are minimally adequate.

b. Desirable, but not absolutely necessary.

c. Can be a general internist, general practitioner, or general pediatrician.

structure is ideally suited for the tertiary hospital to serve as the backbone of community-based surgical education. The extent to which this ideal function of a tertiary hospital can be implemented will depend on the financial and other resources available to the country.

Coordinated Model System for Surgical Care

The proposed system for surgical services requires the coordination and integration of the following:

- wireless communication
- continuing education programs
- regionalized supply system for equipment, essential drugs, and surgical materials
- ambulance service
- uniform data collection system
- coordinated and ongoing monitoring of quality and outcomes of care.

A wireless system of communication could render costly wired systems unnecessary and could connect community clinics, district hospitals, and tertiary hospitals in a dependable way that facilitates consultation and referral. A Web-based system of communication could be particularly important for mentoring and for providing continuing medical education. The Web can also be used to enhance contributions by volunteer surgeons, anesthesiologists, surgical specialists, nurses, and technicians

from around the world. Associations such as the International Surgical Association could develop a Web portal tied to national surgical associations to ensure greater success in this regard.

A regionalized system for the purchase and delivery of equipment and supplies is highly desirable. Such a system could ensure that all equipment and supplies were standardized and made available on demand in an efficient and predictable manner.

Ground ambulance services are essential for patient transfer. In some areas, collaboration with local taxi or bus services might offer the needed support. In some more economically advanced countries, tertiary hospitals might be able to provide ambulance services using fixed-wing aircraft or helicopters.

If the proposed model for a surgical system is to be developed, systems for ongoing data acquisition and for evaluation and monitoring should be built into the model. In this way, not only could information be captured, but also the quality and outcomes of care could be monitored on an ongoing basis.

COSTS AND COST-EFFECTIVENESS OF INTERVENTIONS

In today's resource-constrained world, policy makers increasingly need to be aware of the value of selective health care interventions. Cost-effectiveness analysis is one method that links inputs (costs) with the resulting health care gains measured along a common metric, usually using DALYs.

Even though an extensive body of literature examines the cost-effectiveness of a range of nonsurgical interventions in developing countries (Jha, Bangoura, and Ranson 1998), the literature examining surgical interventions in these countries is more sparse. Moreover, most of the available studies examine surgical interventions for specific conditions (Marseille 1996; Singh, Garner, and Floyd 2000). A common criticism of such studies is that they do not fully capture the choices policy makers face in real life. For example, policy makers must often choose between allocating resources for constructing several community clinics or a single district hospital, both of which provide a mix of surgical and nonsurgical services. Generally, the surgical ward in a district hospital will provide care for a wide range of conditions, such as trauma, childbirth, and abdominal conditions. We assume that for policy makers, knowing the cost-effectiveness of the surgical service, ward, or clinic (as an intervention) is more useful than information about the cost-effectiveness of each condition-specific surgical intervention. Unfortunately, no literature exists that examines the cost-effectiveness of a surgical service or ward. This section attempts to fill that void with respect to district hospitals and community clinics but not in relation to tertiary-level hospitals, which vary in size, available resources, and role from region to region, making it difficult to describe the cost-effectiveness of a prototypical tertiary hospital.

Method for Estimating Costs and DALYs

On the basis of the resource requirements listed in table 67.4, we developed cost estimates for each of the six regions defined by the World Bank. Table 67.5 details the assumptions and table 67.6 provides the regional costs. We defined the standard hospital in such a way as to facilitate comparisons across regions, conceptualizing it as a 100-bed hospital with a male ward and a female ward; two operating rooms; a recovery room, an intensive care unit, or both; an x-ray unit and an ultrasound machine; and a laboratory that can carry out basic blood chemistry tests, examine urine, and cross-match blood. This hospital also has an on-site laundry and kitchen and two vehicles to serve as ambulances. The staff consists of 6 doctors (4 primary care physicians, 1 obstetrician and gynecologist, and 1 general surgeon); 20 nurses; 6 midwives; 2 physiotherapists; and 6 orderlies. The costs of an anesthetist and x-ray technician have been included in the operating costs of the operating rooms and radiology area, respectively. The model assumes that the hospital averages 80 percent occupancy and that two-thirds of inpatients will be surgical cases.¹

We defined a standard community clinic (see table 67.4) as a facility of 100 square meters serving a population of approximately 20,000, staffed by a nurse or nurse-substitute, a skilled birth attendant, and an orderly. Such a clinic treats approximately 4,000 surgical cases per year, with a *surgical case* being

defined as treatment of bruises, simple cuts requiring suturing, foreign body removal, drainage of abscesses, basic burn treatment, normal deliveries, and simple trauma.

As far as possible, we used standardized regional cost estimates provided to the authors. When such information was unavailable, we used our consensus judgment. Given the wide variation in costs between and within regions, we conducted sensitivity analyses to capture the range of possible outcomes. When more than one source of cost estimates was available, the mean of the estimates for that region were used as the best estimate and a high-low range was noted. However, in many cases, only a single cost estimate could be obtained, in which case the data provide a point estimate,² and we vary the cost estimate by ± 20 percent to obtain a high-low range.

Our calculation of the number of DALYs averted was based on the work of McCord and Chowdhury (2003), who calculate the DALYs averted by a 50-bed hospital in Bangladesh, as described in box 67.1. We adjusted this figure to reflect the bed size of our standard district hospital. In the absence of region-specific data, we applied this figure to all six regions after making suitable adjustments. For the community clinic, we estimated that such a clinic averts approximately 200 DALYs per year as a result of surgical treatment, primarily from the incision and drainage of abscesses and the preliminary treatment of burns. Because these DALY estimates are based on a single source, we vary the estimate by ± 20 percent to obtain a high-low range and apply these estimates across the six regions.

Results

Figure 67.1 presents the results of the cost per DALY averted calculations for a district hospital and community clinic. The low estimate represents the scenario in which the costs are the lowest and the DALYs averted are the highest—that is, the best-case scenario. In a similar vein, the high estimate is the worst-case scenario: the costs are highest and the DALY averted is the lowest.

The best estimates for cost per surgical DALY averted at a community health center (panel a of figure 67.1) hover in a narrow range between US\$212 and US\$241. The cost per surgical DALY gained at a district hospital is cheapest for Sub-Saharan Africa at US\$33 (range of US\$19 to US\$102) and most expensive for Latin America and the Caribbean at US\$94 (range of US\$47 to US\$164).

Standard economic costs can differ from costs actually incurred in service delivery, both because in practice not all time may need to be paid for (for example, hospitals may be able to economize on staff because relatives help care for patients) and because low-cost solutions may be found (for example, use of paramedical staff members in place of professionals). Box 67.2 describes some of these strategies and compares the standard economic cost presented above with the much lower financial cost of a nongovernmental organization (NGO) hospital.

Table 67.5 Costing Assumptions for District Hospital and Community Clinic

Category	Assumptions and comments
<i>100-bed district hospital</i>	
Inpatient hospital bed days	The estimate includes “hotel” costs (capital, salaries, overhead, building, equipment, and food) for a hospital running at 80 percent occupancy. Assumption: two-thirds of all cases seen are surgical and costs are adjusted accordingly.
Operating rooms	The estimate includes all operating room–related costs (surgeon, nurses, equipment, and so on). Assumption: the operating room is running for 8 hours/day, 5 days/week, 52 weeks/year.
Laboratory	Assumption: 16 new admissions/day, all of whom will require a laboratory test once during their hospital stay. Yearly costs have been adjusted to reflect the percentage of surgical cases.
X-ray	Assumption: 16 new admissions/day, of whom half will undergo an x-ray examination once during their hospital stay. Yearly costs have been adjusted to reflect the percentage of surgical cases.
Pharmacy	Assumption: all admitted patients will use US\$10 worth of drugs during their stay. Yearly costs have been adjusted to reflect the percentage of surgical cases.
Blood transfusion	Assumption: 400 units of blood transfused/year.
Ambulance	The estimate includes 2 ambulances; 15 percent markup for freight, insurance, and distribution; US\$500/year running costs added; ambulance depreciated over 9 years.
Staff	
Nurses	Assumption: nurses devote two-thirds of their time to surgical patients and costs have been adjusted accordingly.
Midwives	Assumption: midwives devote 100 percent of their time to surgical patients.
Doctors	These are the four doctors whose costs have not been included in the operating room costs listed above. Because they provide ward coverage, two-thirds of their costs are attributed to surgical patients.
Physiotherapists	Assumption: physiotherapists devote two-thirds of their time to surgery patients.
Orderlies	Assumption: six orderlies, each devoting two-thirds of their time to surgical activities.
<i>Community clinic</i>	
Building costs	The estimate includes costs of lighting and power. Assumption: building size is 100 square meters, 20-year straight-line depreciation is used; 25 percent of costs are attributed to surgical patients.
Water supply	Assumption: US\$20 for water supply, of which 25 percent attributed to surgery.
Supplies	The estimate includes surgical trays, sterile and burn dressings, intravenous sets and cannulas, bandages, splints, and plaster of Paris for 4,000 patients. Assumption: local costs of US\$5/patient.
Drugs	The estimate includes local anesthetics, nonsteroidal anti-inflammatory drugs, tetanus toxoid, silver nitrate, and basic antibiotics. Assumption: 4,000 patients, US\$5/patient.
Furniture	The estimate includes autoclave, surgical light, examination table, and beds. Assumption: total cost US\$2,000, straight-line depreciated for 10 years.
Refrigerator	The estimate includes locally manufactured refrigerator, straight-line depreciated for 5 years; surgical cost attribution only.
Wireless telephone	Assumption: US\$200 cost; 25 percent attributed to surgery.
Staff	
Nurses and nurse-substitutes	Assumption: nurses devote 25 percent of time to surgical duties and costs adjusted accordingly.
Skilled birth attendants	Assumption: attendants devote 25 percent of time to surgical duties and costs adjusted accordingly.
Orderlies	Assumption: orderlies devote 25 percent of time to surgical duties and costs adjusted accordingly.

Sources: Authors.

Note: The figures for the district hospital should be viewed with particular caution. First, we used a single source of data for our assumptions. Had we used other data sources, the results could conceivably be different. Second, as a prototype we used a Sub-Saharan Africa district hospital that provides basic, low-tech surgical services. The provision of more sophisticated care can be expected to drive up the costs of care significantly.

Discussion

The data in figure 67.1, when compared with similar data for other services presented in this book, indicate providing basic surgical services is relatively cost-effective. Figure 67.1 also indicates that, from a surgical perspective, the costs per DALY

averted at a community clinic tend to be higher than those averted at a district hospital despite the lower costs of a community clinic. Although these observations may be taken as evidence that surgical services are best provided at the district hospital level, this goal may be impossible to put into practice.

Sources: All district hospital costs and community clinic building and staff costs: DCPD guidelines; other community clinic costs: authors' estimates.

The type of surgical care provided at the community clinic level, though not resulting in a very large DALY gain, is nevertheless important. It is inconceivable to think of a community clinic that does not have facilities for minor foreign body removal, simple suturing of cuts and wounds, or splinting of simple fractures. Furthermore, community clinics' referral and primary treatment functions, which are hard to evaluate separately from the delivery of final treatment, are critical for many conditions, notably trauma.

Costs per surgical DALY averted at the district hospital level seem to fall into three groups. Sub-Saharan Africa and South Asia are the cheapest, with the best estimates of cost

per surgical DALY averted ranging between US\$33 and \$US38; Europe and Central Asia, Middle East and North Africa, and Latin America and the Caribbean seem to be the most expensive, with the cost per surgical DALY averted ranging between US\$77 and US\$94; and East Asia and the Pacific falls in the middle. This finding indicates that, from the perspective of providing surgical care, a district hospital is an exceptional "buy" in Sub-Saharan Africa and South Asia, both areas with high disease burdens. Coupled with evidence that district hospitals are comparatively underfunded compared with national (tertiary) hospitals (Fiedler, Wight, and Schmidt 1999), a prima facie case exists for increasing support for

Box 67.1

Estimation of the DALYs Averted by a Small Hospital in a Developing Country

The DALY estimates in this chapter are based on a report from a 40-bed nongovernmental hospital in rural Bangladesh in 1995 (McCord and Chowdhury 2003). Obviously this experience was localized from one hospital, in one country, at one time, but it is the only analysis available from such a hospital that estimates effectiveness using DALYs or any other measure of the effect of a hospital on the disease burden. The hope is that other similar studies done in a variety of hospital situations will permit generalizing with more confidence, but our personal experience leads us to believe that the disease pattern presented to small district hospitals in poor countries is remarkably constant, especially for surgical conditions.

McCord and Chowdhury (2003) present the methods for calculating DALYs in detail. They reviewed all discharges and deaths every week for three months, confirmed the discharge diagnosis by means of a chart review, and estimated the percentage chance that the hospital stay had prevented death or disability. The review covered all patients discharged, classifying them as medical, surgical, obstetrical and gynecological, or pediatric. Of the discharges, 62 percent were of surgical and obstetrical and gynecological patients. Of the DALYs, 21 percent of those averted were for surgical patients and 61 percent from obstetrical and gynecological patients. Eighty-nine percent of the estimated DALYs averted were generated by averting premature death, and only 11 percent by preventing serious disability. Of the 192 surgical operations, 118 were emergencies. Of 137 obstetrical patients, 81 had complicated deliveries, complications of abortion, or ectopic pregnancies.

Source: Authors.

Our estimates of the risk of death or serious disability were based on tables McCord and Chowdhury created and were necessarily arbitrary, but we believe they are extremely conservative. For example

- If the chance of death or disability was less than 5 percent, it was considered to be 0 percent. Because normal out-of-hospital deliveries had less than a 5 percent chance of death or disability, normal deliveries in the hospital made no contribution to the estimated DALYs averted.
- A cesarean section for obstructed labor was estimated at 10 percent averted risk for the infant and 0 percent for the mother.
- A cesarean for transverse lie was estimated at 90 percent averted risk for the infant and 90 percent for the mother.
- An appendectomy for nonruptured appendicitis was estimated at 10 percent averted risk, because many cases of appendicitis respond to antibiotics outside the hospital setting.
- An appendectomy for a ruptured appendix with generalized peritonitis was estimated at 90 percent averted risk.
- An elective herniorrhaphy for a small hernia was estimated at 0 percent averted risk.
- A herniorrhaphy for a large, disabling hernia was estimated at 80 percent averted risk.
- A herniorrhaphy for a strangulated hernia that did not reduce with conservative management was estimated at 80 percent averted risk.

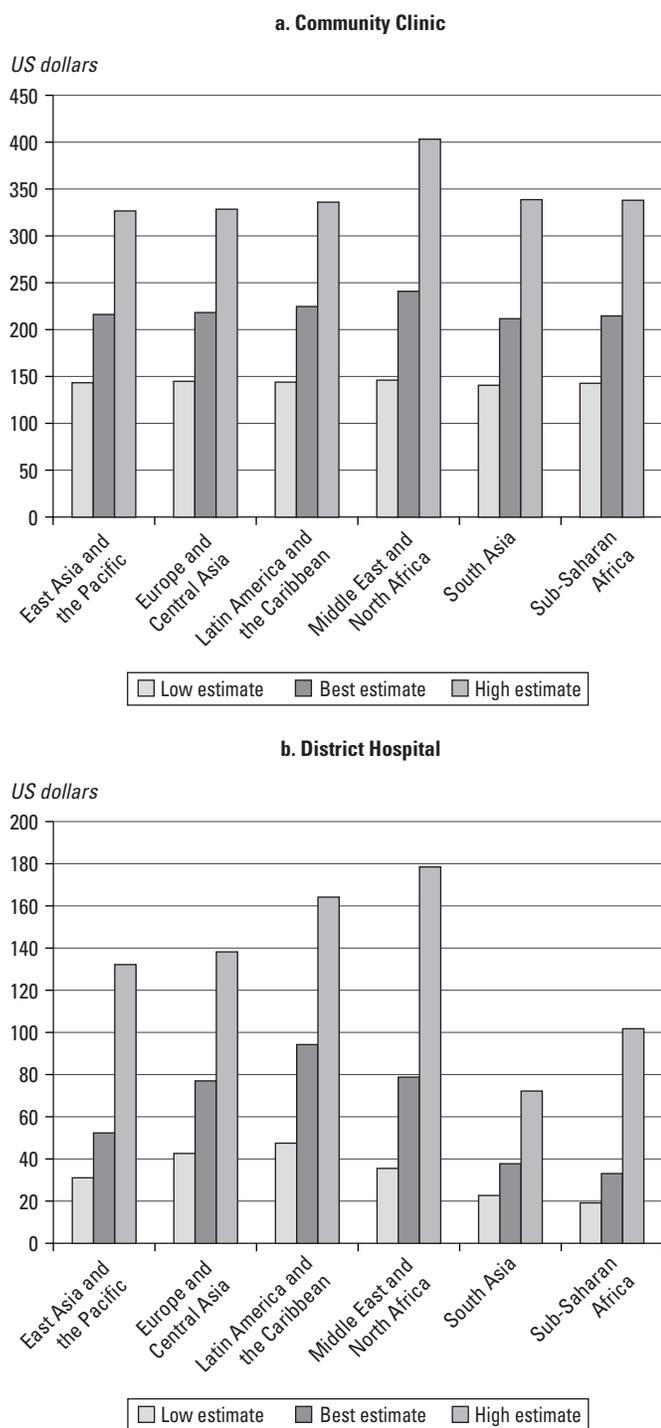

district hospitals in developing countries. However, those providing such support have to be cognizant of realities on the ground, especially political realities, because they have a significant effect on the direction of change (Blas and Limbambala 2001).

Data on the cost-effectiveness of surgical interventions for specific conditions in developing countries are scarce. One notable exception is for the surgical treatment of cataracts (removal of the opaque lens with or without the insertion of an intraocular implant). Blindness from cataracts is a significant public health problem in many developing countries, and as their populations age, estimates indicate that by 2020 more

than 40 million people will be blind or almost blind because of cataracts (Brian and Taylor 2001). Box 67.3 describes a successful program in India.

RESEARCH AND DEVELOPMENT AGENDA

The literature on surgical care in developing countries is so meager that insufficient data are available to formulate an agenda for research and development. Hence, of necessity, the research that needs to be done is extremely basic, much of it

Source: Authors' calculations using costs in table 67.6 and methods for estimating DALYs averted described in box 67.1.

Figure 67.1 Cost per Surgical DALY Averted for a Community Clinic and a District Hospital

information gathering. The following are some of the areas that require investment in research and development:

- Estimates are needed of the burden of disease that requires surgical intervention along with a determination of region-

specific DALYs that can be averted by means of surgical intervention. We have applied the DALYs averted from a single study in a developing country (McCord and Chowdhury 2003) to other regions, a procedure that negates regional differences in disease incidence, health care-seeking behavior, case mix, and clinical practice variations. In addition, the calculation of DALYs averted should ideally be adjusted for region-specific life expectancy and disability weights.

- Estimation of costs, both at a facility and regional level, is needed, including reducing variability in estimation methods (Adam and Koopmanschap 2003). In addition, multiple estimates of costs are needed. For example, Mulligan and others (2003) derive their operating room costs from a single study of ambulatory surgery in Colombia (Shephard and others 1993). Even though they made adjustments to reflect regional characteristics, further research is required to validate their results, especially as they apply to different settings in different countries.
- Better surgical data collection and analysis tools critical to needs assessment should be designed.
- Development of appropriate surgical care models for all levels of care based on local and regional characteristics and surgical needs would be useful.
- Cost-effectiveness and cost-benefit analyses of health systems implementation need to be determined, as do the policy implications of creating the surgical care model proposed in this chapter. The evaluation of surgery as a prevention strategy in public health should include cost-effectiveness analysis of adequate, prompt, initial surgical treatment of injury to prevent chronic disability from poorly diagnosed and treated survivable injuries and of elective treatment of hernia, hydrocele, otitis media, cataract, and clubfoot to prevent complications and disability.
- The surgical workforce in developing countries requires more in-depth study to look at the mixes of workers needed, the level of training required for the widely varying local situations of district hospitals, and the role for part-time surgical talent. The thesis is that volunteer doctors, nurses, and anesthesiologists who now contribute considerably to surgical care in developing countries in a relatively unstructured fashion could do so more effectively and in a manner that could help create sustainable local surgical workforces if a well-coordinated system with extensive information and communication support could be developed. This concept merits in-depth study. If a well-planned, Web-coordinated, global, highly integrated system could be developed, health care volunteers around the world could be organized strategically so as to deliver not only surgical care, but also training of local surgical workforces. The emphasis on training is crucial and would mitigate the complaints often heard that surgical volunteers too often contribute to the care of individual patients but fail to leave behind a

Box 67.2

Surgical Cost in a Bare-Bones Hospital

The estimated economic costs in this chapter assume staffing and service levels generally derived from World Health Organization recommendations for developing countries (Mulligan and others 2003), but in many places, surgical services are delivered in much simpler and less expensive facilities. Independent project hospitals (NGO hospitals) often operate on remarkably tight budgets. Private hospitals, often set up in private houses by individual surgeons, use locally trained staff with minimal “hotel” service. Extremely poor countries operate hospitals with a cost per patient per day of US\$10 or less simply because they cannot afford more. Such hospitals achieve financial savings in several ways:

- Unpaid family members provide personal nursing care and food, eliminating the need for a kitchen and many trained nurses.
- Locally trained staff members substitute for professionally trained personnel.
- Many staff members have duplicate functions. In the operating room the same person may work as surgical assistant, scrub nurse, and orderly who cleans instruments or transports patients.
- Day staff members cover night calls for emergencies.

- Specialized services are provided by general physicians or technicians trained to do surgery or give anesthesia.
- Laboratory tests and x-rays are used sparingly. The only laboratory procedure for an obstetrical patient could be a hemoglobin determination.
- Only basic medicines are provided. More expensive or complicated supplies are purchased outside the hospital by the family.

For one independent, nongovernmental hospital in Bangladesh, we were able to obtain the actual financial cost of all aspects of hospital operations during a three-month period. These costs included salaries, supplies, hotel costs, and depreciated cost of equipment and buildings, as well as an overhead estimate to allocate a share of the total project cost for administration, electricity, transportation, and so on. Separating the surgical service costs for 3 months, extrapolated to 12 months and a 100-bed hospital, we come up with a much lower total cost than the low estimate in this chapter for the economic costs of a model district hospital, as shown in the table below. Part of the difference is caused by differing cost definitions (financial versus economic), but a good part is owing to the use of low-cost approaches to the delivery of surgical care.

mechanism for sustaining surgical care when they have left. Those volunteers who come from the high-tech world of modern surgery should realize that the latest technology is often more of a burden and diversion than a help in poor

countries. Convincing demonstrations of how much can be done without recourse to CT scans, ultrasound, and video-assisted surgery could be the most useful contribution a visitor could make.

Box 67.3

Success Story: Cataract Surgery in India

Prevention strategies aimed at known risk factors, such as tobacco use and exposure to the sun, are unlikely to have a significant effect on the need for surgical treatment of cataracts in the foreseeable future (Ellwein and Kupfer 1995). The benefits of cataract surgery have been well documented in many developing countries.

In 1993–94, with a World Bank credit of US\$118 million, India expanded cataract surgery coverage to the disadvantaged with the goal of reducing the prevalence of blindness. District blindness control societies were set up and given the flexibility of financing different providers of cataract surgery services to low-income groups at the district level (Rose 1997). Mobile camps were a strategy adopted for providing cheap and efficient cataract surgery in rural districts. Because of these efforts, cataract surgery nationally increased from 1.2 million surgeries in 1991–92 to 2.7 million in 1996–97. Singh, Garner, and Floyd (2000) analyze the cost-effectiveness of publicly funded options

Source: Authors.

for delivering cataract surgery in Mysore, India, by assessing outcomes in a systematic sample of patients operated on in 1996–97. Patient satisfaction was 51 percent among those operated on in government mobile camps, 82 percent among those treated at the medical college hospital, and 85 percent among those treated in nongovernmental hospitals. Cost-effectiveness was US\$97 per patient treated for the mobile camps, US\$176 for the state medical college hospital, and US\$54 for nongovernmental hospitals. Javitt (1993) estimates the cost of cataract surgery in India at less than US\$25 per DALY averted.

As the World Health Organization (Brian and Taylor 2001) has stressed, successful and sustainable surgical treatment of cataracts is linked to a spectrum of other equally important activities, including ongoing training of surgeons, nurses, and administrators; reliable and affordable supply chains; and equipment purchase and maintenance.

CONCLUSIONS

The inclusion of this chapter indicates the evolving appreciation that surgery has a role to play in public health strategies. Previous concerns that surgery is a curative intervention performed in expensive, high-tech hospitals precluded appreciation of the potential role of surgery in public health. Public health specialists now recognize not only that surgery has a preventive role, but also that surgical treatment provided in low-tech community hospitals is cost-effective. In addition, a significant number of surgical procedures, including cesarean sections and other abdominal operations, can be successfully performed by surgical technicians (Jamisse and others 2004; Pereira and others 1996).

Surgery has an important role as a public health strategy in at least four areas:

- in the prevention of death and chronic disability in injured patients by the provision of timely, expert, and complete initial surgical treatment
- in the timely surgical intervention in obstructed labor, in pre- and postpartum hemorrhage, and in other obstetrical complications
- in the provision of competent surgery to treat a wide range of emergency abdominal and nonabdominal conditions

- in the surgical care of several elective conditions that have a significant effect on the quality of life, such as cataract, otitis media, clubfoot, hernias, and hydroceles.

Few published data are available to enable reliable estimates of either the burden of surgical diseases or the cost-effectiveness of surgical treatments in a region-specific manner to help policy makers and voluntary groups. This area merits a great deal of attention in relation to research and development. Nevertheless, the clear conclusion is that surgery must be considered a public health priority.

NOTES

1. This structure is based on the authors' personal experiences of practicing in developing countries. We have defined *surgical cases* to include deliveries and cesarean sections.

2. For example, operating room costs are based on the results of a single study by Shepard and others (1993).

Chapter 68

Emergency Medical Services

Olive C. Kobusingye, Adnan A. Hyder, David Bishai, Manjul Joshipura, Eduardo Romero Hicks, and Charles Mock

INTRODUCTION

Emergency medical conditions typically occur through a sudden insult to the body or mind, often through injury, infection, obstetric complications, or chemical imbalance; they may occur as the result of persistent neglect of chronic conditions. Emergency medical services (EMS) to treat these conditions include rapid assessment, timely provision of appropriate interventions, and prompt transportation to the nearest appropriate health facility by the best possible means to enhance survival, control morbidity, and prevent disability (see table 68.1). The goal of effective EMS is to provide emergency medical care to all who need it. Advances in medical care and technology in recent decades have expanded the parameters of what had been the traditional domain of emergency services. These services, no longer limited to actual in-hospital treatment from arrival to stabilization, now include prehospital care and transportation.

Despite the best efforts of primary care providers and public health planners, not every emergency is preventable. Emergency medical care is needed in diverse circumstances: prospective patients range from rural farmers or fishers whose most common mode of transportation may be canoes or animal-drawn carts, to factory workers living in densely populated urban slums, to residents of high-income cities and suburbs. Actual provision of emergency care may range from delivery using trained emergency professionals to delivery by laypeople and taxi drivers. Developing strategies to meet the range of needs

posed by such diverse circumstances will require innovation and a reorientation of public health planning.

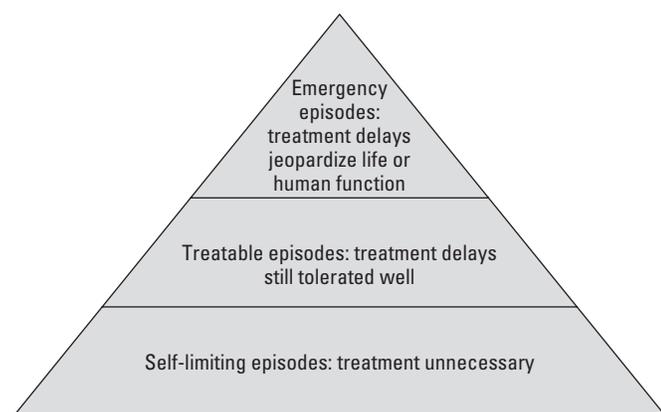

A number of misconceptions about emergency care are often used as a rationale for giving it low priority in the health sector, especially in low-income countries. These ideas include equating emergency care with ambulance transportation, neglecting the role of the community and facility care provided, and assuming that emergency departments and physicians are the only acute care resources. Such a narrow view ignores the important contributions of other disciplines, skills, and personnel. Perhaps the most common misperception is that emergency medical care is inherently expensive and requires high-technology interventions as opposed to simple and effective strategies.

Emergency care, which may be delivered in crisis situations with poor planning and ineffective use of resources, may be inefficient. In many countries, few resources are set aside for possible emergencies, and when situations that demand emergency care arise, they precipitate hurried and costly resource deployment. Efforts to improve emergency care, however, do not necessarily increase costs. This chapter shows that improved organization and planning for emergency care can be done at a reasonable cost and lead to more appropriate use of resources, improved care, and better outcomes (White, Williams, and Greenberg 1996). This chapter does not address nonacute conditions, even though emergency care is often the only recourse for people with nonemergency conditions because of the failure of these other components of the system (see figure 68.1).

Table 68.1 Overview of Emergency Medical Services

	Acute event	On-site management	Transportation	Health facility care
Role of EMS	Recognition	Triage, stabilization, or both	Safe and efficient transportation	Prompt, appropriate, and quality care
Key issues	Surveillance and identification	Trained personnel, equipment	Safe transportation, equipment, referral system	Personnel, equipment, organization of services

Definitions

The current literature is often inconsistent in the use and interpretation of terminology. Accordingly, the specific terms used in this chapter are defined as follows:

- **Emergency care.** Emergency medical care is that care delivered in the first few hours after the onset of an acute medical or obstetric problem or the occurrence of an injury, including care delivered inside a fixed facility.
- **Paramedical personnel.** Paramedical personnel refers to all persons with medical training who are involved in the care and transportation of patients in need of emergency medical care. The length and quality of training vary, from highly specialized personnel with capabilities for advanced life support to those with simple first-aid training and limited field experience.
- **Hospital.** A hospital is a geographically fixed facility in which personnel with some acceptable level of training deliver emergency medical care. The distinctions between a clinic, health center, and hospital are unclear, and the presence or absence of a doctor is not a determining factor in this distinction. A range of facilities from small, basic units up to tertiary care hospitals provides an increasing level of capability for emergency and other care.
- **Triage.** Triage is the screening of patients in the field or in the receiving area of a fixed facility to determine their relative priority for treatment. Triage, which is usually necessary

in the occurrence of mass casualties, may be necessary whenever a large number of patients requiring emergency care present at the same time. It typically entails categorizing patients into three groups: those very unlikely to survive, even with treatment; those whose conditions are minor and who will recover without emergency care; and those with potentially lethal conditions who are likely to survive if they receive timely emergency care. Patients in the last category form the highest priority for emergency care.

- **Stabilization.** A distinction is often made between initial emergency care and stabilization on one hand and definitive medical care on the other. Initial emergency care and stabilization are usually considered the domain of mobile EMS; lower levels of the health care system (for example, clinics and smaller hospitals); and the emergency departments of any fixed facility. Definitive care is usually considered the domain of the hospital and of larger facilities and implies the resolution of the condition needing treatment. However, the distinction is somewhat arbitrary; a more accurate approach is to view care as a continuum. Many of the elements of early care delivered in the course of emergency treatment, whether in the field or in fixed facilities, can be considered definitive (McCord and Chowdhury 2003; McCord and others 2001).

Burden of Disease

Investing in emergency medical care should become a priority. Emergency medical systems address a diverse set of diseases that span the spectrum of communicable infections, noncommunicable conditions, obstetrics, and injuries. All of these conditions may present to the EMS in their acute stages (for example, diabetic hypoglycemia, septicemia, premature labor, or asthma), or they are acute in their natural presentation (for example, myocardial infarction, acute hemorrhage, or injuries). Accordingly, defining the burden of disease addressed by EMS can be problematic.

Malaria causes 300 to 500 million acute episodes worldwide annually and results in an estimated 1 million deaths, mostly in Sub-Saharan Africa. Effective emergency care can avert these deaths, as well as those from acute respiratory and diarrheal diseases in children and from noncommunicable diseases such as diabetes, hypertension, and other cardiovascular diseases. In addition to the acute presentation of chronic conditions, the

lack of access to medical care and lack of sustained effective treatment means that subacute episodes and flare-ups may be life threatening. Early recognition can prevent the emergency precipitated by infectious disease and many other medical conditions or can limit the effects.

More than 500,000 maternal deaths occur each year; 95 percent of these deaths are in low-income countries where emergency care is often lacking. It is estimated that 15 percent of all pregnant women experience a potentially life-threatening condition and will need emergency care. Prenatal screening methods alone may not be effective in reducing this risk ratio. Although identifying risk factors for acute complications is easy, identifying which of the at-risk women will actually develop a life-threatening condition is not possible (Graham 1997). The only way to prevent the deaths is by ensuring access to emergency obstetric care for all pregnant women.

Injuries were responsible for 21.7 percent of global deaths and 31.1 percent of disability-adjusted life years (DALYs) lost in 2001 (WHO 2002). Because both unintentional injuries (chapter 39) and injuries caused by interpersonal violence (chapter 40) are by definition acute events, nearly all require emergency care (see table 68.2). In 2001, more than 80 percent of all deaths attributable to injury were in low-income countries. Most injuries attributable to violence involve a predominantly young and productive population (WHO 2002) that is resilient and can respond well to appropriate emergency care.

The conditions listed in table 68.2 represent 45 percent of all deaths and 36 percent of the disease burden (including

disability) that occur in low-income countries. The numbers represent a conservative estimate of the potential burden, because they do not include all the conditions that could benefit from emergency care and they do not include data from high-income countries.

INTERVENTIONS FOR EMERGENCY CARE: SYSTEMS, STRUCTURES, AND ORGANIZATION

Emergency care must be appreciated as an entire system with interdependent components. These components include pre-hospital care, transportation, and hospital care. Each component is important, but all of them must work together to make a lasting effect on the health of a population. The organization and operation of the prehospital care system will vary by country, but it should be linked to the local hospitals or facilities where patients are taken. When prehospital transportation is poor or absent, deaths occur that could have been prevented even by inexpensive procedures (Mock and others 1998). For example, the majority of maternal deaths may fall into this category. Poor quality of care at the hospitals will lead to in-hospital deaths and may eventually discourage communities that might have the capacity to promptly transfer patients to such facilities (Leigh and others 1997; Prevention of Maternal Mortality Network 1995). Skilled and motivated personnel, appropriate supplies, pharmaceuticals, equipment, coordination, and management oriented to the needs of the critically ill

Table 68.2 Burden of Diseases Potentially Addressed by EMS in Low- and Middle-Income Countries (2001, all ages, both sexes)

Group	Disease	Deaths (thousands)	DALYs (thousands)	DALY rates/1,000 population	YLL (thousands)	YLD (thousands)
I: Communicable	Diarrheal diseases	1,777	58,697	11.25	50,883	7,835

YLL = years of life lost to premature mortality; YLD = years lived with disability; LMICs = low- and middle-income countries.

a. Pertussis, poliomyelitis, diphtheria, measles, and tetanus.

all contribute to make emergency care effective in reducing death and disability.

Prehospital Care

Prehospital care encompasses the care provided from the community (scene of injury, home, school, or other location) until the patient arrives at a formal health care facility capable of giving definitive care. This care should comprise basic and proven strategies and the most appropriate personnel, equipment, and supplies needed to assess, prioritize, and institute interventions to minimize the probability of death or disability. Most effective strategies are basic and inexpensive, and the lack of high-tech interventions should not deter efforts to provide good care. Even where resources allow them, the more-invasive procedures performed by physicians in some prehospital settings, such as intravenous access and fluid infusion or intubations, do not appear to improve outcomes, and evidence suggests that they may, in fact, be detrimental to outcomes (Lieberman and others 2003; Sampalis and others 1994, 1995, 1997).

Prehospital care should be simple, sustainable, and efficient. Because resource availability varies greatly among and within countries, different tiers of care are recognized. Where no formal prehospital system exists, the first tier of prehospital care may be composed of laypeople in the community who have been taught basic techniques of first aid. Recruiting and training particularly motivated citizens who often confront emergencies, such as drivers of public transportation, to function as prehospital care providers can add to this resource.

The second tier comprises paramedical personnel who use dedicated vehicles and equipment and are usually able to get to patients and take them to hospitals within the shortest possible time. This second tier may involve the performance of advanced procedures, the administration of intravenous and other medications by physician or nonphysician providers, or both. This care is not always available in low-income countries; few trained personnel and inadequate funding make round-the-clock coverage impossible. Although providing advanced life-saving measures in the prehospital environment may be beneficial in some cases, these benefits may be negated if such measures divert scarce resources from more basic interventions that can benefit far larger numbers of patients (Hauswald and Yeoh 1997). In most low- and middle-income countries of Africa, Asia, and Latin America, high maternal and child mortality are linked to inadequate emergency care, especially poor access to quality hospital care. In these settings, it is imperative that resources be integrated, instead of one system for injuries and another for obstetric emergencies.

Personnel. Most of the world's population does not have access to formal prehospital care. No personnel are employed for the sole purpose of dealing with medical emergencies

outside of hospitals, and no transportation is dedicated to the task of getting patients in need of emergency care into hospitals. There is a paucity of literature on the effect of first responders, except for one study that evaluated a program to train a core group of paramedics, who then trained thousands of lay first responders in northern Iraq and Cambodia. No data are available on the effectiveness of lay responders compared with the more trained paramedics.

The following discussion introduces a scenario in which the observed mortality rate reduction could be achieved in a developing country's health system by a small group of paramedics working together with a large group of trained lay responders. The scenario uses only emergencies caused by trauma, although it is expected that both the paramedics and the lay first responders would also save lives from medical or obstetric emergencies. Existing studies have not been large enough to document these effects, and they are not included in the estimates of cost-effectiveness.

Trained Lay Responders A case is made for training lay persons able to recognize threatening conditions—whether obstetric, traumatic, or medical. Cultural reasons may require that those responding to obstetric emergencies be traditional birth attendants or similar persons in the community. Husum and colleagues demonstrated that lay people who are given first-aid skills could effectively respond to emergencies in a community with a high trauma burden (Husum, Gilbert, and Wisborg 2003; Husum, Gilbert, Wisborg, and others 2003). In Ghana, it was demonstrated that commercial taxi and minibus drivers trained in first aid could provide effective prehospital care (Mock and others 2002). Lay responders are likely to be successful where the burden of injuries and other emergencies is high. Attrition of both the responders and the skills is a concern unless they are put to frequent use.

Paramedical Personnel In most middle-income countries and some cities of low-income countries, trained paramedical personnel render prehospital care (Mock and others 1998; Tannebaum and others 2001). As for lay responders, coverage varies by country. In most of Sub-Saharan Africa and Asia, paramedical personnel and ambulances transfer patients between health facilities and not from the scenes of injury or from homes (Joshi and others 2003). In middle-income countries, though, they are a major component of existing emergency medical systems (Arreola-Risa and others 2000; Mock 2002). Their presence (coupled with vehicle ambulances) reduces the interval between the recognition of an emergency and the arrival at the hospital, and some evidence suggests that training them in basic life-saving skills improves patient outcomes (Ali and others 1997, 1998; Arreola-Risa and others 2000).

Effectiveness has also been demonstrated for well-placed dispatch sites in urban populations, where the vehicles and

personnel can be optimized. There is no evidence, however, for the effectiveness of training prehospital care paramedical personnel in advanced life-saving skills (Sethi and others 2003). Shorter prehospital times, in general, are considered an important parameter of the quality of prehospital care. These times have the following components:

- *Notification time* is the time elapsed from occurrence of injury or recognition of severe illness until the EMS system is notified.
- *Response time* is the time elapsed from notification until arrival of an ambulance to the site of the ill or injured person.
- *Scene time* is the time taken by prehospital providers from arrival at until departure from the scene.
- *Transport time* is the time elapsed from leaving the scene until arrival at the hospital or other treatment facility.

Notification time is influenced by the availability of telecommunications. Response time is influenced by the capabilities of a dispatch center to handle emergency calls and especially by the geographic distribution of sites of ambulance dispatch. The greater in number and the more widely distributed the number of ambulance stations are, the shorter the response times are.

Geographic distribution and associated response times can be improved in some circumstances by using a tiered or layered response system. This system requires having a relatively larger number of basically trained and equipped first responders with wider geographic distribution and a smaller number of centrally located, more highly trained and equipped second responders. This system allows the first responders to respond more rapidly, with second responder involvement only if needed (Arreola-Risa and others 1995).

Accordingly, paramedical personnel should be introduced in large urban areas where they do not function at present and should be stationed at dispatch sites with dedicated vehicles, fast communications with the hospitals in the area, and links with other emergency services such as the fire and police departments. The communities served by the system should have a well-known and rapid method of calling the paramedical teams when an emergency arises. Because skills depreciate with time, these personnel require refresher courses. Where paramedical personnel already exist as part of the EMS, their numbers and organization (location, training, deployment, and monitoring) should be enhanced to improve response times and, hence, patient outcomes, especially for cardiac and obstetric emergencies. Availability of EMS for a given population can be looked at either as number of units on duty or number of sites of ambulance dispatch. They are usually closely related, with one or two units per site, but not in systems where a large number of units are on duty from one central dispatch station.

The recommended ratio of one unit for 50,000 people suggested by McSwain (1991) results in response times as low as four to six minutes. The ratio does not distinguish between basic life-support and advanced life-support capabilities. Traffic congestion, poor maps, and poor road signs may all increase this response time in cities with poor infrastructure. In Monterrey, Mexico, one unit per 100,000 people manages an average response time of 10 minutes. Hanoi, Vietnam, with one unit for 3 million people, has an average response time of 30 minutes (Mock and others 1998).

Where paramedical services exist alongside lay responder services, these two could be managed by the same organizational unit. The paramedical staff will be more successful in urban areas, where distances between dispatch sites, communities served, and hospitals are short. Other enabling factors are good telecommunications; rapid and dedicated transportation; and coordinating capacity among the community, hospitals, and other emergency services.

Intervention Cost and Effectiveness Training lay responders is an intervention potentially available in low-income countries. Projections for costs and effectiveness have been made based on the following assumptions:

- Serving a population of 1 million requires 7,500 trainees. Sensitivity analysis ranges from 5,000 to 10,000 trained lay responders.
- Trained lay responders can be trained in half a day (St. John Ambulance 1996).
- Training would have to be repeated every three years to maintain efficacy.
- Annually, 2,500 laypeople would be trained on a rolling basis.

Using these assumptions (see annex 68.A for technical details on costing guidelines) would require the following:

- 1,250 days of trainees' time (0.5 days each) valued at salary level 1
- 62.5 trainer days of time, with a ratio of 20 trainees per trainer, valued at wages for salary level 3
- one training facility with a classroom (100 square meters) valued at rent for basic space for 62.5 days
- 2,500 copies of photocopied curricula annually valued at US\$1 each.

The costs of providing trained paramedics can be estimated using the following assumptions:

- Trained paramedic responders can be trained in 25 days (St. John Ambulance 1996).
- Serving a population of 1 million requires 7,500 trainees. Sensitivity analysis ranges from 100 to 200.

- Training would have to be repeated every three years to maintain efficacy.
- Annually, 50 paramedics would be trained.

As a result, the following would be required:

- 25 × 50 = 1,250 days of paramedic trainee time (salary level 1)
- 125 trainer days, with a ratio of 10 trainees per trainer valued at salary level 3
- one training facility offering a classroom (100 square meters) valued at basic building values
- 50 photocopied curricula annually, valued at US\$1 each
- one paramedic kit with stethoscope, gloves, bandages, and splint material for each trainee (kits would be renewed by patient contributions).

The trainees would offer volunteer services after training. We assume that volunteers are highly motivated individuals who consider emergency medical service to their community as the most rewarding use of their leisure time (Fiedler 2000). The opportunity cost of their recurrent emergency service is assumed to be zero. Communities or cultures that have a shortage of individuals with an ethic of volunteer service may have to devote funds toward maintaining incentives for “volunteer” paramedics to serve. In such cases, this strategy may not be cost-effective.

Table 68.3 shows the estimated costs of the lay first responders and paramedics intervention, drawing on the Disease Control Priorities Project’s standardized input prices by region for low, best, and high estimates.

Outcomes According to the World Health Organization burden-of-disease estimates, the global incidence of trauma is 410 per 100,000 or 4,100 per million. Husum, Gilbert, and Wisborg (2003) indicate that first-level responders and trained

paramedics can lower mortality in trauma by 9 percent; thus, in 4,100 traumas, 370 lives can be saved. Dividing the sum of the costs in table 68.3 by the 370 deaths averted provides a rough estimate of costs per death averted. These costs per death averted are divided by the regional life expectancy at age 20 (LE 20), with the assumption that the average age of trauma is 20, to give the cost per life year saved. LE 20 is roughly 50 years in every region except Sub-Saharan Africa, where it is only 37 years. Shortages of equipment and supplies may reduce the effectiveness of the prehospital personnel.

It is possible to offer more refined “regional” estimates of the numbers of deaths averted by using local estimates of the burden of injuries instead of the global estimate of 4,100 injuries per million people. Yet given the uncertainty about regional variation in the effectiveness of the intervention based on administrative, infrastructure, and human resource capacity, it would perhaps give a false impression that a firm and universal basis exists to speculate quantitatively on the relative effectiveness of the intervention in various regions. As a result, the above estimates, as used in table 68.4, serve to inform global dialogue rather than offer specific empirical numbers.

Equipment and Supplies. Equipment and supplies should match the knowledge and skills of the personnel available to use them. Even teams with the least resources should have the following:

- protective wear, especially gloves and aprons
- a stretcher or the equivalent
- pressure dressings (bandages—elastic, if possible—and cotton or gauze dressings)
- splints—various sizes, made out of local materials
- radio, telephone, or other mode of rapid communication.

Annex 68.A provides a comprehensive list for better-resourced communities. Intervention cost and effectiveness

cannot be estimated because no studies are available on this issue from low-income countries.

Traditional and Innovative Communications Systems.

Nowhere is the demand for efficient communication and rapid transportation more critical than in emergency medical care. The best teams equipped with state-of-the-art technology and supplies will be wasted if they cannot be reached quickly or if they have no contact with the hospitals where patients are to be taken. Most of the world's population lives in areas where there is no telecommunications infrastructure, and this situation may not change significantly in the near future. Innovation is needed so that these populations can be enabled to access effective emergency care interventions that already exist without waiting for traditional telephone lines to get to their rural homes. Radio communication is one solution in such settings. Equipping traditional birth attendants and remote health units with radio receiver sets linked to local hospitals has been used to shorten the response time and reduce maternal deaths (Samai and Sengeh 1997). Cellular telephones may offer communities that are remote from standard communications infrastructure an opportunity to leap into a more modern and efficient mode.

Intervention Costs and Effectiveness There are no studies from low-income countries on which to base intervention cost and effectiveness estimates. The costs will depend on whether

the community adopts traditional communication or more modern communication systems. If radio communication were introduced, the purchase and maintenance of radio receivers, supplies, and government licensing costs would need to be estimated. If cellular telephones options were being explored, then the purchase of telephones, plans, licenses, and maintenance costs would need to be included. Where satellite towers need to be installed, however, this cost will be much higher than for all other components. Finally, if traditional landline installation is being considered, the lines, equipment, and telephone bills will need to be taken into account. The health sector may be able to share the costs of such interventions, especially traditional telephone lines, with other development and infrastructure units of a national government.

Basic and Advanced Transportation Systems. Transporting a patient from the location of the acute event to a hospital facility is a critical element of the prehospital component. Lack of transportation is often a major barrier to accessing emergency care (Lungu and others 2001; Samai and Sengeh 1997). In devising a prehospital system of transportation, one should consider locally available resources and the range of viable alternatives for transportation. In some countries such transportation may be part of a formal EMS system, whereas in other cases it is entirely informal. For example, commercial vehicles, the police, and relatives using private motorized or

nonmotorized forms of transportation may bring seriously ill and injured patients to medical facilities (Andrews, Kobusingye, and Lett 1999; Joshipura and others 2003; Kobusingye and others 2002). A bicycle ambulance in Malawi set up to improve emergency obstetric care was actually used more often for injuries and medical emergencies (Lungu and others 2001).

Transportation should be accessible at short notice. A vehicle with a stretcher is ideal, but almost any transportation that will get a patient to a facility where definitive care can be obtained is acceptable. Although a fully fitted and equipped ambulance vehicle complete with trained paramedics delivers better outcomes, ethical and equity considerations dictate that before this vehicle is made available to an elite population in the urban areas, basic transportation must be assured for all who need emergency transportation and care.

In a city setting, a vehicle ambulance can make as many as 20 trips per day. On average this schedule will require salaries for an administrator and two crews, each comprising a driver and two paramedics or nurses, as well as expenses for communication, supplies, pharmaceuticals, and the costs of operating the vehicle. A study of a decision to develop an EMS in Kuala Lumpur (1.1 million people, 243 square kilometers) estimated that the purchase and staffing of 48 ambulances at US\$53,000 each per year would be required, totaling US\$2.5 million per year (Hauswald and Yeoh 1997). The authors noted that, despite the paucity of ambulances, severely injured or ill patients did get to a hospital with only minor delays by using taxis, family transportation, or the police. Ambulances need accurate maps, house numbers, and street or road signs, all of which might not be in place in low-income cities. It was estimated that ambulances were unable to locate patients in 20 percent of calls in Kuala Lumpur because of mapping and signage problems (Hauswald and Yeoh 1997).

A study conducted in Turkey found that ambulance vehicle costs were the leading component of capital costs (Altintas, Bilir, and Tuleylioglu 1999). The cost per trip was US\$163, and the cost per patient transported was US\$180.50, which the authors thought were beyond the means of the private sector. In state-run ambulance services in New Delhi, India, the cost per trip was approximately US\$40, yet one in three of the ambulances served only to transport patients, with no paramedic staff on board (India, Government of Delhi 2001).

The debates in high-income countries about helicopter ambulances provide lessons for low-income countries. In some cases, helicopter services have been discontinued because they were not considered cost-effective (Hutton 1995). A study conducted in the United States, which concluded that helicopters were cost-effective, found that the cost per patient transported was US\$2,214 and that for every 100 flights there were six survivors more than was predicted on the basis of injury severity indices (Gearhart, Wuerz, and Localio 1997). Each additional

survivor cost an average of US\$15,883, and the authors acknowledged that the helicopter had to be used fully to spread the high fixed costs across many patients and trips. A review of civilian helicopter ambulance programs in the United States concluded that the primary factor in the reduction of trauma mortality was not the speed at which the patient was transported but the administration of life-saving care by the helicopter medical crew at the scene or at the outlying hospital (Moylan 1988). In low-income countries, for the very few who benefit from such a high-end intervention, there are likely to be thousands who cannot access care even using the most basic means.

Intervention Costs and Effectiveness Costing transportation systems requires the following assumptions:

- In an urban population, one ambulance unit can serve a population of 30,000 people. Thus, 1 million people would require 33 ambulance units (1 million/30,000).
- Each ambulance unit requires staffing of a rotation of six paramedic-drivers and a seventh paramedic-driver to cover vacation times and sick leaves.
- A supervisor oversees three ambulance units per year.
- A garage for the ambulance and communications equipment would be 100 square meters but would entail rental of office-style accommodations.
- A vehicle to be outfitted as an ambulance can be purchased for as much as an off-road vehicle with a useful life of nine years.
- The cost to modify the vehicle into a basic ambulance is US\$5,000 for a useful life of nine years.
- The ambulance will require fuel and maintenance based on usage of 20,000 kilometers per year.

Given the preceding assumptions,

- The 231-member ambulance staff (33 ambulance units of 7 persons each) would be paid at salary level 2.
- The 10 administrators would be paid at salary level 2.

We ignore the additional burden on the health system from additional visits. Quite possibly, hospital costs will rise as more patients now get to the hospital with the help of ambulances. It is also possible that patients currently arrive in less desperate condition, so that the cost of care is lessened. No studies are available on which to base cost estimates to address those issues.

Table 68.5 shows the estimated costs of the ambulance intervention, drawing on the Disease Control Priorities Project's standardized input prices by region for low, best, and high estimates.

Outcome Based on the World Health Organization's 2001 burden of disease estimates on epidemiology of trauma, ischemic heart disease, and obstetric emergencies, we estimate that for each 10,000 population there will be 9 deaths from trauma,¹

11 deaths from ischemic heart disease,² and 2 deaths from lethal obstetric emergencies.³ For modeling purposes, we confine our attention to trauma, ischemic heart disease, and obstetric cases. Although many possible lethal emergencies may present, such as sepsis, malaria, snakebites, and asthma, by confining attention to the major emergency conditions we locate 2,200 (900 + 1,100 + 200) potentially savable lives in a population of 1 million. The savings are outlined as follows:

- *Savings from trauma reductions.* Saving lives from trauma depends on the quality of trauma care at the destination facility. In one year for 1 million people, there will be 4,100

trauma cases and 900 trauma deaths. With rapid resuscitation and oxygen available through use of ambulances, we assume we can save 300 lives.

- *Savings from myocardial infarction management.* In one year for 1 million people in low-income countries, 1,100 deaths will typically result from myocardial infarction. Low-dose aspirin provided to myocardial infarction victims lowers mortality by 18 percent (Weisman and Graham 2002). In a population without ambulance services, rapid aspirin administration cannot be ensured; with EMS, aspirin use can potentially be increased from about 0 percent to 100 percent for heart myocardial infarction. Therefore, instead

of 1,100 deaths, there will be $1,100 \times (1 - 0.18)$ deaths, saving 200 lives, but with only an average of five life years per life saved.

- *Savings from emergency obstetrics management.* Obstetric deaths for medically attended patients are approximately 100 times lower than for patients who do not receive medical care. Accordingly, an ambulance system essentially saves all of the obstetric emergencies from death; this saving would amount to 200 deaths averted in the case described previously. As a result, in the hypothetical population of 1 million people in low-income countries, 700 lives can be saved by an ambulance system focusing on three causes only: ischemic heart disease (200), obstetric (200), and trauma (300).

The middle section of table 68.6 displays the cost per death averted. To compute life years saved in the last section of the

table, we assume that the 500 deaths averted from obstetric emergencies and trauma occur at age 20, but the 200 deaths averted from ischemic heart disease save only five additional life years per case. Regional life expectancy at age 20 years (estimated) is used as before.

Costs for a Rural Ambulance Service The key difference determining higher costs for rural ambulances is that more ambulance units are necessary to cover the population. We assume that in rural areas one ambulance unit can cover a population of 10,000, although variation will occur, depending on population density and geographical topography. On the basis of this assumption, all of the cost estimates for rural ambulances are essentially three times higher for a population of 1 million, as are the costs per death averted and per life year gained. They are assumed to have the same effectiveness as the urban services because the increase in units aims at delivering the same quality

a. Personnel consist of lay first responders together with paramedics.

of care as in the urban centers. This assumption may not hold true if the quality of care at the receiving facilities is lower than that in the urban areas.

Uncertainty of Estimates Substantial uncertainty remains over the actual effectiveness of the interventions in emergency medicine. The tables in this chapter should be approached with due caution because ultimately the projections of the effectiveness of interventions have been patched together from a handful of intervention trials whose success may or may not be similar in other contexts. The projections include the following:

- Ambulance services can and do save lives by performing field stabilization and by hastening the arrival of critical patients when time makes a difference in the outcome.
- Only several dozen ambulance runs per year for a unit serving a population of 10,000 will actually have the potential to save lives.
- Ambulance services are more cost-effective in denser populations and when roads are more passable, making trips shorter.
- Training lay responders and paramedics can be relatively cost-effective.

The financial support of an ambulance unit may rely on the value perceived by the hundreds of patients who are comforted by having rapid access to care or by knowing ambulances are there if needed, even though their lives and health are not actually improved by ambulances.

Table 68.6 summarizes the best estimates of cost, cost per death averted, and cost per life year.

Health Facility–Based Subsystem

This subsystem refers to a level within the health care system where appropriate definitive care is delivered. Formal health facilities vary immensely between and within countries. In some countries, this subsystem may be a regional hospital with specialists; in others, a district hospital with general practitioners or nonspecialist doctors; and in still others, a health center with competent nonphysician clinicians. In some low-income countries, some types of emergency medical care, for conditions such as acute diarrhea or severe malaria, may be effectively delivered at a health center staffed by nondoctor clinicians. However, such a facility will be grossly inadequate for the management of a severe multiple injury or obstructed labor. The triage process in the prehospital subsystem should determine which patients receive transportation to which facility, instead of merely transportation to the nearest facility. Precious time and lives may be lost when patients are taken to facilities where the desired definitive care is not available.

Because the goal of an effective EMS is the provision of emergency care to all who need it—*universal emergency care*—the following section presents guidelines on the necessary inputs at different levels. Two of the components in hospital emergency care are discussed in more detail: (a) training and (b) equipment and supplies. The first level of formal health care is often staffed by nonphysician clinicians; the second level is staffed by at least one physician and other trained health care professionals; and the third is staffed by specialists in addition to other health care professionals. Some middle-income countries have additional levels (major emergency care centers), and some hospitals are specialized (chapters 65 and 66).

Training. Most in-service training for emergency care professionals working in hospitals is designed to address a particular problem, such as severe injuries, emergency pediatrics, or obstetric emergencies. Yet because of the resource constraints of low-income countries, the same personnel will be confronted with all these problems. Few courses in emergency care have been rigorously evaluated (Black and Brocklehurst 2003; Sethi and others 2003). The Advanced Trauma Life Support (ATLS) course for doctors has resulted in improved patient outcomes in some settings, although it may be too expensive for most low-income countries and inappropriate in settings where doctors do not see the majority of patients. In a tertiary hospital in Trinidad and Tobago, injury mortality was reduced by 50 percent following ATLS training (Ali and others 1993).

Life-saving obstetric skills training was found to contribute to a reduction in maternal deaths. In Kebbi state in Nigeria, this training led to a drop in case-fatality rates among women with obstetric complications from 22 percent to 5 percent. Similar trends were observed in other sites where the intervention was implemented (Oyesola and others 1997; Prevention of Maternal Mortality Network 1995). Emergency Triage Assessment and Treatment has been used in many countries to improve pediatric emergency care (WHO 2000). Other examples are Primary Trauma Care, which is a trauma management course to train doctors and other health workers in district hospitals and remote locations (Wilkinson and Skinner 2000), and Advanced Life Support in Obstetrics (see <http://www.aafp.org/also>). These courses have been beneficial in standardizing protocol-based emergency care, but their outcome evaluations are still awaited. Low-income countries need to identify training models for their versatile emergency care personnel, especially those working at middle-level facilities, who respond to different types of emergencies.

The costs of this intervention are not available in the literature and will require an estimation of trainer costs, space, materials, and refresher courses.

Equipment and Supplies. A specimen list of resources for emergency care required at different levels of facilities is

provided in annex 68.A. This template is flexible, and countries can customize it to suit local conditions, such as existing facility levels and prevailing burden of emergency disease conditions. Equipment and supplies at each level should match the knowledge and skills of the personnel available to use them.

Systems Organization

Emergency care needs to be planned and implemented carefully. The various components that make up the EMS should be linked to ensure that the entire system operates as a unit. A coordinator should be responsible for monitoring and coordinating all emergency medical care in the community or district and should work with a committee to which the other components send representation. A community representative should be a key member of this committee.

Coordination costs are very important and should not be overlooked in the development of a new EMS. Such costs include the salary of the coordinator, an efficient telephone or communication system, a vehicle, fuel, and a budget to organize meetings of stakeholders at least twice a year (Bazzoli, Harmata, and Chan 1998; Nurok 2001).

Health Financing for Emergency Care

Emergency medical systems in low-income countries must be pro-poor in their orientation, which requires explicit consideration of how the poor interact with an EMS and how barriers to acute care for the poor can be overcome. Issues of access to an EMS become critical because the lack of money often keeps people from using emergency services. Direct payment of costs for transportation, medical treatment, and drugs makes lack of money a major barrier to EMS for the poor in every country. As a result, emergencies frequently cripple individuals and families financially in poor communities, often for many years in the future.

Financial protection for emergency health care is a necessity in low-income countries and has not received adequate attention. The goal of such protection is to ensure that individuals and families do not spiral down the pathway to abject poverty as a result of interaction with the national health system. Such financial protection may be achieved by a number of different means, including community financing (Ande and others 1997; Desmet, Chowdhury, and Islam 1999; Macintyre and Hotchkiss 1999). Community loan funds to cover transportation and other requirements for emergencies, especially for obstetrics, have been explored with mixed results (Essien and others 1997; Shehu, Ikeh, and Kuna 1997). Some experience seems to indicate that these approaches can indeed overcome several of the barriers to accessing emergency medical services and should be explored further.

Documentation and Quality Assurance

Quality of care is critical to the interaction of the poor with the EMS. Lack of funds, lower-paid jobs, social class distinctions, ethnicity, and other affiliations make the already vulnerable poor susceptible to receiving poor-quality care. For an EMS to maintain and improve the care of patients, systematic documentation and periodic audits, or other processes to ensure quality of care, need to be incorporated. Quality management systems that are simple, are continuous, and allow for rapid changes in the system need to be implemented.

Because of scarcity of resources, expensive machines and elite specialists should not be advocated for the urban privileged at the expense of the majority of the rural poor. The most difficult decisions concern balancing funds invested in the emergency care capacity of secondary and primary care centers with support for referral and transportation networks to feed tertiary care centers. These decisions are too variable and too system specific to yield to a uniform policy prescription. Two principles are advocated to inform these difficult decisions:

- Collect data on costs, capacities, and outcomes.
- Tighten the integration of the emergency care system to improve function and lead to wiser decisions on where to invest.

Legislative Instruments to Ensure Emergency Care

The issues discussed in the preceding sections supply the rationale for countries to have specific legislation addressing the provision of emergency care. This area requires major cooperation between public health and law, which together provide the legal framework for ensuring that all individuals who deserve emergency care can receive it, irrespective of their personal characteristics or their ability to pay. Having laws that protect trained individuals and laypeople as they provide such care is also important.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

A large proportion of trauma patients in developing countries do not have access to formal emergency medical services. Boxes 68.1 and 68.2 contain examples of interventions to provide appropriate emergency care in such countries.

THE RESEARCH AND DEVELOPMENT AGENDA

The research and development priorities for emergency care are challenging to define because emergency care is a neglected area of research in low-income countries and the needs are

Box 68.1

Improving Trauma Care in the Absence of a Formal Ambulance System

Background: The efficacy of a program that builds on the existing, although informal, system of prehospital transportation in Ghana was assessed. In Ghana, the majority of injured persons are transported to the hospital by some type of commercial vehicle, such as a taxi or bus.

Methods: A total of 335 commercial drivers were trained using a six-hour basic first-aid course. The efficacy of this course was assessed by comparing the process of prehospital trauma care provided before and after the course, as determined by self-reporting from the drivers.

The course was conducted with moderate amounts of volunteer labor and gifts in kind, such as transportation to the course. The actual cost of the course amounted to US\$3 per participant.

Results: Follow-up interviews were conducted on 71 of the drivers a mean of 10.6 months after the course. In the interviews, 61 percent indicated that they had provided

first aid since taking the course. There was considerable improvement in the provision of the components of first aid in comparison to what was reported before the course:

Component of first aid	Before (percent)	After (percent)
Crash scene management	7	35
Airway management	2	35
Bleeding control	4	42
Splint application	1	16

Conclusions: Even in the absence of a formal EMS, improvements in the process of prehospital trauma care are possible by building on existing, although informal, prehospital transportation.

Box 68.2

Training for Emergency Care in India

The training of personnel working in emergency medical services is crucial to the success of efficient delivery of care. Evidence exists to support usefulness of life-support training for emergency caregivers in low- and middle-income countries. Courses such as the ATLS are available and well established in some high- and middle-income countries. In most low-income countries, such training is not available, mainly because of prohibitive costs. The three-day ATLS course costs on average US\$700 per trainee and is taught by six trainers to a group of 20 trainees at a time. The National Trauma Management

Course is an indigenous two-day course developed in India by the Academy of Traumatology (India) with the help of international peers. The curriculum takes into account local conditions and capabilities. The cost is US\$50 per trainee, and the course is taught by local trainers to a group of 100 trainees at a time. Animal specimens are used to teach life-saving procedures instead of expensive commercially produced manikins. More than 2,000 health professionals have been trained in less than three years. The course has now become a national training standard for immediate trauma care in India.

great. As a neglected topic, emergency care is part of the “10-90” gap of health research: less than 10 percent of global research investments are for problems affecting 90 percent of the world’s population (Global Forum 2000).

Approach to Research and Development for EMS

The spectrum of research required is diverse and may be easily understood with the help of the schematic shown in

figure 68.2. The rectangle is a schematic representation of the totality of the global burden of disease that can be potentially addressed by EMS (see “Burden of Disease”). A portion of this potential burden is being addressed (or reduced) by those existing interventions that have been implemented, defined by box A. If the efficiency of current interventions were to be enhanced and their coverage increased, then another portion of the burden defined by box B could be addressed; this increase

D: No emergency care interventions currently available to address this burden		
A: Currently implemented emergency care interventions that are addressing this burden	B: Existing emergency care interventions that are able to address existing burden if efficiency enhanced	C: Potential emergency care interventions that could address this burden if they were made cost-effective

Figure 68.2 Schematic Illustration of the Burden of Disease Potentially Addressed by EMS

in efficiency will require operations research, policy research, and social science research. If existing interventions, which have not been implemented because of their high costs, were made more cost-effective, then another portion of the burden defined by box C could be reduced. This process of making interventions more cost-effective will require economic analysis and clinical research in many instances. Finally, a portion of the burden exists for which we do not have existing interventions, defined by box D; it requires basic and clinical research to develop and pilot interventions that can address other determinants of the emergency care–related burden in the future.

This schematic representation is thus useful to demonstrate two critical needs:

- essential research on emergency care in low-income countries
- a diverse set of research studies and approaches to reduce the burden that can be addressed by EMS.

Priority Setting for Research and Development of Emergency Care

Setting priorities for research and development on EMS needs to be a region-specific, if not country-specific, process. No current list exists of global research and development priorities for EMS, again reflecting the need for more attention and investments in this area. This chapter does not intend to prescribe a list of issues or topics for global research and development efforts, but rather to highlight the gap in global research and development and to suggest possible issues and topics that may be broadly relevant to low-income countries for these efforts in the short to middle term.

A number of methods exist for setting research priorities in the health sector, such as the Combined Approach Matrix promoted by the Global Forum for Health Research (Global Forum 2002) and the Essential National Health Research process promoted by the Council for Health Research for Development. Countries and regions can use these approaches to help develop their research agenda for EMS.

The review of evidence available in the field of emergency care as applicable to low-income countries reveals many gaps

in global knowledge. Following on the illustration of figure 68.2, there is a need to better understand the epidemiology of those conditions that can be addressed by an EMS in a low-income country and which interventions currently in place are addressing them. We have little knowledge of how to enhance the efficiency of these existing interventions and reduce their costs. Most important, the lack of intervention trials done in low-income countries creates a major research priority for the field of EMS. Well-designed, locally appropriate interventions that establish their effectiveness are urgently needed and should include both interventions that may be available in high-income countries and new ones. Economic analysis is another area for major research input in the field of EMS, where cost and cost-effectiveness information from low-income countries is scant. These gaps only reflect the need for a more systematic analysis of where research investments should be directed in the next five years for EMS.

CONCLUSIONS: PROMISES AND PITFALLS

Emergency medical systems are a critical component of national health systems in low-income countries. Governments and ministries of health in low-income countries need to pay specific attention to the development of EMS in their countries and to ensure that the evolution of any EMS is both evidence based and appropriate to their national needs. More important, the context and implementation of EMS should help health equity and not widen existing health disparities.

This chapter highlights not only the urgent need for more attention to EMS in low-income countries but also points out an opportunity for these countries in defining better EMS for their needs. In promoting the systematic development of an evidence-based EMS, low-income countries could help define more effective and cost-effective emergency systems than currently exist in high-income countries. This opportunity should not be lost as a result of political inattention or lack of funds; the international and national stakeholders must move forward to stem the preventable loss of life from the lack of an EMS.

Emergency care needs to be planned as an integral component of public health systems in low-income countries. Too little is known about the true extent of the need for emergency care, the designs of EMS that would work well for different communities and populations, and the costs and benefits of delivering emergency care in low-income countries. These gaps are a call for more investments in the research, development, and implementation of EMS, especially in these countries. Universal emergency care is consistent with the right to health care because, by definition, emergency care is a matter of life and death. Society should endeavor to ensure that prompt appropriate care is available in critical moments when a delay in care—or the delivery of inappropriate care—could mean loss of lives.

Annex 68.A Essential Resources for the Delivery of Emergency Care in Hospitals

Resources	Major emergency care center	Regional emergency care center	District emergency care center	Primary emergency care center
<i>Organization and administration</i>				
Multidisciplinary emergency care team	✓	✓		
Maintenance of statistical data	✓	✓	✓	
<i>Resources</i>				
Immediate access to radiology or CT and ultrasound scan facility on site	✓	✓		
Blood bank on site	✓			
Access to blood bank		✓	✓	
Radiological technician on site 24 hours a day	✓	✓		
Radiological services available promptly			✓	
<i>Clinical laboratory services</i>				
Laboratory services on site available 24 hours a day (including, but not limited to, the following tests)	✓	✓		
Hemoglobin, glucose, gram stain, blood slide test	✓	✓	✓	
Bacterial cultures	✓	✓		
<i>Quality improvement</i>				
Evidence of quality improvement program in accident and emergency department	✓	✓	✓	
Monthly morbidity and mortality review	✓	✓		
Medical nursing audit and utilization review	✓	✓		
<i>Personnel</i>				
Designated doctor in charge, member of the emergency care team, with special competence in care of critically ill and injured patients, present in the emergency care unit 24 hours a day	✓	✓		
Designated doctor in charge, member of the emergency care team, with special competence in care of critically ill and injured patients, available on call			✓	
Nursing personnel with special competence in the care of the critically ill and injured patients, designated member of the emergency care team, present in the emergency unit 24 hours a day	✓	✓	✓	
All personnel trained in airway, breathing, and circulatory support techniques	✓	✓	✓	✓
<i>Equipment required for resuscitation per station shall include but not be limited to</i>				
Bag valve resuscitator with reservoir	✓	✓	✓	
Sphygmomanometer (blood pressure cuff)	✓	✓	✓	
Cervical collars	✓	✓	✓	✓
Chest decompression set	✓	✓	✓

NOTES

1. There are 4,715,000 trauma deaths in low- and middle-income countries per population of 5,219,401,000; thus, there are 9.033 trauma deaths per 10,000 people.

2. There are 5,699,000 ischemic heart disease deaths per 5,219,401,000 population; thus, there are 10.9 ischemic heart disease deaths per 10,000 people.

3. There are 2,000 to 4,000 births among 10,000 people based on crude birth rates of 26 (South Asia), 39 (Sub-Saharan Africa), 22 (Latin America), and 17 (East Asia). Maternal mortality runs at 1 per 1,000 people.

Complementary and Alternative Medicine

Haile T. Debas, Ramanan Laxminarayan, and Stephen E. Straus

The objective of medicine is to address people's unavoidable needs for emotional and physical healing. The discipline has evolved over millennia by drawing on the religious beliefs and social structures of numerous indigenous peoples, by exploiting natural products in their environments, and more recently by developing and validating therapeutic and preventive approaches using the scientific method. Public health and medical practices have now advanced to a point at which people can anticipate—and even feel entitled to—lives that are longer and of better quality than ever before in human history.

Yet despite the pervasiveness, power, and promise of contemporary medical science, large segments of humanity either cannot access its benefits or choose not to do so. More than 80 percent of people in developing nations can barely afford the most basic medical procedures, drugs, and vaccines. In the industrial nations, a surprisingly large proportion of people opt for practices and products for which proof as to their safety and efficacy is modest at best, practices that in the aggregate are known as *complementary and alternative medicine* (CAM) or as *traditional medicine* (TM).

Much of this book considers the formidable challenges to advancing human health through the further dispersion of effective and economical medical practices. This chapter considers both proven and unproven but popular CAM and TM approaches and attempts to portray their current and potential place in the overall practice of medicine.

With globalization, the pattern of disease in developing countries is changing. Unlike in the past, when communicable diseases dominated, now 50 percent of the health burden in developing nations is due to noncommunicable diseases,

such as cardiovascular diseases, diabetes, hypertension, depression, and use of tobacco and other addictive substances. Because lifestyle, diet, obesity, lack of exercise, and stress are important contributing factors in the causation of these noncommunicable diseases, CAM and TM approaches to these factors in particular will be increasingly important for the development of future health care strategies for the developing world.

DEFINITIONS AND DOMAINS OF COMPLEMENTARY AND ALTERNATIVE MEDICINE AND TRADITIONAL MEDICINE

We refer to medical practices that evolved with indigenous peoples and that they have introduced to other countries through emigration as traditional medicine. We refer to approaches that emerged primarily in Western, industrial countries during the past two centuries as scientific or Western medicine, although we acknowledge that not all Western medicine is based on scientifically proven knowledge. The terms *complementary* and *alternative* describe practices and products that people choose as adjuncts to or as alternatives to Western medical approaches. Increasingly, the terms *CAM* and *TM* are being used interchangeably (Kaptchuk and Eisenberg 2001; Straus 2004).

Endless varieties of practices are scientifically unproven and poorly accepted by medical authorities. For the sake of organizing an agenda for research into these approaches, the U.S. National Institutes of Health has grouped them into five

somewhat overlapping domains (<http://nccam.nih.gov/health/whatiscam>) as follows:

- *Biologically based practices.* These include use of a vast array of vitamins and mineral supplements, natural products such as chondroitin sulfate, which is derived from bovine or shark cartilage; herbals, such as ginkgo biloba and echinacea; and unconventional diets, such as the low-carbohydrate approach to weight loss espoused by the late Robert Atkins.
- *Manipulative and body-based approaches.* These kinds of approaches, which include massage, have been used throughout history. In the 19th century, additional formal manipulative disciplines emerged in the United States: chiropractic medicine and osteopathic medicine. Both originated in an attempt to relieve structural forces on vertebrae and spinal nerve roots that practitioners perceived as evoking a panoply of illnesses beyond mere musculoskeletal pain.
- *Mind-body medicine.* Many ancient cultures assumed that the mind exerts powerful influences on bodily functions and vice versa. Attempts to reassert proper harmony between these bodily systems led to the development of mind-body medicine, an array of approaches that incorporate spiritual, meditative, and relaxation techniques.
- *Alternative medical systems.* Whereas the ancient Greeks postulated that health requires a balance of vital humors, Asian cultures considered that health depends on the balance and flow of vital energies through the body. This latter theory underlies the practice of acupuncture, for example, which asserts that vital energy flow can be restored by placing needles at critical body points.
- *Energy medicine.* This approach uses therapies that involve the use of energy—either biofield- or bioelectromagnetic-based interventions. An example of the former is Reiki therapy, which aims to realign and strengthen healthful energies through the intervention of energies radiating from the hands of a master healer.

Alternative systems of medicine use elements from each of these CAM and TM domains. For example, traditional Chinese medicine incorporates acupuncture, herbal medicines, special diets, and meditative exercises such as tai chi. Ayurveda in India similarly uses the meditative exercises of yoga, purifying diets, and natural products. In the West, homeopathic medicine and naturopathic medicine each arose in the late 19th century as reactions to the largely ineffectual and toxic conventional approaches of the day: purging, bleeding, and treatments with heavy metals such as mercury and arsenicals.

DEMOGRAPHY, USE, TOXICITY, AND EFFICACY

The use of CAM and TM varies widely between and within countries. The World Health Organization (WHO) has published and

Table 69.1 Estimated Use of CAM and TM by Patients and Practitioners Worldwide

Region or country	Extent of use
Africa	Used by 80 percent of the population for primary health care
Australia	Used by 49 percent of adults
China	Accounts for 30 to 50 percent of total health care Fully integrated into the health system 95 percent of Chinese hospitals have TM units
India	Widely used 2,860 hospitals provide TM
Indonesia	Used by 40 percent of the entire population Used by 70 percent of the rural population
Japan	72 percent of physicians practice TM
Thailand	TM integrated into 1,120 health centers
Vietnam	Fully integrated into the health care system 30 percent of the population is treated with TM
Western countries	CAM and TM not strongly integrated into the health care system France: at least 75 percent of the population has used CAM at least once Germany: 77 percent of pain clinics provide acupuncture United States: 29 to 42 percent of population uses CAM

Source: WHO 2002.

summarized numerous surveys of use (table 69.1). In developing nations, TM is the sole source of health care for all but the privileged few. By contrast, in affluent countries individuals select CAM approaches according to their specific beliefs. For example, as many as 60 percent of those living in France, Germany, and the United Kingdom consume homeopathic or herbal products. Only 1 to 2 percent of Americans use homeopathy, but 10 percent of adults use herbal medicines, 8 percent visit chiropractors, and 1 to 2 percent undergo acupuncture every year (Ni, Simile, and Hardy 2002). Use of CAM and TM among patients with chronic, painful, debilitating, or fatal conditions, such as HIV/AIDS and cancer, is far higher, ranging from 50 to 90 percent (Richardson and Straus 2002).

There is remarkably little correlation between the use of CAM and TM approaches and scientific evidence that they are safe or effective. For many CAM and TM practices, the only evidence of their safety and efficacy is embodied in folklore. Beginning more than 1,500 years ago, data on the use of thousands of natural products were assembled into impressive monographs in China, India, and Korea, but these compendiums—and similar texts from Arabic, Egyptian, Greek, and Persian sources and their major European derivatives—are merely catalogs of products and their use rather than formal analyses of safety and efficacy.

Table 69.2 Some Natural Products That May Alter Drug Actions

Herbal product	Class of drug
Ephedra (<i>ma huang</i>)	Alpha and beta adrenergics
Garlic	Anticoagulants; some HIV protease inhibitors
Ginkgo biloba extract	Anticoagulants
Glucosamine	Antidiabetics
Saw palmetto	Androgens
St. John's wort	HIV protease inhibitors; some chemotherapy drugs; cyclosporine A; birth control
Valerian	Sedatives

Source: Niggemann and Gruber 2003.

Many people who today choose herbal products in lieu of prescription medications assume that because these products are natural, they must be safe, even when the evidence for this assertion is essentially anecdotal. Recent studies have shown that herbals are highly variable in quality and composition, with many marketed products containing little of the intended ingredients and containing unintended contaminants, such as heavy metals and prescription drugs. A few herbals are banned outright in several countries. Comfrey and kava have been associated with liver failure, aristolochia with genitourinary cancer (De Smet 2002), and ephedra with heart attacks and strokes (Shekelle and others 2003). More important, herbals contain ingredients that can accelerate or inhibit the metabolism of prescription drugs (table 69.2). The most notorious of these is St. John's wort, which affects the metabolism of nearly 50 percent of all prescription drugs (Markowitz and others 2003). The cumulative data on the pharmacological and potential adverse effects of herbal supplements now dictate that patients discuss their use of supplements with knowledgeable practitioners before initiating treatment.

As to evidence of the efficacy of CAM and TM approaches, thousands of small studies and case series have been reported over the past 50 years. Few were rigorous enough to be at all compelling, but they are sufficient to generate hypotheses that are now being tested in robust clinical trials. The existing body of data already shows that some approaches are useless, that for many the evidence is positive but weak, and that a few are highly encouraging (table 69.3).

ECONOMICS OF COMPLEMENTARY AND ALTERNATIVE MEDICINE AND TRADITIONAL MEDICINE

Although social, medical, and cultural reasons may account for why people in a given country prefer CAM and TM to conventional (Western) medicine, economic forces are also at play.

This section describes the socioeconomic determinants of seeking treatment from traditional healers and providers of CAM; reviews the evidence on the cost-effectiveness of CAM and TM; and discusses cost-effective approaches to regulating, improving, and expanding the use of CAM and TM. Much of this evidence is from industrial countries; few studies have been conducted in or are applicable to low- and middle-income countries. This caveat is important for two reasons. First, the CAM and TM modalities discussed in this section may not be used in many developing countries. Second, the limited data on cost-effectiveness may not be applicable in the case of those countries. Nevertheless, the data give a rough picture of the relative cost-effectiveness of a number of CAM and TM practices.

Economic Factors That Influence the Use of Complementary and Alternative Medicine and Traditional Medicine

Users of CAM and TM approaches choose health practices that resonate with their beliefs about health (Astin 1998). Although economic factors play a role in this choice, the underlying incentives are not always predictable. For instance, a common misconception is that patients opt for CAM and TM services because they are cheaper alternatives to conventional medical care. Even though there are certainly instances when the cost of treatment using CAM or TM is much cheaper than the cost of accessing a conventional medical service, several studies have found that CAM and TM cost the same or more than conventional treatments for the same conditions (see, for example, Muela, Mushi, and Ribera 2000).

At least one study has shown that financial considerations are rarely the primary factor in choosing a traditional healer, ranking behind such reasons as confidence in the treatment, ease of access, and convenience (Winston and Patel 1995). In the United States, the average cost of a single visit to a Navajo healer was US\$388, and the average annual cost of using a traditional healer represented roughly a fifth of the reported annual income of respondents in a survey (Kim and Kwok 1998). The high cost of using a healer was cited as the most common barrier to seeking care from this source. In Kenya, the average charge per patient per visit to a TM practitioner was K Sh 46 (US\$4 in 1981), which was significantly greater than the average charge per visit even in private health care facilities (Mwabu, Ainsworth and Nyamete 1993). Finally, a survey in Zimbabwe reported that the median cost of consulting an herbalist was Z\$23 per visit, compared with Z\$1 for a government clinic and Z\$29 for a private doctor (Winston and Patel 1995). The same survey found that outcomes tended to be better when patients went to government clinics (67.3 percent of visits resulted in a good outcome) than when patients consulted herbalists (50 percent of visits resulted in a good outcome).

TM is not always more expensive than conventional medicine, however. Survey respondents in Ghana reported that the

Table 69.3 Levels of Evidence for the Efficacy of Selected CAM and TM Approaches

CAM or TM approach	Potential use	Study outcome	Level of evidence	Source
<i>Artemisia annua</i>	Treating drug-resistant malaria	Positive	A	van Agtmael, Eggelte, and van Boxtel 1999
Black cohosh	Controlling menopausal symptoms	Mixed	B	Kronenberg and Fugh-Berman 2003
Cranberry	Preventing urinary tract infection	Positive	B	Jepson, Mihaljevic, and Craig 2000
Echinacea	Preventing or treating viral colds	Mixed	B	Barrett 2003; Taylor and others 2003
Garlic	Lowering blood cholesterol	Positive	C	Le Bars and others 1997
Ginkgo biloba extract	Preventing or treating dementia	Mixed	B	Kanowski and Hoerr 2003
Ginseng	Improving energy and immunity against infection	Mixed	C	Richy and others 2003
Glucosamine	Relieving osteoarthritis	Positive	A	Reginster, Deroisy, and Rovalty 2001
Hawthorn	Improving cardiac function	Mixed	B	Pittler, Schmidt, and Ernst 2003
Milk thistle	Improving liver function	Positive	C	Jacobs and others 2002
St. John's wort	Treating moderate to severe depression	Negative	A	Hypericum Depression Trial Study Group 2002
	Treating mild depression	Positive	B	Di Carlo and others 2001
Saw palmetto	Relieving symptoms of benign prostatic hypertrophy	Positive	B	Gerber and others 2001
Acupuncture	Relieving arthritis pain	Positive	B	Berman and others 1999
	Relieving the pain of tooth extraction	Positive	B	Lao and others 1995
	Treating hypertension	Mixed	C	Chiu, Chi, and Reid 1995
	Relieving nausea from chemotherapy	Positive	A	Shen and others 2000
	Relieving addiction withdrawal	Mixed	B	Margolin and others 2002
	Treating asthma	Negative	B	Linde, Jobst, and Panton 2000

A = multiple high-quality, randomized, controlled trials; B = single high-quality trials or smaller, less rigorous trials; C = weaker clinical trials; Mixed = conflicting results among studies of similar quality.

cost of malaria treatment at a health clinic ranged from €1,900 to €3,000 (US\$1.30 to US\$2.00 in 1997), treatment at home using drugs bought from pharmacies or health care workers ranged between €200 and €1,000 (US\$0.10 to US\$0.70), and treatment by an herbalist was virtually free (Ahorlu and others 1997).

Another common misconception is that the poor are more likely to use TM. At least one study shows that this may not be true. In Zimbabwe, the mean monthly income of households visiting an herbalist, Z\$877, was greater than the mean monthly income of households using government clinics, Z\$718 (Winston and Patel 1995).

Although some traditional healers charge more than conventional practitioners, their fees may be negotiable, the method of payment may be flexible (often on credit or in

exchange for labor), and payment may be contingent on outcome. The availability of an outcome-contingent contract favors TM over Western medicine when the disease condition requires providers to both exert effort in curing patients and induce patients to comply with their recommendations. Nonetheless, this strategy may be difficult to apply to the larger health care system.

Furthermore, patients tend to seek care from traditional healers for conditions such as mental illness, impotence, and chronic disorders, which they perceive as requiring greater involvement by the extended family and kinship group. Accordingly, the availability of financial support for seeking treatments for these disorders is greater than it is for illnesses such as malaria or diarrhea, for which patients more often seek conventional treatment.

Few published data are available on the financial costs of TM in low- and middle-income countries. The data presented here on the use of traditional healers are extracted from the World Bank's living standards surveys in Vietnam to provide one nationally representative snapshot of the situation. Of 28,254 individuals in the sample, 10,033 had consulted a health care provider in the four weeks preceding the survey. These consultations included both home visits and visits to a provider. Of the 10,033, 1,829 had been to a public provider, 1,431 to a private provider, 7,650 to a pharmacy, and 259 to a traditional healer.¹ The most common reasons for visiting a traditional provider were headache, followed by cough and fever. The per visit drug cost for consulting a traditional healer was D 46, and the total cost per visit was D 51, compared with drug costs of D 38 and total costs of D 41 for going to a private clinic.

One commonly cited motivation for using CAM and TM is that their use might lower the incidence and costs of side effects associated with conventional treatments, but the published evidence on this point remains mixed. There is some evidence that CAM is used in addition to conventional treatments (Thomas and others 1991), but CAM may also have the effect of displacing conventional treatments. An outpatient survey found that, of 246 patients who had been receiving conventional treatment from the Royal London Homeopathic Hospital since the onset of care, a third had halted their conventional treatment and another third had reduced their intake of conventional medication (van Haselen 2000).² The extent to which homeopathic treatment displaced conventional treatment varied by indication. The use of homeopathic treatment often replaced conventional treatments in patients with skin and respiratory infections; in patients with cancer, its use was purely complementary and therefore added to overall health care costs.

Thomas and others (1991) observe that patients who use CAM and TM also commonly access conventional medical care. In industrial countries, most CAM usage complements conventional care, but this is also common in developing nations. For instance, Mwabu (1986) provides evidence from Kenya that patients are likely to use more than one type of provider from the range of those available, such as government facilities, mission clinics, private clinics, pharmacies, and traditional healers. Furthermore, the choice of provider depends on patients' illness, condition, socioeconomic status, and education. If an initial visit to one kind of provider did not resolve the disease satisfactorily, a follow-up visit was made to a different kind of provider. Finally, the quality of care—including efficiency of service and waiting time at government and private clinics—is an important determinant of whether patients choose to go to traditional healers. Most traditional healers surveyed in a second study referred patients to Western practices for treatment when necessary (Mwabu, Ainsworth, and Nyamete 1993).

Economic Evidence

Although most studies tend to focus on a specific CAM or TM practice, Sommer, Burgi, and Theiss (1999) looked more broadly at whether the provision of CAM and TM services through prepaid health plans or government insurance reduces the overall costs of health care and found that it does not. A possible reason is that few individuals who are offered access to CAM use them, and those who do might access those services in addition to, not in place of, more conventional health services.

Studies that compare the cost-effectiveness of different CAM and TM approaches using the same analytical framework are rare. One such study in Peru looked at the costs and cost-effectiveness of treatment using conventional medicine and TM (EsSalud and OPS 2000). Complementary medical practices evaluated included acupuncture, homeopathy, tai chi, meditation, reflexology, hydrotherapy, naturopathy, and massage. Patients were enrolled in either the Western medicine group or the CAM group. Patients were not randomized between the two treatment groups, but they were matched by disease pathology and severity, age, and sex. Furthermore, selected patients had completed at least one year in the health system, as the investigators reasoned that this would enable them to evaluate their follow-up. Overall, the investigators found that complementary medicine was between 53 and 63 percent less expensive than conventional medicine for achieving equivalent levels of effectiveness. Complementary medicine was especially cost-effective for osteoarthritis, hypertension, facial paralysis, and peptic ulcers.

The rest of this section looks at the economic evidence on specific forms of CAM or TM.

Acupuncture. Lindall's (1999) study finds that an acupuncture referral for musculoskeletal conditions costs a mean of US\$422, roughly 60 percent less than the cost of referral to a Western practitioner. However, this study was not randomized, and patients had to have failed first-line drug treatment before being offered the choice of second line-treatment, either with acupuncture or with Western medicine.

Homeopathy. Evidence indicates that the cost of homeopathic medication is lower than the average cost of allopathic products, which would be an economic factor in favor of its use if homeopathy were proven to be effective. A study by the National Health Service in the United Kingdom found that the drug costs associated with homeopathy were lower than those of allopathic practitioners (Swayne 1992). A four-year study of 100 patients that compared homeopathic drug costs with those of conventional drugs found an average cost saving of US\$96 during the study period for those using homeopathic drugs (Jain 2003).³

Ayurveda. A study that compared medical expenditures over a four-year period for participants in a comprehensive program of ayurvedic-based natural medicine (which included antioxidant strategies, mind-body medicine, and other techniques) with participants whose expenditures were covered through a BlueCross BlueShield health insurance plan found that the expenditures for the ayurvedic group were 50 percent lower per person (Orme-Johnson and Herron 1997). However, the study was not randomized and failed to control for the inclination of only a subset of people to accept and remain compliant with ayurvedic approaches.

Chiropractic. Some studies found that spinal manipulation is less expensive than conventional treatments for episodes of back pain. One nonrandomized study found that the cost of chiropractic treatment over a five-year period, including both provider costs and equipment costs (US\$28,902), was 24 percent less than the cost of Western pain therapy (US\$38,029) (Kumar, Malik, and Demeria 2002). Moreover, 15 percent of patients in the chiropractic group were able to return to work, compared with none in the control group.

However, other larger and better-controlled studies failed to find a difference between chiropractic and physical therapy in terms of either outcomes or costs (Cherkin and others 1998; Skargren and others 1997; Skargren, Carlsson, and Oberg 1998). A study of adults with low back pain who were randomly assigned to physical therapy or chiropractic manipulation or were just given an educational booklet found no significant differences in either the mean costs of care or the outcomes between the physical therapy and chiropractic groups (Cherkin and others 1998). Three-quarters of the participants in these groups—who incurred costs of roughly US\$430 over the two-year period of the study—reported that their outcome was either good or excellent, compared with a third of those who were assigned booklets; however, the mean cost of care for the booklet group was only US\$153 for the two-year period.

Mind-Body Treatments. Little evidence is available on the cost-effectiveness of practices such as meditation and yoga, but the cost of acquiring the skills required for these practices, as well as the time costs of practicing them, are so low relative to conventional medicine that evidence of their clinical effectiveness might suffice to justify their use on economic grounds. Available evidence from clinical studies suggests that mind-body treatments can be cost-effective (Caudill and others 1991; Friedman and others 1995; Hellman and others 1990; Sobel 1995). Blumenthal and others (2002) find significant declines in coronary events and in predicted costs of care for patients who were assigned to a one-and-a-half-hour long weekly class on stress management, relative to usual care for each of the first two years of follow-up and after five years.

Beyond Cost-Effectiveness: Ancillary Benefits and Costs of CAM and TM

Although cost-effectiveness is one guiding rationale for determining resource allocations for expanding (or restricting) access to CAM and TM, additional societal benefits and costs, such as effects on biodiversity, must also be considered. CAM and TM could provide a rationale for conserving species, but overharvesting of endangered species for medicinal purposes is also a concern. According to WHO, 85 percent of the world's population (principally those in developing countries) depends on plants for medicine, and 25 percent of prescription drugs have an active ingredient derived from a flowering plant (Cox 2001). The possible extinction of medicinal plants is of concern not only to developing countries but also to industrial countries, as in the cases of poaching of American ginseng and overharvesting of native saw palmetto. Similarly, the reliance of Chinese TM on tiger genitals, bear gallbladders, and black rhinoceros horns has played an important role in poaching and threatens to wipe out these mega fauna.

Local knowledge and culture regarding the uses of medicinal plants may be important determinants of whether a certain species will survive (Etkin 1998). In addition to the biodiversity value of these saved species, scientists may be able to analyze these plants for potential clinical application on a broader scale than TM permits. Although preserving traditional knowledge of healing practices helps preserve the culture and identity of indigenous populations, CAM and TM may impose significant costs. In such instances, promoting conventional treatments that do not depend on endangered species may bring important benefits to society.

EXPANDING THE BENEFICIAL USE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE AND TRADITIONAL MEDICINE

Despite the uncertainty about the clinical efficacy and cost-effectiveness of certain CAM and TM practices, expansion of their use in instances in which moderate evidence of their efficacy and good evidence of their safety exists could yield health, social, and economic benefits. A number of surveys show that local pharmacies are the primary source of treatment for many ailments, especially in rural areas where government or private clinics are less accessible. In these situations, improving the quality of TM might serve as an effective substitute for allowing the unregulated use of conventional medical treatments. Training traditional healers is substantially less expensive than training doctors or nurses. A study of 52 traditional healers interviewed as part of a survey in Kenya estimated that the average out-of-pocket (cash) costs of training to be a traditional healer were K Sh 418 (US\$40 in 1981) (Mwabu, Ainsworth, and Nyamete 1993).

Traditional healers can also be recruited into a more broadly based system for delivering public health; for example, with additional training, traditional healers can serve as primary health care workers (Hoff 1997) and provide advice on such matters as sexually transmitted diseases and oral rehydration therapy (Nations and de Souza 1997; Nations and others 1988; Ndubani and Hojer 1999). In addition, permitting access to CAM and TM within the context of the conventional health care system would facilitate access to multiple health services at one location.

Comprehensive policy on CAM and TM is lacking in most countries, including the United States. According to the 1994 Dietary Supplement, Health, and Education Act, the U.S. Food and Drug Administration cannot require proof that dietary supplements and herbal products are safe and effective before they are sold, although it is charged with requiring good manufacturing practices. The quality of herbal products is not regulated, and herbal products typically differ from source to source and from batch to batch in terms of their component ingredients and respective amounts and in terms of whether they contain contaminants. In the United States, no single entity is responsible for all aspects of CAM and TM control, education, information, and research, and no national, voluntary system of self-regulation exists. National nongovernmental organizations, such as the Accreditation Commission for Acupuncture and Oriental Medicine, the American Board of Medical Acupuncture, the Council of Chiropractic Education, the Council of Homeopathic Education, and the Commission on Massage Therapy Accreditation, accredit education in some CAM and TM fields, but such accreditation bodies do not exist in many developing countries. Nearly all countries lack rigorous research training programs in CAM and TM.

A common misperception is that in the developing world CAM and TM is used primarily by poorer, uneducated populations, while in industrial countries it is used more by affluent and better-educated segments of the population (Eisenberg and others 1998). In both settings, relatively little evidence supports this view. Many investigators have failed to critically assess the use of CAM and TM by minority and immigrant populations in Western nations. In Africa, nearly 85 percent of the population uses TM, often as the only way to obtain primary health care, and wealthier people in developing countries often use TM (WHO 2002). Investments in improving the quality and consistency of TM could reduce the cost of health care delivery, especially for chronic conditions such as arthritic pain and AIDS, where TM interventions may improve patients' sense of well-being, appetite, and energy. At the same time, in the absence of resources to extend the public health infrastructure, a network of certified CAM and TM providers could provide the infrastructure for delivering other care, such as immunizations and maternal-child health programs.

Recognizing the redistributive nature of investment in TM is important. Indigenous people will seek the help of traditional healers because of proximity, familiarity, and trust. Investments in TM could therefore be used strategically to increase access to conventional preventive and therapeutic care. Including the traditional healer as part of the health care team may thus be an important strategy both to attract patients and to upgrade the skills and training of traditional healers.

How equity is affected by the proportions in which different condition-specific interventions are combined and how other interventions (regulations, tax policy, managerial changes) are likely to affect equity need to be studied. Given that the majority of indigenous populations in developing countries use TM for their primary health care, the availability, safety, and affordability of TM, including herbal medicines, should be ensured as a matter of equity. One way to do this is by supporting local production of safe and effective herbals such as artemisia at affordable prices. In addition, rigorous research on TM should be supported. WHO is currently conducting collaborative studies on herbal treatments for HIV/AIDS, malaria, sickle cell anemia, and diabetes. Ineffective or unsafe herbal products identified by such studies should be removed from use, while those with proven efficacy and safety should be made available for therapeutic use.

LESSONS LEARNED AND IMPLEMENTATION

The pervasiveness of different modalities of TM and CAM varies greatly from country to country. For example, in China, where traditional Chinese medicine is well integrated into the health system, many different modalities may be used to treat a given condition. In the United States, by contrast, CAM programs are slowly being integrated with conventional medicine. Several medical schools have nascent CAM programs and have integrated them into medical school curricula to differing degrees. One of the more acclaimed programs of this kind in the United States is that developed by Andrew Weil at the University of Arizona Health Sciences Center. His Integrative Medicine Fellowship Program trains physicians in CAM and TM and strives to produce a new delivery model whereby physicians, patients, and nurses form a healing team for the care of the patient. However, this program needs to be critically evaluated before its adoption by more institutions can be urged.

Despite the complexity, diversity, and controversy surrounding CAM/TM approaches, some notable success stories reveal the influence of globalization, whereby modalities discovered in the developing world have been adopted in the West, with or without modifications, and vice versa.

Artemisinin

Artemisinin is a recently developed, active metabolite of artemisia, an herbal extract that has been used in China for centuries to treat fever. Chinese scientists determined the active ingredient of the herbal in the 1970s, and Western pharmaceutical companies have developed several derivatives as drugs for use against resistant *Plasmodium malaria* (Li and others 2000). Randomized clinical trials have shown that one such drug, dihydroartemisinin-piperazine, is effective against drug-resistant *Plasmodium falciparum* malaria (Hien and Dolecek 2004). Another artemisinin derivative, artesunate, was shown to increase parasite clearance and reduce the gametocyte count when added to existing drugs to combat malaria (Adjuik and others 2004).

Acupuncture

Another CAM and TM modality that has considerable acceptance is acupuncture. Many pain management clinics, hospitals, and academic centers in the West now provide acupuncture services, and some insurance companies reimburse for acupuncture services. Rigorous clinical trials have demonstrative positive efficacy in two areas: (a) management of postoperative nausea and emesis (Shen and others 2000) and (b) amelioration of the pain of chronic osteoarthritis (Ezzo and others 2001; Soeken 2004; Tukmachi and others 2004). Studies providing rational explanations of the mechanisms whereby acupuncture might be achieving its effects complement the evidence about its efficacy; for example, one mechanism of action appears to involve opioid-dependent brain pathways. This kind of two-step process—that is, initial demonstration of clinical efficacy followed by scientific research into the mechanism of action—is one way that CAM and TM will gain scientific acceptance and integration into conventional medicine.

Chiropractic Medicine and Osteopathy

Chiropractic medicine was invented in the American heartland during the waning years of the 19th century. It uses spinal manipulation to treat an array of conditions thought to arise because of abnormal alignment of or stresses on vertebrae, most often in patients with musculoskeletal complaints. Two aspects of chiropractic medicine are success stories. First, even though practitioners of conventional medicine ostracized practitioners of chiropractic medicine in the late 19th century and the first half of the 20th century, it has gradually evolved into a viable healing discipline that is increasingly accepted by the conventional medicine community. The evolution of chiropractic can be compared with that of osteopathy. Osteopathy was developed in the United States in parallel with chiropractic, but the field elected to accommodate rather than reject allopathic techniques.

The second success story is research showing that chiropractic manipulation for low back pain is superior to bed rest, physical therapy, or provision of an educational booklet (Cherkin and others 1998). Chiropractic manipulation has also shown results comparable to those achieved with nonsteroidal, anti-inflammatory drugs in alleviating back pain (Straus 2004).

Homeopathy

Homeopathy is a success in terms of its broad appeal and use, not because of the strength of evidence supporting it. Indeed, few conventional scientists and physicians find homeopathy to be plausible. According to the “principle of similars” underlying homeopathy, practitioners choose remedies that, when given in high concentrations, produce symptoms similar to those that the patient presents with. The substance is then put in solution and serially diluted by as much as 10^{60} , well beyond the point defined by Avogadro’s number (at which a single molecule of the original substance could remain in the solution). Homeopathy claims that the acts of serial diluting and vigorous shaking imprint information into water so that medicinal properties are retained even when no or few molecules of the starting medicine are present.

As implausible as this claim may seem, homeopathy is used worldwide with reported success (Jonas, Kaptchuk, and Linda 2003). Randomized controlled trials have suggested that it might be effective for treating influenza (Vickers and Smith 2000), allergies (Taylor and others 2000), and postoperative ileus (Barnes, Resch, and Ernst 1997). However, critics have questioned the quality and analyses of these trials. Some have questioned the validity of pooling data from trials of different populations, interventions, and outcome measures, as several reviews of homeopathy have done. Jonas, Kaptchuk, and Linda (2003, 393) assert that “there is a lack of conclusive evidence on the effectiveness of homeopathy for most conditions. Homeopathy deserves an open-minded opportunity to demonstrate its value by using evidence-based principles, but it should not be substituted for proven therapies.”

Mind-Body Intervention

The work of David Spiegel at Stanford University on group support for breast cancer patients excited wide interest in the potential value of mind-body interventions (Spiegel and others 1989). The study was a randomized controlled trial with a 10-year follow-up involving 86 women with metastasized breast cancer. A one-year psychosocial intervention consisting of weekly supportive group therapy with self-hypnosis for pain showed that the mean survival time in the treated group was 37 months, compared with 19 months for the control group. Moreover, Spiegel (1994) notes that appropriate psychotherapy (both group and individual) not only reduced depression and

anxiety and improved coping skills, but also saved money by reducing the number of office visits, diagnostic tests, medical procedures, and hospital admittances. Although Spiegel's findings have not been replicated, they do illustrate the potential benefits of mind-body intervention and have led to studies of possible mechanisms through which such interventions may operate.

THE RESEARCH AND DEVELOPMENT AGENDA

The lack of product quality and consistency and the absence of compelling data on the safety and efficacy of most CAM and TM approaches present major challenges to any effort to optimize the distribution of precious health resources. These difficulties also pose opportunities for research. Other formidable challenges include the variability in training, credentialing, and licensing CAM and TM practitioners. Increasingly, efforts are being made in several countries to regulate both products and practitioners. Ultimately, stringent controls on training, practices, and products must be complemented by rigorous research to ascertain which approaches are safe and effective—and for which indications.

The global use and potential effect of CAM and TM practices, the lack of adequate data validating their safety and efficacy, and the existence of highly effective conventional alternatives for many of them dictate that resources should be devoted to fuller characterization and standardization of CAM and TM approaches. Investing precious resources in integrating such approaches further into health care infrastructures can be justified only on the basis of compelling data. This point leads to the question of what constitutes a rational agenda for this work.

For resource-rich industrial nations, one model for CAM and TM research is that being implemented by the National Center for Complementary and Alternative Medicine (NCCAM) of the U.S. National Institutes of Health (<http://nccam.nih.gov>). In 2004, NCCAM planned to invest US\$117 million in research and research training. It is supporting some 800 individual projects at present, including studies of the composition of natural products and their pharmacological effects, studies of the neurobiological mechanisms of acupuncture and the placebo effect, and clinical trials with 30 to 30,000 participants. NCCAM now has a strategic plan for its international programs that emphasizes research, training, and efforts to learn about the rich, indigenous TM heritage. Australia, through a government agency similar to NCCAM, is conducting research and training programs in collaboration with its indigenous people. Although the scope of NCCAM's research agenda is larger than what most other nations could accommodate, its underlying philosophy should be universal. That is, the standards for research into CAM and TM approaches

should be no different from those used in conventional biomedical research.

Both CAM and TM and biomedical practitioners need to understand the strengths, limitations, and contributions of their particular approaches so that they can work together in ways that ensure the best possible care for their patients and the achievement of their shared goals of improved individual and public health. Once these issues have been addressed, countries could devote additional resources to studying those CAM and TM approaches that appear to be the most promising in relation to their most pressing public health problems. Some priority areas for CAM and TM research are widely applicable, including studies of approaches to palliate chronic pain and suffering, relieve depression, help release the grip of addictive substances, and slow the progression of degenerative disorders such as arthritis and dementia.

NOTES

1. Because some individuals had gone to more than one provider during the four-week period, the total comes to more than 10,033.
2. The median duration of current treatment at the Royal London Homeopathic Hospital was three years.
3. This study did not take into account the costs of physician time, the costs of laboratory tests, or patients' costs.

Chapter 70

Improving the Quality of Care in Developing Countries

John W. Peabody, Mario M. Taguiwalo, David A. Robalino,
and Julio Frenk

Although the quantity rather than quality of health services has been the focus historically in developing countries, ample evidence suggests that quality of care (or the lack of it) must be at the center of every discussion about better health. The following examples are illustrative: In one study evaluating pediatric care in Papua New Guinea, 69 percent of health center workers reported that they checked for only two of the four examination criteria for pneumonia cases. Only 24 percent of these workers were able to indicate correct treatment for malaria. When clinical encounters were observed at aid posts, providers met minimal examination criteria in only 1 percent of cases (Beracochea and others 1995). In a study in Pakistan, only 56 percent of providers met an acceptable diagnostic standard for viral diarrhea, and only 35 percent met the acceptable standard for treatment (Thaver and others 1998).

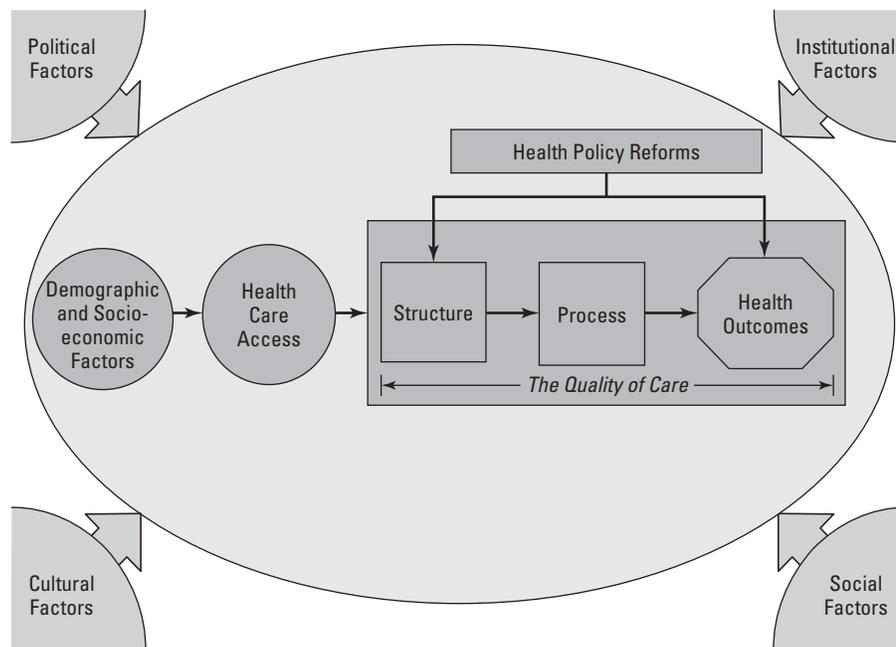

QUALITY DEFINITION AND POPULATION FRAMEWORK

These deficiencies in quality of care represent neither the failure of professional compassion nor necessarily a lack of resources (Institute of Medicine 2001). Rather, they result from gaps in knowledge, inappropriate applications of available technology (Murray and Frenk 2000), or the inability of organizations to change (Berwick 1989). Local health care systems may have failed to align practitioner incentives and objectives, to measure clinical practice, or to link quality improvement to better health outcomes.

Increasing evidence, much of it developed since the mid 1990s, shows that quality can be improved rapidly. However, to improve clinical practice—and thus quality of care—quality must be defined and measured, and appropriate steps must be taken (Silimper and others 2002). This chapter highlights approaches to improving clinical practice and quality of care that take place over months instead of years. Indeed, better quality can improve health much more rapidly than can other drivers of health, such as economic growth, educational advancement, or new technology.

Definition and Framework

Health systems provide health actions—activities to improve or maintain health. These actions take place in the context of and are influenced by political, cultural, social, and institutional factors (shown along the edges of figure 70.1). Demographic and socioeconomic makeup, including genetics and personal resources, affect the health status of individuals seeking care. Access to the health care system is required to obtain the care that maintains or improves health, but simple access is not enough; the system's capacities must be applied skillfully. Thus, *quality* means optimizing material inputs and practitioner skill to produce health. As the Institute of Medicine defines it, quality is “the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” (Institute of Medicine 2001, 244).

Source: Peabody and others 1999.

Figure 70.1 Quality-of-Care Framework

Elements of Quality. Quality comprises three elements:

- *Structure* refers to stable, material characteristics (infrastructure, tools, technology) and the resources of the organizations that provide care and the financing of care (levels of funding, staffing, payment schemes, incentives).
- *Process* is the interaction between caregivers and patients during which structural inputs from the health care system are transformed into health outcomes.
- *Outcomes* can be measured in terms of health status, deaths, or disability-adjusted life years—a measure that encompasses the morbidity and mortality of patients or groups of patients. Outcomes also include patient satisfaction or patient responsiveness to the health care system (WHO 2000).

Structural measures are the easiest to obtain and most commonly used in studies of quality in developing countries. Many evaluations have revealed shortages in medical staff, medications and other important supplies, and facilities, but material measures of structure, perhaps surprisingly, are not causally related to better health outcomes (Donabedian 1980). Although higher technology or a more pleasant environment may be conducive to better-quality care, the evidence indicates only a weak link between such structural elements and better health outcomes (Donabedian 1988). The notable exceptions are cases in which physical improvements either increase access to primary care in very poor settings or increase the volume of a clinical procedure, such as cataract surgery, that is specifically linked to

better health outcomes (Javitt, Venkataswamy, and Sommer 1983). At best, however, structure is a blunt approximation of process or outcomes; structural improvements by themselves rarely improve the health of a population.

Process, by contrast, can be measured with every visit to a provider. Measuring process is difficult, however, particularly in developing countries. The private nature of the doctor-patient consultation, a lack of measurement criteria, and the absence of reliable measurement tools have limited the ability to assess process (Peabody, Tozija, and others 2004). However, new methods are being developed that can provide valid measurements of clinical practice (Thaver and others 1998). In addition, evidence-based clinical studies have steadily revealed which process measures lead to better health outcomes. This combination of ubiquity, measurability, and linkage to health outcomes makes the measurement of process the preferred way to assess quality.

Although good outcomes are the objective of all health actions, outcomes alone are not an efficient way to measure quality for two reasons. The first is the quality conundrum. A patient may receive poor-quality care but may recover fully, or a patient may receive high-quality care for an illness such as cerebral malaria and still not recover. Second, adverse health outcomes are relatively rare and obviously do not occur with every encounter.

The classic framework of structure-process-outcome is well established. However, in recent years the concept of quality has been expanded to include specific aims for improvement. For example, the Institute of Medicine's (2001) landmark report,

Box 70.1

The Institute of Medicine's Six Elements of Quality

1. *Patient safety.* Are the risks of injury minimal for patients in the health system?
2. *Effectiveness.* Is the care provided scientifically sound and neither underused nor overused?
3. *Patient centeredness.* Is patient care being provided in a way that is respectful and responsive to a patient's preferences, needs, and values? Are patient values guiding clinical decisions?
4. *Timeliness.* Are delays and waiting times minimized?
5. *Efficiency.* Is waste of equipment, supplies, ideas, and energy minimized?
6. *Equity.* Is care consistent across gender, ethnic, geographic, and socioeconomic lines?

Source: Institute of Medicine 2001.

Crossing the Quality Chasm, broadens the concept to include other, more contextual elements to illuminate how process changes can improve care. It focuses on six aims: patient safety, effectiveness, patient centeredness, timeliness, efficiency, and equity (see box 70.1).

Quality Assessment Perspectives. We can look at the Institute of Medicine's aims from two perspectives: patient perception, and technical or professional assessment. Patients' perceptions of quality depend on their individual characteristics and affect their compliance, follow-up decisions, and long-term lifestyle changes (Zaslavsky and others 2000). Interpersonal relationships, cultural appropriateness, and gender sensitivity—long thought to be luxuries of wealthier countries—are also major determinants of patient access and utilization in developing countries. These findings have led to the inclusion of patient satisfaction and patient responsiveness as outcome measures.

Technical assessment concerns whether providers meet normative standards for appropriateness of care or adherence to explicit evidence-based criteria. Although patient perception or satisfaction is important, researchers increasingly rely on objective, evidence-based quality criteria that can be more readily linked to better health outcomes at both the individual and the population levels.

Population-Level Considerations. Quality is typically assessed through the interaction between individual doctors and patients. However, emerging evidence shows that the average quality of care given by groups of doctors and other providers is an important determinant of overall community health status. For example, in a cross-sectional analysis in the former Yugoslav Republic of Macedonia, researchers found not only that patients' health status was significantly higher in areas where quality was higher but also that the overall self-reported health status of those members of the general population who

had not recently received care was higher (Peabody, Tozija, and others 2004).

Our quality-of-care framework supports these findings. When process is improved among groups of providers, the aggregate improvement in quality leads to better health outcomes for the entire patient population. In addition, resources can be allocated among clinical interventions based on actual effectiveness and the overall impact of care on the population. For example, cancer chemotherapy may be available and may prolong the lives of cancer patients. However, it may result in fewer lives saved than the expansion of coverage of directly observed treatment short-course coverage for tuberculosis patients.

QUALITY OF CARE IN DEVELOPING COUNTRIES

The process of providing care in developing countries is often poor and varies widely. A large body of evidence from industrial countries consistently shows variations in process, and these findings have transformed how quality of care is perceived (McGlynn and others 2003). A 2002 study found that physicians complied with evidence-based guidelines for at least 80 percent of patients in only 8 of 306 U.S. hospital regions (Wennberg, Fisher, and Skinner 2002). It is important to note that these variations appear to be independent of access to care or cost of care: Neither greater supply nor higher spending resulted in better care or better survival. Studies from developing countries show similar results. For example, care in tertiary and teaching hospitals and care provided by specialists may be better than care for the same cases in primary care facilities and by generalists (Walker, Ashley, and Hayes 1988).

One explanation for variation and low-quality care in the developing world is lack of resources. Limited data indicate, however, that high-quality care can be provided even in environments with severely constrained resources. A study in Jamaica, which used a cross-sectional analysis of government-run

primary care clinics, showed that better process alone was linked to significantly greater birthweight (Peabody, Gertler, and Liebowitz 1998). A study in Indonesia attributed 60 percent of all perinatal deaths to poor process and only 37 percent to economic constraints (Supratikto and others 2002).

Cross-system or cross-national comparisons provide the best examples of the great variation in clinical practice in developing countries. In one seven-country study, researchers directly observing clinical practice found that 75 percent of cases were not adequately diagnosed, treated, or monitored and that inappropriate treatment with antibiotics, fluids, feeding, or oxygen occurred in 61 percent of cases (Nolan and others 2001). Another study compared providers' knowledge and practice in California and FYR Macedonia, using vignettes to adjust for case-mix severity. Although the quality of the overall or aggregate process was lower in FYR Macedonia, a poor country, the top 5 percent of Macedonian doctors performed as well as or better than the average Californian doctor (Peabody, Tozija, and others 2004).

In a study commissioned for this chapter, an international team measured quality in five developing countries (China, El Salvador, India, Mexico, and the Philippines), using the same clinical vignettes at each site. The team evaluated the process for common diseases according to international, evidence-based criteria. Quality varied only slightly among countries. The within-country range of quality of doctors was 10 times as great as the between-country range. Such wide variation strongly suggests that efforts to improve health status must involve policies that change the quality of clinical care.

POLICY INTERVENTIONS TO IMPROVE QUALITY

The success of quality improvement policies can be measured by their ability to raise the average level of health and reduce variation in quality. Two types of policies are intended to improve quality and thus health outcomes:

- those that influence provider behavior by altering the structural conditions of organization and finance or that involve the design and redesign of health care systems
- those that directly target provider behavior at the individual or the group level.

Within each category, the evidence is examined to see the effect of the policy on the health outcomes of populations.

Interventions Affecting Provider Practice by Changing Structural Conditions

Although structural components such as materials and staff are not strongly linked to outcomes, other components of structure—organization and finance—can influence process

by changing the socioeconomic, legal and administrative, cultural, and information context of the health care system.

Legal Mandates, Accreditation, and Administrative Regulations.

Legal mandates, accreditation, and administrative regulations affect quality by controlling entry into the practice of health care. These policies include the licensing of professionals and facilities, their accreditation or certification to perform certain procedures, and the formal delineation of functions that various types of health workers can legally perform. Although these policies assume that providers' prior qualifications are good predictors of actual performance in health care delivery, there is little evidence that such policies have a positive effect on process or outcomes. They are more successful at barring unqualified persons from practicing than at ensuring quality among those who are allowed to practice. A review of health sector regulations in Tanzania and Zimbabwe, for example, revealed that the regulations primarily control entry into the market and ensure a minimum standard of quality (Kumaranayake and others 2000).

Hospital accreditation, with its periodic reviews of health facility performance standards, can potentially provide ongoing regulatory pressure for improvement. To date, research has not demonstrated that hospital accreditation programs are linked to improvements in health outcomes. In a randomized controlled trial of a hospital accreditation program in the KwaZulu-Natal province of South Africa, researchers showed a conclusive link between the implementation of the program and improvements in the accreditation standard indicators. However, they were unable to link those indicators to improvements in health outcomes (Salmon and others 2003).

Malpractice Litigation to Enforce Legal Mandates To be effective in promoting quality, malpractice litigation must rely on adequate legal and judicial systems, which are deficient in most developing countries. In India, one of the few developing countries with the appropriate legal structure in place, inclusion of the medical sector under the Consumer Protection Act of 1986 allows victims to receive redress for negligent medical practice. Although improvements have resulted, some argue that the system needs greater involvement of professional organizations to be effective (Bhat 1996).

Professional Oversight Peer review is as old as professional societies. The power and the influence of such societies vary widely among countries (Heaton 2000). Large provider organizations, such as hospitals or public health institutions, often routinely collect information on provider practices and patient outcomes and use those data to guide, educate, supervise, discipline, or recognize providers. In the Philippines, public health managers used a checklist of 20 observable behaviors against which health workers in remote provinces were rated. The

performance of providers in facilities where workers were reviewed was significantly better than in comparable facilities that did not adopt the reviews (Loevinsohn, Guerrero, and Gregorio 1995). Others, however, assert that the “quality by inspection” environment engendered by oversight leads to an antagonistic relationship between workers and managers and precludes cooperative problem solving and continuous improvement (Berwick 1989). A qualitative study evaluating supervisor-provider interactions in health care facilities in Zimbabwe found that supervisors were adept at giving technical feedback but were not as proficient at making suggestions for improvement or at working with providers and patients to solve problems (Tavrow, Kim, and Malianga 2002).

National and Local Clinical Guidelines In many industrial countries, evidence-based clinical guidelines are used to ensure high-quality care, better health outcomes, and cost-effective treatments. (Examples of institutions supporting this approach are the U.K. National Institute for Clinical Excellence, the U.S. Agency for Healthcare Research and Quality, and the Dutch College of General Practitioners.) Guidelines are typically developed for a clinical disease or symptom. They should be derived from evidence-based criteria resulting from well-designed clinical investigations or expert opinion. Because they are derived from empirical studies, guidelines in developing countries can, in principle, be identical to those in industrial countries. When resource constraints limit transferability, diagnostic and treatment guidelines may have to be modified. Technologies such as x-ray studies have gained widest acceptance in preventive and primary care services, such as integrated management of childhood illness, where they serve both as clinical standards and as educational guides. Including physicians in the development and review of guidelines has proved particularly effective in the challenging process of implementing guidelines.

Sharing Information on Quality Improvement Technology. Worldwide interest in quality has given rise to new professional bodies, scientific publications, and institutions dedicated to sharing ideas and innovations in quality improvement. Organizations such as the Robert Wood Johnson Foundation, the Nuffield Trust, and the Institute for Healthcare Improvement cultivate ideas for improvement, bring people and organizations together to learn from each other, and take action to achieve results. Although the sharing of information on quality health care practices has long been an established part of provider education and training networks, the sharing of information on successful systemwide policies for process improvements could potentially accelerate the scale-up of quality practice.

One organization active in developing countries is the Council on Health Research for Development (COHRED),

which promotes, facilitates, and evaluates the Essential National Health Research strategy in such countries as Benin, the Arab Republic of Egypt, and Indonesia. COHRED aims to develop a system of effective health research to improve health services, including quality of care. The Quality Assurance project funded by the U.S. Agency for International Development has studied and shared information about quality in the developing world since 1990. Under the Quality Assurance project umbrella, researchers have studied and implemented quality measurement and improvement interventions and have used these case studies to develop a library of tools and articles to promote global quality improvement.

Public-Private Provision of Care. In most health care systems, a professional regulatory framework governs the network of civil servants delivering health care. These civil servants operate alongside autonomous, self-governed, private providers— independent for-profit physicians and health clinics and non-profit nongovernmental organizations (NGOs). Two conclusions arise from the often heated debate about the right balance between public and private services. First, private practitioners provide a significant amount of care in developing countries. Second, though there is no one prescription for striking the right public-private mix, in some cases the public regulatory framework has led to private provision of higher-quality care. The government of Senegal successfully contracted with community-based groups for preventive nutrition services. Eighteen months after nutrition services were implemented, severe malnutrition disappeared among children age 6 to 11 months (Marek and others 1999). The success of the program has led to its expansion nationwide.

Targeted Education and Professional Retraining. Continuing medical education is a common approach to improving clinical practice, but it neither changes clinical practice nor advances health outcomes (Davis and others 1995). Newer techniques—targeted education, case-based learning, and interactive and multimodel teaching techniques—have had some success. In Guatemala, distance education targeting diarrhea and cholera case management increased accurate assessment and classification of diarrhea cases by 25 percent. Rehydration did not improve, however, and improvements in counseling were insignificant (Flores, Robles, and Burkhalter 2002). In Tanzania, training staff in the control of acute respiratory infections of young children yielded reductions in under-five mortality within two years (Mtango and Neuvians 1986).

Organizational Change. In recent years, organizational change in the health care system has been shown to influence quality of care and to further the six aims of the Institute of Medicine by focusing on the continual design and redesign of

systems. The emphasis is on developing organizational and individual capabilities where they most profoundly affect the process of care. Design and redesign interventions assume that simply adding a new resource or a new process in isolation will not improve care because better care is the product of many processes working together. Although change interventions have not been widely used in the developing world because they require large investments to plan and implement, four related models of organizational change have been successful in changing provider practice in developing nations:

- **Total Quality Management in health care** Advances in business management practices to continually design and redesign systems for quality improvement have been effectively adapted for health systems. In Total Quality Management, also known as *Continuous Quality Improvement*, teams use mutually reinforcing techniques in a cycle of planning, implementing, evaluating, and revising to improve the quality of clinical and administrative processes. These techniques include process mapping, statistical quality control, and structured team activities. In rural Bihar, India, private practitioners who treat sick children were provided with standard case-management information, were given feedback on their performance, and were tracked and monitored over time. This strategy produced significant improvements in practitioners' case-management skills (Chakraborty, D'Souza, and Northrup 2000). In Malaysia, anesthesia safety has been improved through the implementation of consensus-based protocols that emphasize (a) communication among the operating, recovery, and ward team members; (b) individual feedback; and (c) frequent monitoring to identify areas for improvement (Tan 1999).
- **Collaborative Improvement Model** The early success of Total Quality Management techniques has given rise to a related model, the Collaborative Improvement Model. It addresses broad and complex systemic processes within health care systems and has facilitated the scale-up of quality improvements. This model, designed to continuously improve organizational and individual performance, comprises four elements: definition of an aim, measurement, innovation, and testing to see whether the innovation meets the original aim. This approach strikes a pragmatic balance between the need for action and the need to be scientifically grounded. It has been used with success in Peru and the Russian Federation. In Peru, the collaborative improvement model was used by multidisciplinary teams in 41 clinics to design changes aimed at achieving world-class tuberculosis care. The preliminary results have led to impressive changes in the process of care, but it is too early to determine whether they have been effective in improving quality (Berwick 2004).
- **Plan-Do-Study-Act cycle** The Plan-Do-Study-Act (PDSA) cycle calls for action-oriented learning in quality improve-

ment. Team members using the PDSA model design a quality-improvement intervention (plan), implement it on a small scale (do), evaluate the results (study), and implement or alter the intervention accordingly (act). Often multiple PDSA cycles are necessary before the appropriate improvement method can be identified. All improvement techniques that involve the design and redesign of systems use some form of the PDSA cycle. Successful scale-up of a PDSA prototype is possible with careful leadership oversight. A team of investigators in Russia's Tula province developed a series of successful interventions for adults who have poorly controlled hypertension. The interventions, which were started in 20 clinics, were expanded to 500 clinics within 18 months. The scale-up resulted in a sevenfold increase in patients receiving hypertension management at the primary care level and an 85 percent reduction in admissions for hypertension. In Tver province, the same group addressed problems related to prenatal care. They began with 5 hospitals and scaled up to cover all 42 hospitals and all maternity clinics in the province. The result was a 99 percent reduction in newborns with hypothermia and a reduction in pregnancy-induced hypertension from 44 percent to 6 percent (Berwick 2004). Although the experience of researchers implementing interventions that are based on system redesign in the developing world has been largely positive, it is not clear whether the resources and leadership exist to bring these interventions to scale through country or regional policies. Further evidence is needed concerning the real-world feasibility and cost-effectiveness of system redesign.

- **Internal enabling environment** Creating the right environment for change involves leadership and leadership training, clinicians empowered to make quality improvement decisions, and resources for quality improvement planning activities (Silimper and others 2002). The internal enabling environment in Costa Rica promoted strong leadership that led to the adoption of structural adjustment loans in the early stages of health sector reforms. The loans were used to maintain such public health programs as mother and child nutrition, even though public spending dropped and prices increased dramatically (Peabody 1996). An enabling environment can also be created by teams of individuals, each representing different stakeholder groups (physicians, nurses, staff members, patients, and so forth) or simply by a strong leader with an interest in teamwork and the resources to support a discrete quality improvement function for team members.

Interventions Directly Affecting Provider Practice

Practitioners are often forced to provide care in uncertain settings. Technical limitations may reduce the ability to diagnose

or predict outcomes, or they may have only probabilistic knowledge about the efficacy of their proposed treatment for a particular patient. The nature of clinical practice is often solitary, and physicians have few available ways to gauge their clinical acumen and skills. Performance-based feedback, however, can reward high-quality care and increase knowledge about appropriate actions. If the feedback mechanism is effective, it can also serve as the basis for establishing systemwide incentives for improving quality of care.

Training with Peer Review Feedback. In Mexico City, physician retraining on treatment of diarrhea, combined with the concurrent creation of a peer-review structure, decreased the use of antibiotics and increased the use of oral rehydration therapy (ORT). These improvements continued to be seen in a follow-up evaluation 18 months later (Gutierrez and others 1994). The approach has been effectively expanded to prescribing practices for rhinopharyngitis among primary care physicians, using an interactive training workshop and a managerial peer-review committee (Perez-Cuevas and others 1996).

Performance-Based Remuneration. A potentially powerful instrument for accelerating quality improvements involves making payments directly to providers who meet quality standards that are based on process indicators associated with favorable patient outcomes. Systems that tie performance to remuneration use relatively small incentives—equivalent to 3 to 10 percent of the provider's total compensation. Performance-based remuneration has been successfully used in the United States to compensate both private and public providers (McBride, Neiman, and Johnson 2000).

Examples of performance-based incentives come from developing countries too. The Nicaraguan Ministry of Health has implemented a pilot program in six hospitals that offers an incentive bonus (a maximum average of 17 percent of hospital revenue) for facilities that achieve performance targets that include quality measures (Jack 2003). In Haiti, a performance-based payment scheme was set up for NGOs that provided services to the population. The scheme resulted in all three participating NGOs reaching target immunization coverage rates (Eichler, Auxila, and Pollock 2001). Thus, payment for specified and observable performance (in terms of provider effort, client coverage, or health impact on the population) can be usefully applied to NGOs and private providers.

The specific features of performance-based remuneration are crucial. A study evaluating the South African government's experience in contracting with private organizations to operate district hospitals found no cost savings—in fact, the government was spending more than if it provided the services itself. The contracting may have failed because remuneration was not based on specific process or outcome measures. Instead, the

contractor's obligation, the methods of monitoring performance, and the sanctions for nonperformance were only minimally specified (Broomberg, Masobe, and Mills 1997).

High Volume of Care. Evidence exists that a high volume of care by individuals or institutions leads to better health outcomes (Habib and others 2004). Physician experience (learning) and practice (repetition) lead to fewer complications, less resource use, and better quality for a variety of procedures, such as cataract surgery and laparoscopy (Brian and Taylor 2001). More complex procedures, including endarterectomy, cancer surgery, and coronary bypass surgery, have shown similar effects.

Volume effects leading to better health outcomes are not confined to surgical procedures (Zgibor and Orchard 2004). Facilities specializing in the care of chronic diseases such as diabetes, myocardial infarction, and heart failure are also associated with better outcomes. Debate exists over how much of the volume effect is due to specialist care. The benefits of high-volume care persist, however, even after controlling for referral and case-mix biases. When carefully trained nonphysicians are substituted for physicians, volume effects persist but can be accomplished at significantly lower costs. In one study, nurse practitioners and physician's assistants were able to provide high-quality care for common outpatient conditions such as hypertension, diabetes, asthma, otitis media, pharyngitis, and back pain at substantially lower costs than that of physicians (Douglas and others 2004).

Performance-Based Professional Recognition. Providers work in a community of peers in which professional status, prestige, and recognition are often as valuable as material rewards. Nonmonetary incentives, such as public recognition or disclosure, administrative privileges, and awards from professional organizations, can promote improvements in quality. Uganda, for example, implemented the Yellow Star Program as part of a broader health services improvement project. This program evaluated health facilities on a quarterly basis, using 35 indicators of technical and interpersonal quality, and awarded a large yellow star to facilities that scored 100 percent in two consecutive quarters. The star was then prominently displayed outside the facility.

The Mexican Ministry of Health has implemented a strategy that combines the accreditation and the training strategies discussed earlier with nonmonetary incentives. The National Crusade for Quality in Health Care introduces quality-oriented incentives to health facilities and medical schools. It also includes public recognition in an effort to encourage learning and to change practice. The National Crusade has already generated measurable improvements in the responsiveness of state-level health systems (Secretaría de Salud de Mexico 2003).

Both types of policies examined in this section are associated with better quality and better health outcomes—lower

premature mortality and avoidable morbidity, increased patient satisfaction, and more health-seeking behaviors. When effective, these policies result in increased coverage rates, better prescribing patterns, and increased adherence to clinical guidelines. They can spell the difference between an individual's survival or death, between an individual benefiting from the encounter with the health sector or being harmed by it, and between an individual and society rising from poverty or sinking deeper into it.

MEASURING QUALITY

Improving quality requires that we measure it accurately. The successful outcomes discussed in the previous section rely on the links between policy and changes in clinical practice. Such links, however, can be created and demonstrated only when valid and reliable measures of process are easily understood, inexpensive to obtain, resistant to manipulation, and related to better health outcomes.

Measuring Structure

Material measures of structure abound. Numerous facility-based surveys in developing countries have cataloged capital equipment and staffing levels, and financial reports track budgets and expenditures (but rarely production costs). Facility inventories of drugs and supplies are generally available; service utilization figures are routinely reported to national-level authorities. Such measurements, however, are often beside the point. Even when material structural deficiencies are corrected, they are not reliably linked to changes in health outcomes. Measuring the organization and financing of health care is more difficult. Although descriptions of the organization and financing of health systems exist, objective functional assessments of systems (such as patient flows, the patient referral system, or details of the relative pricing of services) are less often available.

Measuring Process

Technical advances have mitigated longstanding difficulties in measuring process. Five approaches and their strengths and weaknesses merit consideration: chart abstraction, direct observation and recording of visits, administrative data, standardized patients, and clinical vignettes.

Chart Abstraction. Chart abstraction, or review of the medical record, has long been used to measure technical quality. Such familiar quality evaluations as clinical audits, physician report cards, and profiles are based on chart abstraction. The core strength of the medical record is that it is ubiquitous and can generally be obtained after each encounter. Chart reviews, however, suffer from problems of legibility when notes are handwritten. Often they are generated for reasons other than recording the actual events of the clinical visit (legal protection

or obtaining payments, for example) and thus lack crucial clinical details. One prospective study showed that charts identified only 70 percent of items performed during the clinical encounter (Luck and others 2000). In a related analysis, 6.4 percent of the items recorded in the chart were false and had never really occurred.

Where resources and infrastructure are sufficient, the electronic medical record (EMR) is becoming a priority for health systems worldwide. EMR technology promotes uniformity, legibility, and communication, which can lead to guideline use and reduce prescription errors. It also holds the promise of managing populations rather than individuals by aggregating patients into groups. However, the EMR has not always lived up to its potential. In many countries, some impressive successes have occurred—as have spectacular failures, costing billions of dollars (McConnell 2004). The great heterogeneity in record-keeping practices, problems with medical records (both paper and electronic), and costs of trained medical abstractors have led to a search for other reliable ways to measure quality.

Direct Observation and Recording of Visits. Direct observation and recording of visits is a commonly used approach in developing countries (Nolan and others 2001). Ethically, the provider and the patient must be informed of the observation or recording, which introduces participation bias because provider behavior may change as a result of being evaluated. In addition, trained observers are costly, and variation between observers is difficult to remedy.

Administrative Data. Administrative data, collected for purposes of managing the delivery of care, are available in all but the poorest settings. A data collection system, once established, is ubiquitous and can provide information on charges and many cost inputs. Administrative data, however, lack sufficient clinical detail to be useful in evaluating process. In a 2003 study, an incorrect diagnosis was recorded in the data 30 percent of the time (although the diagnosis was made correctly). Overall, these data reflected the actual clinical diagnosis only 57 percent of the time (Peabody, Luck, Jain, and others 2004). As information systems advance, accuracy problems may be mitigated, although the lack of adequate clinical detail will continue to limit the use of administrative data.

Standardized Patients. Standardized patients can be a gold standard for process measurement (Luck and Peabody 2002). Trained to simulate illness, standardized patients present themselves unannounced into a clinical setting to providers who have previously given their consent to participate in the study. At the conclusion of the visit, the standardized patient reports on the technical and interpersonal elements of process. Standardized patients are reliable over a range of conditions and provide valid measurements that accurately capture

variation in clinical practice among providers over time. However, they are expensive and useful only for adult conditions and only those conditions that can be simulated. Thus, they are not practical for routinely evaluating quality.

Clinical Vignettes. Clinical vignettes were developed explicitly for measuring quality within a group of providers and evaluating quality at the population level. Vignettes are responsive to variation in quality, and providers readily accept them if they are given anonymously (Peabody, Luck, Glassman, and others 2004). More than 20 vignettes have been used in 13 countries around the world. They can be administered on paper, by computer, or over the Internet. Providers are typically presented with several cases. When process is being measured for many providers, each provider is presented with the same case or set of cases, thus eliminating the need for case-mix adjustment. The provider completing the vignette is asked to take a history, do an examination, order the necessary tests, make a diagnosis, and specify a treatment plan. The questions are open ended and include interactive responses that simulate the visit and evaluate the physician's knowledge. In two separate, prospective validation studies among randomly selected providers, vignettes consistently demonstrated greater predictive validity of process than did the abstracted medical record. Vignettes have been validated against the gold standard of standardized patient visits, and they reflect actual clinical practice, not just physicians' knowledge. Vignettes have several other advantages. Because exactly the same case can be given to many providers, vignettes are useful for comparison studies. They are also useful for pre- and postevaluations of policy interventions designed to improve quality. Finally, they are inexpensive to administer and straightforward to score, making them particularly useful in developing countries.

ECONOMIC BENEFITS AND COSTS OF QUALITY CARE

Policy interventions can lead to higher-quality process of care and can rapidly improve a population's health outcomes, but is quality improvement cost-effective? This section shows that it is. We compare the economic benefits of better quality of care at the individual and population levels with the costs of implementing quality improvement interventions. We then discuss why these interventions not only increase individual and social welfare but also are cost-effective in the long run.

Individual Economic Benefits

Individuals benefit from better quality of care because they are physically, emotionally, and mentally healthier. These benefits can be quantified subjectively by self-report, objectively by

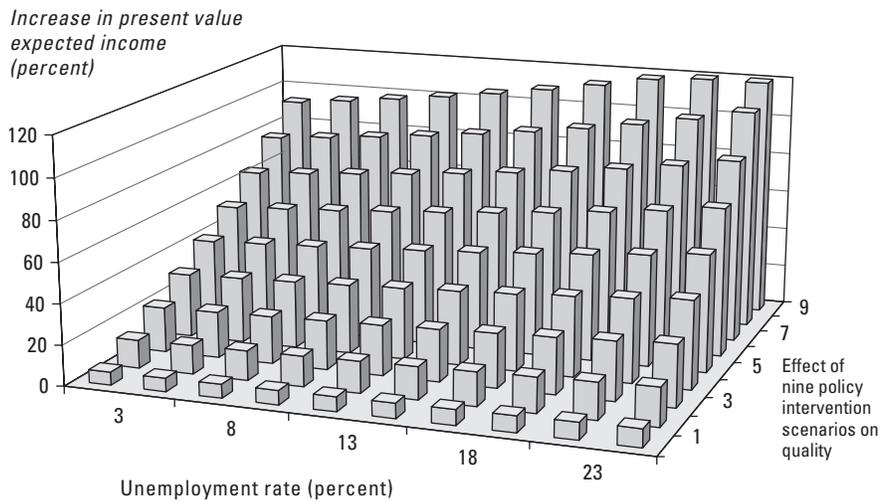

physiological assessments (such as blood pressure), and monetarily by measuring income. Other things being equal, a healthy individual generates more income than one who is often sick. This benefit goes beyond the period of illness. Research on early childhood development has shown that higher-quality prenatal and postnatal care not only decreases mortality but also improves subsequent school performance, which is critical to future labor productivity (Van der Gaag 2000). The monetary benefits of better individual health can be assessed by examining the individuals' expected income in the context of a life cycle model. Expected income depends on the risk of death at various points in time and the corresponding opportunities for educational attainment. This scenario can be simulated by improving quality and then estimating how much the higher quality lowers mortality and increases education attainment, both of which increase an individual's future income (see figure 70.2).

Social Macroeconomic Benefits

Societies that have healthier populations also have higher levels of human capital and a greater capacity to generate wealth. Higher quality of care for the individual increases society's human capital by reducing both the number of premature deaths (thus increasing the labor force) and the amount of temporary or permanent disability (thus improving worker productivity). Providers and insurers also benefit from lower costs by avoiding unnecessary or inappropriate care. Thus, society benefits from both better health and lower public expenditures for treatment, which can then be reallocated to other productive uses. Interventions that improve quality have an especially high social value when they have large positive externalities (for instance, when better process reduces the incidence of a communicable disease). Sometimes, however, society benefits but some stakeholders do not. For example, physicians who provide better preventive care may experience less demand for their curative services and associated resources.

Several attempts have been made to estimate the correlation between health outcomes and long-term economic growth. The high prevalence of such diseases as malaria has been linked in some studies to a slowing of economic growth by one to two percentage points per year. These studies were severely limited by the number of countries and by the many unobserved factors excluded from the models (Sachs 2001). These limitations suggest another way to estimate the benefits of higher quality on health outcomes and long-term economic growth. Because diagnostic accuracy and treatment of malaria can be improved with better-quality care, improving quality should increase national income through reductions in mortality rates.

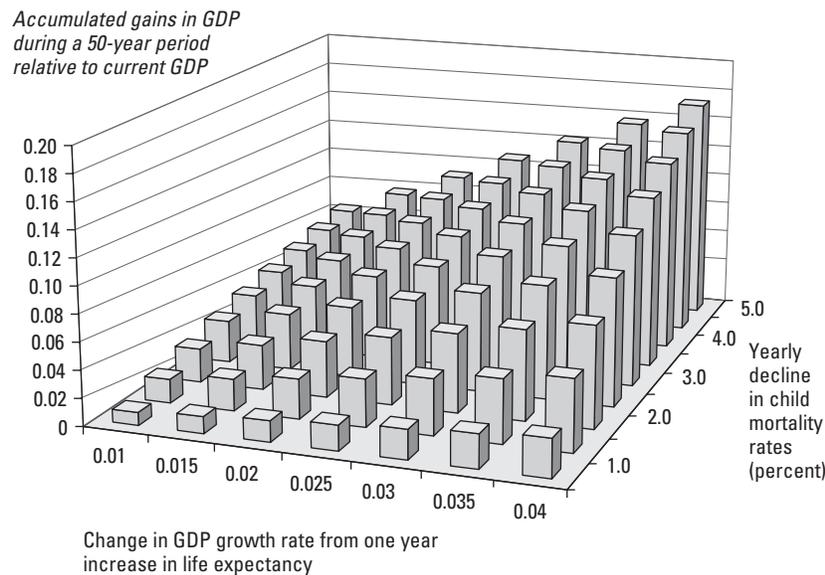

Indeed, cross-country data suggest that a one-year increase in life expectancy is associated with an increase in the gross domestic product (GDP) growth rate of 1 to 4 percentage points (Bloom, Canning, and Sevilla 2001). Our own simulations show

Source: Authors' calculations.

Note: These results model the effect on income of a policy intervention that leads to higher quality. The effect is determined as an increase in the present value of income for varying rates of unemployment. Higher quality is based on nine different scenarios of quality improvement. For each successive scenario, infant mortality rates are reduced by 1 percent and educational attainment is increased by 5 percent. The baseline possibilities are for the Islamic Republic of Iran.

Figure 70.2 Economic Benefits of a Quality Intervention That Reduces Child Mortality Rates and Leads to Higher Educational Attainment

Source: Authors' calculations.

Figure 70.3 Gains in GDP Resulting from Reductions in Child Mortality Rates

that quality improvements can result in as much as a 5 percent annual reduction in child mortality rates, which can generate, over 50 years, economic gains equivalent to 18 percent of current GDP (see figure 70.3). Similar results would be obtained if the effect of better quality on morbidity and disability were simulated.

Economic Costs

Policies that improve the quality of care have both direct and indirect costs. Direct costs relate to the human and physical resources needed to implement the intervention. Indirect costs come from more subtle changes, including alterations in the quantity of health services provided, in provider demand for

various inputs (such as equipment and medication), in the market prices of health care, in government health budgets, and ultimately in the macroeconomy. For interventions at the local level, such as training doctors in a particular region, it is usually sufficient to measure direct costs. Although the level of detail required can be overwhelming when the interventions are complex, the calculations are usually straightforward. The costs of local interventions depend on local prices of such inputs as labor, transportation, training kits, food, space rental, and accommodations. The cost of training providers in the appropriate treatment of childhood illnesses ranges from a low of US\$1 to a high of US\$430 (Santoso, Suryawati, and Prawaitasari 1996).

The direct and indirect costs of interventions at the central or local government level are harder to quantify. Expanding training programs to all public providers, enforcing standards for private and public providers, changing payment systems, and developing policies to protect consumers against malpractice are macro-level interventions that have direct program-level costs. They affect the economy as a whole by changing the allocation of public resources and the relative prices of goods and services. Macroevaluations of health policy interventions are seldom conducted, even though systemwide interventions are likely to have the highest effect on quality and health-related benefits.

Cost-Effectiveness of Improved Process

Two interventions that vividly illustrate the cost-effectiveness of improvements in clinical practice and outcomes have been chosen: detection and treatment of acute respiratory illnesses and appropriate drug use and treatment for diarrhea.

Better Treatment of Pneumonia in Children. Part of the high mortality from childhood pneumonia in the developing world can be explained by poor-quality care, which is defined as the inability either to accurately diagnose or to treat the disease. Our prototype intervention has two cost components: the cost of implementing an educational activity for providers and the cost of treating nonsevere and severe childhood pneumonia. The former component is based on a study and uses conservative high-end cost estimations (Kelley and others 2001); the latter is the midpoint from another study (Stansfield and Shepard 1990). The number of lives saved depends on the effect of the intervention—that is, the change in the percentage of cases diagnosed and treated; the prevalence rate of both types of pneumonia; the population covered by each provider; the case-fatality ratio; and the effectiveness of the treatment. Both the case-fatality ratio and the effectiveness ratio were fixed at middle values suggested by earlier work (Stansfield and Shepard 1990). For the other parameters, a large range of variation was considered, producing 450 scenarios. Finally, six

impact levels were considered, which were based on two previous studies (Chakraborty, D'Souza, and Northrup 2000; Mtango and Neuvians 1986).

The analysis showed that, under average conditions, improving quality of care for conditions of acute respiratory illness can be very cost-effective. When the baseline quality is low and the disease prevalence is high, an intervention that raises quality has a cost-effectiveness ratio of US\$132 to US\$800 per life saved; if the policy intervention is ineffective or the prevalence of pneumonia is low, the average cost of saving a life could be more than US\$2,000. When 60 percent of cases are already appropriately diagnosed and treated, the cost-effectiveness ratio rises to US\$5,000 per life saved.¹

Better Treatment of Diarrhea. Diarrhea remains one of the leading causes of childhood morbidity and mortality in the developing world. The diarrhea incidence rate among children in resource-constrained countries can reach six to seven episodes per year (Thapar and Sanderson 2004). ORT is the accepted standard of care for acute diarrhea. Unfortunately, a large proportion of cases are still treated with nonrehydration medication, including antibiotics and antidiarrheals. Improved diagnosis of dehydration and reduced use of unnecessary medications, however, lead to better outcomes.

Various interventions can make sizable changes in the diagnostic and prescribing patterns of providers. Verbal case review, combined with a package of additional intervention referred to as INFECTION (Information, Feedback, Contracting with Providers to Adhere to Practice Guidelines, and Ongoing Monitoring), increased the proportion of cases treated correctly from 16 percent to 48 percent (Bloom, Canning, and Sevilla 2001). One study reports that small group, face-to-face interventions reduced antimicrobial prescriptions by 16 percent and antidiarrheal prescriptions by 7 percent among a group of providers treating acute diarrhea in Indonesia (Santoso, Suryawati, and Prawaitasari 1996). The same study showed that formal seminars reduced antimicrobial use by 10 percent and antidiarrheal use by 7 percent. On the basis of these studies, an average cost per intervention was used, ranging from US\$25 to US\$125.

The savings from switching to a less costly treatment (instead of antibiotics, for example) were subtracted from the direct costs that are related to implementing the training activity. Because other savings, such as those related to a lower use of inpatient services, were ignored, the estimates are conservative. Savings could be greater: Two years after an ORT unit was established at the Kamuza Central Hospital in Malawi, 50 percent fewer children with diarrhea were admitted to the pediatric ward, and those admitted required 56 percent less intravenous fluid for rehydration (Martines, Phillips, and Feachem 1990).

Again, the number of lives saved depends on the disease prevalence; the effect of the policy on treatment quality; the

population covered by each provider; the average case-fatality ratio, which was set at 6 per 1,000 on the basis of Snyder and Merson (1982); and the effectiveness of the treatment. For the latter parameter, reductions in mortality rates following ORT treatment of 40 to 60 percent and reductions in effectiveness ratios of 5 to 100 percent have been reported (Shepard, Brenzel, and Nemeth 1986). Accordingly, the effectiveness ratio was set at 80 percent. As before, alternative values for the other parameters were adopted, generating 450 scenarios.

Educational interventions to improve the quality of care for treatment of diarrheal diseases are also highly cost-effective. In general, the cost of saving a life through educational interventions is less than US\$500 and could be as low as US\$14. Scenarios with high cost per life saved (more than US\$6,000) are when prevalence rates are low or when implementation costs for quality-related interventions are high.

Although the data available to estimate the costs and benefits of health outcomes and process are limited, these simulations, combined with published reports of successful policy interventions, clearly show the cost-effectiveness of interventions that improve health outcomes through better quality of care. However, reliable measures of quality are necessary to design and evaluate these interventions.

RESEARCH AGENDA ON QUALITY

Most of the issues discussed throughout this chapter represent important topics for research. Establishing a research agenda requires prioritizing both the type of research and the topics to be studied. Quality-of-care research must also strike a balance between relevance to decision making and excellence in scientific rigor (Frenk 1992).

Observational studies are needed to document the extent and correlates of quality at various levels: individual providers, institutional providers, health care systems, and whole populations. Apart from offering much-needed basic descriptions (especially in developing countries), these studies can test specific indicators of the dimensions of quality and can compare the measurement approaches discussed earlier.

Intervention studies introduce planned changes into health care settings and assess their consequences. It is fundamentally important that intervention studies compare one provider group or policy alternative with another. In addition, control groups must be used so that any observed change can be attributed to the intervention itself rather than to another source of variation. The external validity of studies is often undermined by the choice of highly specific sites, making it difficult to generalize the findings and to build a body of sound evidence. If randomized trials cannot be conducted, the preferred option is quasi-experimental studies with clear control groups and longitudinal designs (Peabody and others 1999).

Such studies should be complemented by cost-benefit and cost-effectiveness analyses. Sometimes, in public health emergencies, for example, control groups may not be practical or ethical, in which case real-time operations research is an acceptable substitute.

In the area of research topics, top priority should be given to quality monitoring and assurance strategies to gain an understanding of exactly what the health system is contributing to society and at what cost. Quantifying the associated costs of different variants of quality monitoring and assurance strategies should also be a high-priority item on the quality research agenda. The second priority should be to increase the evidence base regarding the effects on provider behavior of public policies concerning quality of care and whether they lead to better health outcomes. We need to learn more about the long-term effects of different contracting and remuneration policies on providers' practices and the consequent results of such policies for health outcomes. Finally, we need to understand how contracting and remuneration policies affect problems unique to the developing world, such as the use of doctor substitutes and the migration of skilled providers to wealthier countries.

CONCLUSION

Good quality means that providers are able to manage an individual's or a population's health care by timely, skillful application of medical technology in a culturally sensitive manner within the available resource constraints. Eliminating poor quality involves not only giving better care but also eliminating underprovision of essential clinical services (systemwide microscopy for diagnosing tuberculosis, for example); stopping overuse of some care (prenatal ultrasonography or unnecessary injections, for example); and ending misuse of unneeded services (such as unnecessary hysterectomies or antibiotics for viral infections). A sadly unique feature of quality is that poor quality can obviate all the implied benefits of good access and effective treatment. At its best, poor quality is wasteful—a tragedy in severely resource-constrained health care systems. At its worst, it causes actual harm.

Despite the urgency of improving health in developing countries, quality of care has been largely ignored. Both providers and patients agree this must change, but how can this goal be reached? From the information marshaled for this chapter, we can draw five conclusions:

- Better quality leads to better health outcomes in developing countries.
- Process, the proximate determinant of health outcomes, can be measured in valid and reliable ways, such as clinical vignettes and electronic medical records.

- Measured in the above ways, the process of care in developing countries is poor.
- The process of care can be improved in the short term.
- Policies affecting structural conditions, including the actual process of care or the continual design and redesign of the health care system, have been shown to be effective in developing countries.

We believe that two broad strategies would help to rapidly improve health care quality in developing countries:

- encouraging explicit comparative research on outcomes and process
- disseminating empirical findings on quality variation.

Encouraging Explicit Comparative Research on Outcomes and Process

Comparisons highlighting different outcomes can be compelling. For example, when 30-day mortality rates for coronary artery bypass surgery at various facilities were disclosed in the United States, care started to shift from many low-volume hospitals to high-volume hospitals (Chassin 2002). In developing countries, comparisons show that the insured are more likely to have cesarean sections than are the uninsured (Barros and others 1991). Although critics of comparative analysis are justified in saying that systems and populations vary, such criticism misses an important point: Differences in outcome highlight possibilities that help in the search for the underlying causes of poor quality. Although poor quality may have many causes, one of them is almost always poor clinical practice, which can be remedied. We also favor a league or summary table approach to making comparisons. In this approach, the providers being compared agree on criteria before prospective assessments are done. The data for the comparison should be of the highest quality; the league tables themselves should be easy to interpret; and the findings should be rapidly available (Devers, Pham, and Liu 2004). The league table itself should be set up at the regional, national, and international levels so that a variety of benchmarks are available.

Implementing quality comparisons will greatly facilitate the process of policy evaluation and cost-benefit analysis and help indicate directions for future research. Access to accurate, consistent quality-of-care data will compel external funders, such as the World Bank, to build quality assurance into their lending and development programs. As major health programs such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria are scaled up around the world, mechanisms to measure and improve care quality will grow more important.

Disseminating Empirical Findings on Quality Variation

Public dissemination of information on quality, particularly in low-literacy countries, does not seem to create the individual-

based choice market that many have envisaged. Instead, it motivates managers and providers to undertake changes that improve the delivery of care (Schneider and Lieberman 2001). Outside pressure—perceived or real—appears to extend the quality debate beyond traditional boundaries, allowing for innovative collaborations and “out of the box” thinking (Devers, Pham, and Liu 2004). Nongovernmental and private organizations involved in health care delivery should also be required to report basic quality measures, perhaps as a condition for funding, thus ensuring that similar pressure to improve quality is exerted outside the public sector.

Public dissemination can create shock waves when poor quality is “discovered,” leading to popular demand to increase quality. For example, findings of widespread medical errors in the United States, estimated to have resulted in as many as 98,000 deaths per year, launched the medical safety revolution (Institute of Medicine 2001). Dissemination among physicians and surgeons by means of report cards and ratings has been effective at changing clinical practice. One advantage of dissemination among providers is that the results can be more refined and technical than ratings meant for wider audiences. Dissemination is the responsibility of public research and public initiative. Because dissemination is inherently controversial, it requires public financing—even more than other public goods (Jamison, Frenk, and Knaul 1998).

Ultimately, improving quality is about value. In health care, price is not a reliable proxy for quality and cannot be used as a guide. Because patients and consumers cannot directly observe quality, their ability to demand high-quality services is limited, and they are often left to settle for a market that has suboptimal equilibrium and poor quality of care. In addition, providers often lack knowledge of optimal treatments and technologies and thus are not aware of how they can produce higher-quality care. Because the provider-patient interaction is so private and personal, quality of care is hard to observe and to measure. New measurement tools, however—such as clinical vignettes and the electronic medical record—are being developed and improved. As research links care with outcomes and cost inputs, we can expect to have more accurate and reliable data about clinical practice for use in making quality assessments.

Investments in quality, however, must be judged critically as well. When we invest in quality, an investment can be beneficial but can come at a cost. So while quality goes up, value can go up or down—or costs can go up while quality actually goes down or stays the same, thus pushing the value of care down and undermining other efforts to improve quality. Finally, as we showed for acute respiratory illness and diarrhea, quality can go up and costs go down, thus increasing overall value. Examples of this optimal outcome must be actively sought out and reported, because the success of a given investment cannot be known in advance (Berwick 2004).

Improving health status does not have to rely solely on macroeconomic growth or other long-term development indicators. Health outcomes can be rapidly improved in the short term by ensuring the appropriateness of the circumstances or setting under which the health care encounter occurs (structural improvement) or by increasing the likelihood that health care providers behave in ways most beneficial to patients under the prevailing circumstances (process improvement). However, this improvement will not occur spontaneously or routinely, despite the best intentions of beneficiaries, providers, and governments. Quality improvement tools and technologies and information on successful quality improvement policies must be consistently shared among developing countries to build local capacity. Funding and incentives must also be consistent with high quality. Finally, the political will to ensure that quality becomes a top priority on the health reform agenda must be sustained.

NOTE

1. As a reference, if the average expected value of a life is close to US\$30,000, even the highest cost-effectiveness ratio found in the analysis (US\$12,000 per life saved), would imply a cost-benefit ratio below 50 percent, assuming an initial average wage of US\$1,000 growing at 2 percent per year, a 5 percent discount rate, and unchanged mortality rates.

Chapter 71

Health Workers: Building and Motivating the Workforce

Charles Hongoro and Charles Normand

Policy on human resources for health should support health policy objectives and be a means for achieving policy goals. The implication of such a focus is that health systems development should start by identifying the tasks that must be carried out and the skills needed to perform them. Meeting policy goals depends on being able to recruit, train, and retain staff with the necessary bundles of skills. Traditionally, skills are defined by membership of a profession, especially medicine, nursing, midwifery, and the allied health professions. Low- and middle-income countries (LMICs), often from necessity, have widened the range of health care workers to meet the service needs, with some people trained in extremely basic skills and others receiving enhanced training, such as nurses trained in emergency obstetrics. What is meant by a doctor or nurse also varies.

Even though structures and institutions vary widely, some problems are common to most LMICs. First, persuading doctors to work in remote rural areas is difficult, and they typically do not remain long in such posts. Second, emigration of doctors and nurses is extensive. Third, it is common for doctors to work in both the public and the private sectors (referred to as *dual practice*), sometimes harming public services. Dual practice may encourage doctors to skimp on their public health efforts, to pilfer supplies, and to induce demand for their private services (Bir and Eggleston 2003).

Many health sector human resource (HR) problems are predictable from a simple labor market perspective, given the combinations of incentives confronting health care workers and the constraints policy makers face. Experience in LMICs shows how problems have arisen and what policies have succeeded.

Economics predicts that employers will employ workers as long as the additional value of their services is at least as great as the cost of employing them, and workers will work if the rewards are of greater value than those accruing to other uses of their time. If key professionals are in short supply, higher salaries will be needed to attract them. Workers will invest in training if they value higher future incomes and more interesting work above the costs of income lost during training and of fees paid for training programs. This chapter focuses on how health systems might build and improve HR capacity.

Appropriate HR capacity is critical for the effective implementation of disease control interventions. Salaries account for 50 to 80 percent of health sectors' recurrent costs (Bach 2000). Table 71.1 shows the number of physicians and nurses per 100,000 population in selected countries. The number of health workers is related to the level of development because of the tight resource constraints facing LMICs and because of supply constraints, often exacerbated by migration of skilled workers (Awases, Gbary, and Chatora 2003) and prevalence of AIDS. In Africa, where the disease burden is high and increasing rapidly, the number of health workers is particularly low. Most African countries export health professionals to high-income countries.

A study in six African countries showed that most health workers intend to migrate for higher salaries. In Ghana, 70 percent of 1995 medical graduates had emigrated by 1999 (Awase, Gbary, and Chatora 2003). Pay differentials provide strong incentives to migrate. For example, a junior doctor in the United Kingdom averages a monthly salary of US\$3,029 and a registered nurse averages US\$1,500, compared with US\$300

Table 71.1 Numbers of Physicians and Nurses, Selected Countries and Country Groups, 1998

Country	Physicians per 100,000 population	Nurses per 100,000 population	Physician-nurse ratio
Angola	5	100	0.05
Bangladesh	19	11	1.7
Bolivia ^a	29	14	2.1
Botswana	20	100	0.2
Brazil	136	44	3.1
Burkina Faso	<3	20	0.15
Central African Republic	<3	<10	0.3
Equatorial Guinea	20	50	0.4
India	106	94	1.1
Nepal	4	5	0.8
Pakistan	57	34	1.7
Papua New Guinea	7	67	0.1
Peru ^b	10	7	1.4
South Africa	20	100	0.2
Sri Lanka	37	103	0.4
Low-income countries	73	132	0.6
Middle-income countries	142	278	0.5
High-income countries	286	750	0.4
Global average	146	334	0.4
Global median	114	233	0.5

per month for a Ugandan medical officer and US\$180 for a registered nurse.

Scaling up service provision using current provision models would require large increases in resources and could require a change in strategy by development partners toward supporting recurrent costs (Jha and Mills 2002). The labor market model indicates that higher salaries would be needed to attract additional staff members, so funding would have to increase more than in proportion to the number of staff members employed.

Many LMICs pay health workers on civil service scales, which they control to contain overall government spending. This practice further widens the gap between salaries for professionals at home and abroad.

Although improved economic performance and increased development assistance may allow some increases in health spending, in most LMICs it is not plausible that such increases would be sufficient to make the necessary skills available without a range of strategies, including better regulation, stronger incentives, and initiatives to make key skills available at lower cost.

HEALTH CARE PROVISION AND ASSOCIATED HUMAN RESOURCE NEEDS

Studies on developing services to meet the Millennium Development Goals emphasize the importance of making health workers with the appropriate skills available and motivating them (Jha and Mills 2002). The problems include lack of technical skills, low motivation, and poor support networks (Kurowski and others 2003). This chapter, therefore, focuses on HR planning, training and professional development, incentives for workers to accept and stay in posts and to deliver services, and alternatives to conventional professional groups.

Incentives and Motivation

The labor market model outlined earlier provides a framework for analyzing the role of incentives. A health worker will accept a job if the benefits of doing so outweigh the opportunity cost. Improving recruitment and retention requires either offering higher rewards that make alternative employment less attractive or making qualifications less “portable”—that is, less likely to be recognized in other countries. The development of new health professions in many countries is a way of reducing the portability of qualifications, thereby reducing the opportunity cost of jobs at home. Another advantage is that training can be more specific to local health system needs, but ensuring quality and safety are important issues.

Health workers will choose to train and increase their skills if the rewards of doing so exceed the cost. In general, the supply of skilled professionals rises as rewards increase, because more will seek training, more will return to the workforce, and fewer will move to other jobs or other countries. Because health workers value both financial and nonfinancial rewards, they will work for lower salaries if other job characteristics are attractive.

The causes of health HR problems in developing countries are complex, and attempts to address them must reflect this complexity. Table 71.2 suggests a framework for exploring links between factors at individual, organizational, and health system levels. The framework is inspired by a systems approach, which gives prominence to the roles of and relationships between different component parts in influencing the whole.

The individual health worker level serves as a starting point for exploring the determinants of health worker behavior and performance (Kyaddondo and White 2003). *Performance* here means productivity and quality of services. Individuals respond to individual concerns through coping strategies, such as informal and dual practices, with associated consequences. There are multiple links between individual health worker behavior and organizational and systemic factors. Organizational and system arrangements define

Table 71.2 Framework for Diagnosing HR Issues in the Health Sector

Level	Issue
Individual health worker	
Internal capacity	Knowledge, skills, competencies, attitude
Remuneration	Salary and perquisites, payment methods
Work environment	
Immediate environment	See organizational-level issues
Distant environment	See systemic-level issues
Productivity	Outputs or outcomes per given unit of time or per individual or group of individuals
Responses to organizational and systemic constraints	Low motivation, morale, productivity, and quality of services Informal practices, for example, unofficial fees, dual practice, misuse of public resources, and unethical practices Emergence of unskilled informal practitioners
Organizational level	Presence or absence of an appropriate physical and operational context—that is, availability of materials and facilities to deliver services of acceptable quality, workload management, and organizational norms and practices (organizational culture, management and leadership styles) Organizational autonomy across key strategic and functional issues
Systemic level	Level of bureaucracy and decentralization in the health system, and funding and regulatory arrangements Policy context—for example, pro-market policies and diversification of the health care market in the spirit of a public-private mix Socioeconomic and political context Medico-legal policy and enforcement

Note: This chapter uses a narrow definition of *health system* that considers socioeconomic and political issues as part of a wider context.

the incentive context for health workers and influence both organizational and individual performance.

Therefore, the configuration of the health system must create incentives for appropriate supply and deployment of health workers. HR development experts tend to focus more on problems encountered in the lower tiers of this framework. Political pressure for short-term solutions partly explains why many countries do not address HR problems comprehensively. The wider context can also be important. Good governance at the national level is necessary to make policy interventions at the health system level or below effective.

Financial Incentives

Most of the comparatively scarce evidence on the relative importance of financial and other incentives for health workers at the individual level comes from developed countries. Two findings emerge from recruitment and turnover studies. First, at extremely low salaries, financial incentives are particularly important (Normand and Thompson 2000). Second, at least half of the variation in turnover can be attributed to financial incentives (Gray and Phillips 1996). These findings leave considerable scope for improving retention using organizational changes, but such changes will be only partially successful if much better financial rewards are available elsewhere.

International migration has increased as restrictions on moves to high-income countries have been eased (Bach 2000). Many developed countries have shortages of health professionals and actively recruit from low-income countries, thereby raising the opportunity cost of remaining at home.

Health Care Systems' Responses to Health Worker Issues

Health sector reforms have been widespread in recent years, often with international support. These reforms tended to focus more on structures and financing and less on resource issues (Martineau and Buchan 2000). Other government reforms aimed mainly at improving efficiency and reducing the cost of government administration have often had large effects on the health workforce (Adams and Hicks 2000; Corkery 2000). Some changes have attempted to introduce better incentives, such as performance-related pay and renewable contracts, and to remove underperformers and ghost workers. Evidence on the effects of these reforms suggests that more emphasis should have been placed on designing incentives to improve performance and retention and on moving further away from workforce quotas and norms. Using the three levels of analysis, the following sections consider policies, management, and incentives and how they can help match skills to needs.

HEALTH CARE STAFF

Workforce planning should be dynamic and should link policy goals to staff members' skills and numbers and to performance-enhancing incentives.

Workforce Planning to Meet Policy Goals

Several factors make workforce planning in health particularly difficult, including changing needs as service models change, long training time for some professions, and lack of direct government control over the number of professionals being trained, for example, because of the growth of private medical

schools, such as in Bangladesh, or because of people going overseas for training (although Singapore has addressed this problem by restricting the colleges that the government recognizes for registering doctors). The greatest difficulty comes from the unpredictable loss of skilled staff members to private health sector jobs, jobs abroad, and jobs outside health. Thus, a close link exists between HR planning and incentives and regulation. In Ghana, nurse training has often been the only available form of tertiary education for women, and many of those who are trained do not practice.

A key to more rational workforce planning is better coordination between health planning and planning for training and education. Powerful interest groups can oppose the expansion of training. Training establishments often oppose change because it may disrupt existing arrangements and threaten current staff members. The development of new professional groups faces particular resistance from existing professional groups, which, quite correctly, perceive the new groups as posing a threat to their interests. For example, some dentists in South Africa expressed concern over training of dental technicians who carry out a wide range of preventive and restorative dentistry at lower fees (Matomela 2004).

Models for HR needs are easy to devise, but determining the appropriate model parameters is difficult. For example, health planners must estimate the length of a nursing career—potentially up to 45 years but often much less, especially if nurses are willing to work outside nursing (Phillips and others 1994). Good data are needed on dropout rates from training. HR sections of health ministries are usually poorly resourced, have low status, and work with poor-quality data, and this situation must be changed if planning is to improve.

Basic Skills Training and Continuing Skill Development

Whereas the quality of basic training of health professionals varies widely in LMICs, the provision of continuing education and development is almost universally inadequate. Hence, skill levels of staff members fall over time. Evidence indicates that good-quality continuing professional development is a positive incentive and helps to retain staff members. Requirements to undertake continuing education can be made a condition of continued professional registration and can thereby provide some guarantee of competence.

Good basic education includes development of both professional skills and learning skills. Basic training and continuing development should be planned together. In many cases, the large investment in basic training is lost because of lack of maintenance, so that shifting some resources to updating and renewing skills is efficient.

A further challenge is to align the content of training to the skills professionals need. Many training programs in LMICs provide skills oriented toward service needs in developed

countries, although there have been attempts to change this balance. For example, more than 25 percent of Malawi's curriculum for medical students focuses on community health. Given that any training program can cover only a portion of relevant knowledge, focusing on locally relevant topics is increasingly important. Educational reforms in many medical schools in Africa and elsewhere are based on the community-based educational model (Jinadu, Olofeitime, and Oribador 2002).

Numbers and Types of Health Professionals

Categories of workers result from combinations of previous and current needs, national traditions, interest group pressures, and historical accidents. Doctors, nurses, and some paramedical professions have wide international recognition but vary in definition. Professional traditions and professional bodies bring some safeguards for quality and safety, and at best, professionals champion the needs of patients. Membership of a recognized profession can bring desirable independence from management. However, internationally recognized qualifications make it easy for professionals to migrate to countries offering higher incomes and better careers.

Most developing countries have new categories of staff that do not match internationally recognized professions (Buchan and Dal Poz 2003). Examples include nurses with extended training and roles and people working at subnurse levels with training of a few weeks to three years. Bangladesh has family welfare visitors, health assistants, and medical assistants who might elsewhere be classified as nurses or auxiliary nurses; in Uganda, clinical officers have three years of training and work as subdoctors; and nursing aids in Uganda have three months of training. Training is for specific roles without the generic training in conventional professions. Typically, such employees are mobile nationally, but they do not transfer easily across countries.

In the labor market model, employers want to employ staff members if their contribution to service provision is of greater value than the cost of their employment. Because those with portable qualifications can work in other countries, salary levels needed to retain workers reflect that possibility. Theory suggests that staff members will develop new skills if such an investment of their time and money produces significantly increased salary or benefits. Many countries cannot fulfill their requirements for health workers, but normally this difficulty reflects salaries that are too low to attract staff. However, raising salaries may make employment of the full complement of staff members unaffordable.

Staffing norms serve little useful role if the salaries needed to fill the posts are unaffordable. Decisions about how many people should be employed and in what capacities should be based on the contributions those employees will make and the costs of employing them. Staffing norms can be useful for

planning, but they require careful analysis of affordability of care, the skills needed, and the way to provide those skills most efficiently. Several countries have of necessity turned to new models of provision using staff skilled in the delivery of key elements of high-priority services, such as immunization and emergency obstetric care.

Safety and Effectiveness of New Health Professions

Research on the new professions is limited, and much of the material is anecdotal (Buchan and Dal Poz 2003). A growing literature from developed countries indicates that nurses can be safe and effective in place of doctors in primary care (Venning and others 2000). The fear is that the absence of a formal profession and the lack of internationally recognized training could damage quality and safety. This issue is important, but even if new professionals are less safe than doctors, they may be much safer than the absence of a service such as emergency obstetric care. In some countries, new professions play a major part in the provision of services. A good example is Malawi, where clinical officers with extensive training (but much less than that of doctors) are a major resource, carrying out surgical procedures and administering anesthetics as well as providing medical care. In some countries, regulations govern such extended roles (McAuliffe and Henry 1995).

Fenton, Whitty, and Reynolds's (2003) study of emergency cesarean sections carried out by clinical officers in Malawi found that the overall maternal death rate was 1.3 percent, which is high, but much lower than if services had not existed. Perinatal deaths were 13.6 percent. None of the anesthetists was medically qualified, but outcomes were better when these practitioners had received anesthetics training (maternal deaths were 0.9 percent compared with 2.4 percent). The researchers found no significant difference in outcome between medically qualified surgeons and those trained as clinical officers. Care should be taken in interpreting the results of one study, but it does suggest that well-trained clinical officers can safely substitute for doctors in providing some important procedures.

Human Resource Policy and New Staff Groups

New staff groups are increasingly providing essential services in LMICs. In Zimbabwe, a new cadre called primary health care nurses, whose qualifications are lower than general nurses, was introduced in 2003 to curb external migration by nurses (Chimbari 2003). At the system level, such a development requires regulation and standard setting; at the service provision level, appropriate supervision and management is needed; and at the individual level, incentives and training need to be considered. Employing fully qualified doctors and nurses might be the safest option, but failing to provide services because of staffing constraints is unlikely to be the next best option.

HEALTH WORKER INCENTIVES

The World Health Report 2000 defines *incentives for health workers* as “all the rewards and punishments that providers face as a consequence of the organizations in which they work, the institutions under which they operate, and the specific interventions they provide” (WHO 2000, p. 61). Health workers face a hierarchy of incentives or disincentives generated by the work they do, the way they are paid, and the organizational and system context in which they work. Incentives are generally designed to accomplish the following:

- to encourage providers to furnish specific services
- to encourage cost containment
- to support staff recruitment and retention
- to enhance the productivity and quality of services
- to allow for effective management.

Responses of providers to incentives depend on context and on the stage of their career. Incentives that induce productivity vary with experience, stage in a career path, and changes in providers' social responsibilities. Ideally, incentive structures should recognize the evolutionary nature of work expectations.

Typically, incentives vary by type of employer: nongovernmental organization, public, or private. Public sector incentives tend to be the weakest because resource constraints and bureaucratic rules on civil servant employment constrain the use of both financial and nonfinancial incentives.

Typology of Incentives

Extrinsic incentives can be individual and organizational, monetary and nonmonetary (table 71.3). Discussions of provider behavior in LMICs have focused mainly on financial incentives, partly because of their low income levels compared with industrial countries. The challenge is to establish an optimal mix of financial and nonfinancial incentives that generate the desired behavior of health workers.

Experience from vertical programs for priority diseases or services—for example, poliomyelitis, malaria, family planning, and sexually transmitted diseases—provide evidence about different incentives. Programs often offered staff members better pay and incentive packages than those other public health workers received (Beith and others 2001). The exact effects of stronger incentives are unknown, but these programs generally succeeded, as evidenced by the eradication of leprosy, the near eradication of poliomyelitis in many countries, and the large drop in average fertility in developing countries in the 1990s.

Successful vertical programs used combinations of incentives, including better salaries, field and transportation allowances, streamlined management, specialized training, better facilities and material resources, and results-oriented

Table 71.3 Typology of Incentives

Individual incentives	Organizational incentives	Environmental incentives
<i>Financial</i>	<i>Internal</i>	Amenities
Salary	Autonomy	Transportation
Pensions	Accountability	Job for spouse
Illness, health, accident, and life insurance	Market exposure	School for children
Travel and transport allowances	Financial responsibility	
Child care allowance	<i>External</i>	
Rural location allowance	Governance	
Heat allowance	Public finance policy	
Retention and professional allowances	Regulatory mechanisms	
Subsidized meals, clothing, and accommodation		
<i>Nonfinancial</i>		
Vacation days		
Flexible working hours		
Access to training and education		
Sabbatical and study leave		
Planned career breaks		
Occupational health		
Functional and professional autonomy		
Technical support and feedback systems		
Transparent reward systems		
Valued by the organization

Note: These are mostly extrinsic incentives.

management to support improved health worker productivity and program performance. Goals were clearly specified, were understood and shared by the staff, and were often linked to incentives. The choice of vertical structures also reflects the perceived difficulties of using existing health systems, with their excessive bureaucracy, underfunding, and lack of capacity to implement integrated disease control.

Vertical programs must eventually be reintegrated into the system. The HIV/AIDS pandemic is a good example of a disease that might require targeted interventions until the capacity of health systems in LMICs improves to a level that allows the disease to be managed like other diseases. The success in integrating vertical programs depends on the parallel development

of health system capacity, which depends in part on the alignment of health workers' objectives with policy and with system goals.

Aligning health worker and system objectives is difficult. The aim is to have satisfied health workers who are motivated to work harder (Hicks and Adams 2001). Evidence is limited, but financial and nonfinancial incentives are mutually reinforcing, and changing the culture of the health system to make goals more readily understood and shared can make financial incentives more powerful. Such change in the organization of health care can be politically sensitive because it can give health sector workers advantages over other public employees.

Incentives may have conflicting effects. For example, decentralization might create the autonomy needed for effective management, but without transparent management and career structures and job security, providers might view such a change as a threat (Kyaddondo and White 2003). Getting the balance right requires understanding the socioeconomic and political circumstances and may be helped by using participatory approaches to policy making and implementation.

Context

Context is defined here from an individual or an organizational provider's perspective. It constitutes what Adams and Hicks (2000) refer to as *external incentives*—that is, methods used by health systems to control the activities of health organizations or funders.

The power of incentives depends on context. Health systems in developing countries have varying cultural and economic histories that shape providers' expectations and responses to incentives. Financial incentives are strong when health workers' incomes are low, as in most developing countries. Nevertheless, examples of strong nonfinancial incentives exist in countries such as Thailand, where family ties and kinship affect health workers' decisions on where to work. Such nonfinancial incentives affect the size of the financial incentives needed to change where people choose to work.

History and experience determine a country's working culture and norms. In developing countries, most health systems are large bureaucracies whose management is driven centrally by guidelines, standards, and reporting systems. Incentives in such systems work against innovation, risk taking, and improved efficiency. A possible approach is to introduce changes that are based on the ideas of so-called new public management. New public management replaces line management with contracts or agreements between funders and policy makers on the one hand and providers on the other. Providers are given more managerial autonomy and are controlled by means of contracts and regulation. This approach can more easily embody new financial incentives, and autonomous providers can develop cultures that are more innovating. Such

a radical change in managerial context can, in principle, make other incentives easier to use.

Other dimensions of context are the regulatory framework and its enforcement. Most developing countries have regulations governing the activities of the health sector. These regulations tend to be outdated or poorly enforced (Bloom, Han, and Li 2001). The main reason for regulatory ineffectiveness is low institutional capacity and widespread corruption. The symptoms of regulatory failure are widespread informal activities, dual practice, malpractice and medical negligence, and the presence of unqualified drug sellers (for example, in Bangladesh and Tanzania) and practitioners (as in India) (Bhat 1996; Killingsworth and others 1999; McPake and others 1999). Where the regulatory system is dysfunctional, providers tend to pursue their individual interests, often in private practice, to the detriment of organizational and system performance. Effective incentive systems that are based on performance require regulation and governance structures that minimize the common problems of patronage and corruption (Rasheed 1995).

Health system organization factors include governance and the degree of decentralization. Links exist between working culture and norms and the structural aspects of health system organization. The locus of control and decision making play an important part in health worker behavior. In theory, designing incentive schemes that are responsive to health workers' needs is much easier in a decentralized system. This theory is based on the belief that subnational units are better placed to make effective decisions on funding, regulating, and organizing frontline activities than are centralized units. However, experience in developing countries shows that lack of capacity at subnational levels has constrained decentralization, sometimes leading to unintended effects such as wrong priorities (Bloom, Han, and Li 2001). Any move toward decentralization requires investment in new management skills and capacities.

Incentives in Practice

Many countries have attempted to reform their economies and health sectors to improve general economic and health system performance. For example, Cambodia, the Arab Republic of Egypt, Uganda, and Zambia have attempted civil service reforms (Corkery 2000). These reforms include attempts to reduce the size of the civil service to lower costs and to improve productivity using incentives such as formal employment contracts and performance-based pay and promotion. Such reforms have been largely unsuccessful in developing countries because of the political difficulties in reducing the size of the civil service. Structural and organizational changes are typically unpopular with labor unions, especially if union members perceive them as threatening their well-being. Experience also underscores the difficulties of aligning system and organizational objectives with individual providers' objectives (Martineau and Buchan 2000).

The effect of incentives can be assessed in terms of their objectives (Adams and Hicks 2000). Table 71.4 summarizes incentive packages used in selected countries. The results shown should be interpreted with caution, because of problems of attribution and poor data. Adams and Hicks (2000) argue that economic incentives in payment mechanisms for physicians conform to economic logic, but little is known about the response of other categories of health workers to such incentives.

Experience in Thailand illustrates the labor market model outlined earlier. In general, public doctors prefer to practice in urban areas, where conditions are usually more attractive and opportunities for private practice are better. Thailand pays public doctors who work in rural and remote areas significantly more than those working in urban areas, and this incentive has persuaded some to move (Wibulpolprasert and Pengpaiboon 2003). The government also added nonfinancial incentives, such as changing physicians' employment status from civil servants to contracted public employees, providing housing, and introducing a system of peer review and recognition. These initiatives were coupled with significant environmental changes, including sustained rural development. In most developing countries, providers in rural areas are paid less than those in cities, and it is hard to recruit and retain health workers in rural areas.

China provides another example of how changes in the environment—for example, the introduction of pro-market policies—can change provider behavior, in this case from relying on government salaries alone to the use of “red packages” (Bloom, Han, and Li 2001). These red packages were gifts that were traditionally exchanged as an expression of mutual appreciation, but they have now evolved into informal cash payments from patients to health workers.

Health systems have a spectrum of workers with different skills and expectations, and incentives for one group can have negative effects on others (Adams and Hicks 2000). Policy makers must strike a balance between competing interests of professional groups and system goals. The unionization of labor and the growth of professional associations or councils can give health workers considerable bargaining power.

Solving one problem can create others. This situation often occurs when governments respond to the grievances of the most vocal professional groups, usually doctors, and neglect other groups. This piecemeal approach has caused HR crises, such as strikes and go-slows. Although health workers are normally somewhat motivated to pursue health policy goals, their own interests can conflict with those goals. Providing higher salaries to health workers, by increasing costs, can reduce access to services by some social groups (Bloom, Han, and Li 2001).

Compensation

Provider payment systems transfer resources from payers (governments, insurers, and patients) to providers (Maceira 1998)

Table 71.4 Incentive Packages for Health Workers, Selected Countries

Objectives	Incentives	Complementary measures	Constraints	Results
Recruiting and retaining staff in the country	Pay competitive salaries Include seniority awards in pay scales	Fiscal policies that increase the after-tax marginal value of salaries	Budget limitations Low public service salaries Policies to reduce salaries as a share of operating costs	Helped retain physicians in Bahrain
	Allow after-hours private practice in public institutions	Service standards and controls to prevent reduced work effort in the public system	Work effort that may be concentrated in private practice, leading to a deterioration of quality in public practice	Considered successful in Bahrain In some countries, resulted in deterioration of public systems where providers also engage in independent private practice (McPake and others 1999)
	Tolerate informal payments	Not applicable	Informal charges that limit access and may impede reforms that involve formal user fees and exemptions	Resulted in widespread use of informal payments in Eastern and Central Europe, Sub-Saharan Africa, and some East Asian and Pacific countries (Balabanova and McKee 2003; Chakraborty and others 2002; Thompson and Witter 2000)
Recruiting and retaining staff in rural areas	Provide higher salaries or location allowances (Wibulpolprasert and Pengpaiboon 2003) Base remuneration on workload	Decentralized administration Freedom to allocate institutional revenues or savings from operational efficiency to fund incentives Improved infrastructure and staff competence	Overall staff shortages Budget limitations Professional and lifestyle disadvantages Smaller potential for earnings from private practice than in urban areas Conflicting financial incentives (for example, loss of housing allowance in Bangladesh) Risks posed by internal conflicts and civil wars (for example, Colombia and Uganda)	Premium payments for working in rural areas found successful in Thailand (Wibulpolprasert and Pengpaiboon 2003)
	Require service in defined areas as condition of licensing or specialty training Provide opportunities for government-sponsored further education	Consistent application of policies on transfers and tenure	Loss of confidence if health workers perceive the selection process as arbitrary Providers' concerns that a temporary posting may become indefinite	Aided retention of professionals in Ghana and Zimbabwe (Chimbari 2003)
	Provide housing and good-quality educational opportunities for health workers' families	Adequate salary	Budget limitations	Found successful for nurses but not doctors in Nepal
	Recruit trainees from rural areas	Emphasis on public health and family practice in training curricula	Traditionally, overrepresentation of urban area students in student populations	Found successful in Thailand

Table 71.4 Continued

Objectives	Incentives	Complementary measures	Constraints	Results
Enhancing the quality and availability of primary care	Provide training and promotion opportunities for nurses and medical auxiliaries Train multifunctional health workers Mobilize women volunteers from communities, traditional birth assistants, and local leaders	Clear job descriptions and criteria for promotion	Opposition by professional associations to expanded roles for multifunction health workers in Nepal Limited training capacity in Uganda	Resulted in successful retraining of health assistants and other health workers in rural areas in Nepal to make them eligible for promotion Resulted in regrading of state-certified nurses to state-registered nurses in Zimbabwe (Chimbari 2003; Pannarunothai, Boonpadung, and Kittidilokkul 2001)
Encouraging teaching and research and reducing the internal brain drain	Pay health workers more if they do not practice privately	None	Allowances perhaps uncompetitive with private practice earnings	In Nepal, found successful in basic medical sciences but resulted in massive resignations in clinical departments Uncommon incentive, although a few countries (for example, Thailand) do pay professional allowances or nonpractice allowances
Improving the quality of care	Specify clinical guidelines in provider contracts License institutions and professionals based on defined standards Pass laws requiring the registration of drugs and other potentially dangerous substances	Leadership role by professional organizations Inclusion in the curricula of medical schools Tradition of professional self-regulation Acceptance of civil and legal authority	Vested interests of professional associations Weak peer review systems Low consumerism and weak advocacy Regulatory capture and a culture of self-protection Low capacity to enforce laws and regulations	Uncommon in developing countries Some success recorded in Cambodia's contracting experiment Reduced number of hospitals and unqualified doctors in Estonia Resulted in limited success according to evidence from most developing countries (Bhat 1996)

Source: Adapted from Adams and Hicks 2000.

and can be structured to provide financial incentives. Most studies focus on payment mechanisms for doctors and their effect on productivity, costs, and quality of services (Bitran and Yip 1998). Table 71.5 summarizes common payment mechanisms and the desired incentives. The evidence shows that the operation of payment mechanisms is sensitive to the payment structure and how it is implemented (Berman and others 1997; Bitran and Yip 1998; Chomitz and others 1998).

Payment systems are more successful when built on existing traditions and culture (that is, when they take into account gift systems or, indeed, levels of corruption). It is normally best to use a combination of payment methods. For instance, if there is a shortage of public providers, they might be paid a basic salary for normal working hours and fees for service for after-

hours work. This method creates incentives for providers to do extra work and increase throughput, but providers may divert patients to after-hours services, and the method's feasibility depends in part on monitoring and governance standards. The challenge is to find payment combinations that motivate providers to provide desired volume and quality of services while containing costs.

Empirical Evidence on Payment Methods

Evidence of provider payment systems that have successfully aligned system and provider incentives is still limited (Bitran and Yip 1998). Interesting findings come from small-scale experiments such as Cambodia's New Deal (box 71.1). Health

Table 71.5 Major Payment Mechanisms

Payment mechanism	Key incentives for providers
Fees for service	Increase the number of cases seen Increase service intensity Provide more expensive services
Case payment (for example, diagnosis-related groups)	Increase the number of cases seen Decrease service intensity Provide less expensive services
Daily charge	Increase the number of bed days through longer stays or more cases
Flat rate (bonus payment)	Provide specific bonus services and neglect other services
Capitation	Attract more patients to register while minimizing the number of contacts with each and minimizing service intensity
Salary	Reduce the number of patients and the number of services provided
Global budget	Reduce the number of patients and the number of services provided

Source: Bennett, McPake, and Mills 1997.

workers' salaries were considered by many to be below the minimum required for a decent life, and workload is increasing because of HIV/AIDS.

The Cambodian experiment attempted to align individual health workers' and system goals through performance-based bonus payments and a set of internal regulations. Regulations can alter the working and organizational culture in a way that allows individual-based incentives to work. There were problems in enforcing penalties for violating regulations. Failure to enforce regulations may lead providers to lose confidence in the system. Countries with limited administrative and institutional capacity should use simple payment mechanisms that are enforceable within their capacity constraints (Barnum, Kutzin, and Saxexian 1995). A lesson from the experiment is that the context matters, and any strategy for offering incentives to workers must be embedded in traditions and cultural practices.

In a competitive environment, contracts are a useful tool for aligning health workers' behavior with organizational and system objectives. In the Cambodian example, contracts between the purchaser and district-level facilities—and between district-level facilities and management committees—were an attempt to establish accountability structures that specify targeted activities. More interesting was the attempt to transfer some management risk and responsibilities to individual health workers using subcontracts that permitted management committees to monitor their activities and pay them accordingly, though whether the contracts were well specified is not clear, and the administrative and transaction costs are unknown. The use of contracts requires management and monitoring capacity.

Introducing financial incentives for health workers is costly. Policy makers in governments and development partners need to ensure that adequate funding is available and sustainable. Resources are also needed to improve working environments and system capacities. Both financial incentives and other incentives are important, but services are likely to improve only if financial incentives are strengthened.

Group Incentives

Health workers typically work in teams. This system weakens financial incentives because the efforts of individuals may have little influence on overall performance. Indeed, individual incentives can worsen team cooperation. For example, if promotion is competitive and depends on measures of individual productivity, this approach can be a disadvantage for those who work for system goals in cooperative ways.

Designing effective group incentives is difficult. Paying group bonuses for achieving a given level of output can work only if individual team members feel adequately rewarded for their efforts and if there is no perceived free-rider problem. Most of the limited evidence on group incentives is for developed countries and shows that much depends on the production process and the organization of the teams (Ratto, Propper, and Burgess 2002). Group financial incentives tend to be weak, and using other approaches such as team building, better sharing of information, and improved working conditions is probably better.

Influence of System Capacities and Sustainability Issues on Incentives

The theoretical merits and demerits of different incentives are well understood, but system capacities and financial constraints may limit their applicability. Few developing countries have health systems that are capable of effectively implementing and operating some of the payment systems shown in table 71.5. The overall funding for the health sector may be too low to pay providers more. Also, the skills and expertise needed to design and implement contract- and case-based payment methods may be inadequate, and the country may lack the information technology needed to capture relevant data to support such contract- or case-based payment methods. Most health workers in developing countries are civil servants, and the particular needs of health workers may be lost in a general public service. Some countries are considering delinking health workers from public service commissions and setting up independent health commissions to run the health sector. In Zambia, however, delinking failed because of a lack of capacity at both the national and the local levels to implement the necessary HR changes (Martineau and Buchan 2000). Evidence from Trinidad and Tobago suggests that insufficient government commitment impeded the transfer of staff members

Box 71.1

Cambodia's New Deal Experiment: The First Year

The New Deal experiment in Sotnikum district, Siem Reap province, was launched in 2000 by the Ministry of Health, Médecins Sans Frontières, and the United Nations Children's Fund. It is an example of a concerted attempt to break the vicious circle of underpayment of health staff members and underuse of public health services by tackling the problem of low official income. The New Deal was developed following wide consultations and consensus building, and locally credible management structures were established to monitor and enforce the new framework.

Staff motivation was a major problem among health workers, as manifested by high levels of absenteeism from work, low time input at work (an average of one to two hours a day), and poor quality of services. Informal charges, drug thefts, and dual practice by public health workers were common, largely because of their low public salaries: government staff received US\$10 to US\$12 per month, compared with a minimum of US\$100 required for a basic standard of living. At the same time, because of informal charges and extensive use of unregulated private services, households spent more than US\$30 per inhabitant per year on health services, equivalent to 11 percent of total household expenditure.

The New Deal was seen as a vehicle for improving services by enhancing personal income, and its overall objectives were (a) to improve access to quality health care, (b) to build up the health system, and (c) to act as a catalyst for changes in national health policy. The principle underlying the improvements in the personal income of public health workers was that they would better comply with internal regulations governing (a) job descriptions and working hours; (b) payment of informal fees; (c) misappropriation of drugs, materials, and funds; and (d) diversion of patients to private practice.

Source: Soeters and Griffiths 2003.

The district (referral) hospital, health centers, and operational office were each managed by an elected management committee, and individual contracts were signed between staff members and management committees. The contracts stipulated that a bonus would be paid in exchange for strict adherence to internal regulations. The benchmark bonus level was set at an average of US\$60 to US\$90 per person per month. The management committee was responsible for enforcing the new framework of accountability. Official fees were also introduced on the assumption that the population would agree to pay for better public service.

The district got its funding from government appropriations, user fees, and external subsidies from various sources; however, given the overall lack of funding available for the scheme, Médecins Sans Frontières and the United Nations Children's Fund had to provide an initial injection of funds to support the bonus system.

At the hospital level, individuals signed contracts with the management committees, and compliance with internal regulations improved. The staff was generally present, fees were transparent, emergencies were attended at night, patients received drugs, and informal payments were not demanded. Use of health services increased significantly after the arrangement had been introduced. The number of documented violations was limited, though problems were encountered in sanctioning penalties. Staff members started receiving bonuses that gradually grew beyond the negotiated maximum, creating a hospital debt crisis by midyear, compounded by understaffing and underemployment problems, which meant that most staff members worked overtime. Nevertheless, the quality of services improved significantly, and per capita family expenditures on health fell 40 percent.

from the public service, leading to disillusionment among workers and effective opposition from unions (England 2000).

In countries with thriving private sectors, devising strong incentives for public sector workers is difficult. For instance, in Uganda, the private not-for-profit sector used to have better working conditions and pay than the public sector and consequently had better staffing levels. The government had to increase public sector salaries significantly in the 1990s to attract health workers back. The use of fees for service in the private sector when public health workers are paid a salary is

likely to encourage private practice among public workers. Thus, the effects of methods and levels of payments are influenced by what is happening in the private sector.

Optimal Combination of Health Worker Compensation and Incentives

Although the optimal mix of provider compensation depends on context and policy objectives, some general policy guidelines on the design of payment methods to achieve organizational

and system goals are available. Linking compensation to performance makes intuitive sense, but care is needed in working out the details. Health workers respond to both financial and nonfinancial incentives, but the extent of the effect varies, and the two can interact.

For new payment systems to work well, health workers must be governed by effective managerial authority. Because new payment systems aim to encourage particular behaviors and hold providers accountable, clear responsibility must be delineated within provider organizations. This delineation may be easier to achieve if the management of providers has some autonomy. Evidence from developing countries that have attempted to introduce managerial autonomy and corporatization of health service institutions, such as public hospitals and medical stores, indicates that delinking health workers from government control is politically sensitive. Nevertheless, such organizational or system changes are desirable if new payment methods are to create the right incentives and achieve the desired changes.

Part of the context for incentive systems is what type of disease control activities are best provided through markets or hierarchies. Traditionally, the public sector has been dominant. The economic arguments for government involvement are well understood, but delivery of services within the framework of government policy objectives can be by private (both for-profit and not-for-profit) providers. Thus, the private sector is increasingly involved in the social marketing of condoms and bednets, franchising, and contracting (Bennett, McPake, and Mills 1997).

From an economic viewpoint the only issues are the cost, quality, and sustainability of such arrangements. Emerging evidence on private sector involvement in health services suggests that the private sector is willing to participate in non-clinical disease control activities if the incentive structure is right. Private not-for-profit providers, such as hospitals and clinics associated with churches, have traditionally complemented government health care activities, especially in poor and peripheral populations (Gilson and others 1997). In recent years, Bangladesh has experimented with contracting nongovernmental organizations to provide primary care services in urban areas. Lessons from this experience are still emerging and indicate that, despite many early mistakes, this form of provision can be innovative and can help make a break from bureaucratic traditions. Such contracting depends on having contracting skills in both parties to the contract. A good understanding of context and incentives is also crucial.

In summary, incentive or payment packages should attempt to link payment with individual or group performance and should be assisted by supportive organizational and system changes if the desired provider behavior is to be achieved. No single best combination of payment methods exists.

ADVICE FOR GOVERNMENTS

Governments in developing countries face huge challenges in strengthening their health systems, especially their HR capacity, if cost-effective disease control interventions are to achieve their desired results. Strengthening their systems will entail developing self-sustaining systems for the supply, use, and retention of health workers. The following considerations are important in relation to putting effective policies and incentive structures in place:

- Countries should explicitly link the planned number of each category of staff members to health policy goals and set priorities, taking overall resources into account when planning HR needs.
- Countries should recognize that the salaries necessary to recruit and retain staff members will depend on the opportunities such workers have for other employment within the country and abroad, and planned numbers in each category should be based on this reality.
- Countries should understand both that qualifications that are recognized internationally are likely to attract higher salaries and that such qualifications may only be partially suited to the needs of essential health services in LMICs. They should focus on developing the most important skills by training new types of health workers, taking into account evidence that use of such health workers can be safe when properly trained. Many countries will be unable to prevent the loss of professionals with portable qualifications, because salaries offered will be far below those available elsewhere.
- Countries' training policies should take into account the decline in skills over time and the need to allocate scarce resources between basic training and continuing staff development.
- Countries should adapt and not imitate compensation and incentive structures, given the evidence that effective incentive structures depend on local conditions and traditions as well as on universal principles.
- Policy makers should remember that the availability and cost of suitably qualified human resources will affect feasibility and cost-effectiveness of disease control interventions.
- When developing vertical disease control programs, program managers must avoid introducing powerful incentives that damage existing services by drawing away key personnel.
- Policy makers should identify potentially harmful, unintended consequences when designing regulation and incentive systems. For example, if doctors are allowed to practice in both public and private services, the effects of private practice on incentives in public practice tend to be negative unless carefully monitored.
- Countries should recognize that the use of incentives to improve performance normally requires good regulatory frameworks and skilled managerial resources.

RESEARCH AND DEVELOPMENT AGENDA

New staff categories are emerging in many LMICs, and these workers are an important part of the workforce. Such staff categories are likely to increase, given migration and the high cost of employing people with portable qualifications, but little research is available on the appropriateness and safety of the new sets of skills, and little is known about the range of new professions, the content of and approach to training, the extent of professional supervision, and the outcomes of treatment. Sharing experience of such staff categories would be valuable. Priorities, therefore, include a study to map the different new staff groups in health systems in LMICs and to classify their tasks, roles, and training, and studies to compare the outcomes of conventional and new staff groups.

In addition to gaining a better understanding of the patterns, roles, and performance of new staff groups, data are needed on the length of time such workers remain in their posts, the extent to which their new qualifications are portable, and their migration patterns. Information is also lacking on how best to provide professional supervision for these new staff groups and how to encourage such employees to be professional in their work.

Limited evidence is available on the relationship of different health care compensation methods to individual and organizational behavior in developing countries. The following are possible research areas (and some practical steps) that might help fill information gaps and further understanding of the role of health worker compensation and incentives in disease control in developing countries:

- *Databases.* A useful step would be to set up HR databases for developing countries as the Pan American Health Organization has done for its region.
- *Literature review.* A review of unpublished materials on countries' experiences with using different payment and compensation mechanisms at national or subnational levels would also be useful. Failed experiments are seldom published, but they provide useful lessons.
- *HR supply.* Traditional HR planning models are no longer effective in handling health system dynamics in developing countries. More research is required to develop HR models in health that include the effects of HIV/AIDS, migration, scaling-up of existing interventions, new technology, and reforms. The underlying question should be how HR supply mechanisms can meet health systems' needs in terms of numbers, knowledge, skills mix, and competencies.
- *Demand and utilization.* Getting the size of the health workforce right is important in its own right, but that alone is insufficient for improving health workers' motivation and productivity. Research needs to focus on how to improve the motivation and performance of health workers

in resource-constrained environments and on what is needed to retain professionals in such settings. We know little about how health care workers make decisions about a range of incentives and disincentives generated by organizations and the systems in which they work. For example, what does it take to convince doctors and nurses to work in rural and remote parts of a country? To what extent are financial and nonfinancial incentives important in attracting people into training as health workers, deploying them to needy areas, motivating them, and retaining them in the system?

To a significant extent, current problems in improving access to care, in widening the range of effective services that are provided, and in improving the quality of care depend on better matches of skills to needs, better motivation of staff, and clearer understanding of how improved structures and incentives will work. Perhaps as important is that much of the debate focuses on developments within traditional patterns of staffing of services, but new patterns are increasingly emerging, and the extent of evaluative research is inadequate for drawing strong conclusions on how such developments can alleviate the constraints facing health systems. The development of incentive systems should be coupled with the development of organizational and institutional capacity that supports sustainable HR development in general.

Ensuring Supplies of Appropriate Drugs and Vaccines

Susan Foster, Richard Laing, Bjørn Melgaard, and Michel Zaffran

In 1988, the World Health Organization (WHO) reported that 30 percent of the world's population, some 1.725 billion people, lacked regular access to essential medicines. By 1999, the 15 percent of the population who lived in high-income countries purchased and consumed 90 percent of all medicines, by value (WHO 2004f). Again as of 1999, a recent WHO report estimates that 30 percent of the world's population, including 47 percent of Africans, 65 percent of people in India, 29 percent of people in the Eastern Mediterranean, and 26 percent of Southeast Asians (excluding those from India), had no access to essential medicines (WHO 2004f). So although access has significantly improved in a number of countries, a large fraction of the world's population still has no effective access to modern medicines or vaccines. The majority of these people are either extremely poor or are living in remote rural areas where the supply of drugs is limited or nonexistent—or both.

Many diseases can be effectively treated, managed, or prevented with pharmaceuticals and vaccines. The WHO figure of 30 percent of the world's population lacking access understates the reality; even within countries with apparently good services, some populations lack access. Similarly, immunization coverage globally has remained static for more than a decade at about 75 percent of children fully immunized, with about 27 million children born every year with no access to immunization services. Some effective vaccines, such as hepatitis B (HepB), are still not in routine use in many countries.

Medicines and vaccines are developed as a result of innovation by researchers and pharmaceutical companies. The global pharmaceutical market was worth more than US\$400 billion in 2004, and more than 80 percent of this market is in North

America, Europe, and Japan. Lipitor (atorvastatin), a cholesterol-reducing drug and the world's best-selling drug in 2002, had sales of US\$8.6 billion, and growth was 20 percent annually. Zocor (simvastatin), another cholesterol reducer and the second-best seller, had sales of US\$6.2 billion and was growing at 13 percent (IMS Global Learning Consortium 2003). These figures contrast with the dearth of research on neglected diseases prevalent in developing countries. For example, of the 1,325 new medicines launched between 1975 and 1997, only 11 were specifically for tropical diseases (Trouiller and others 2002). Médecins Sans Frontières (MSF) in 1999 initiated its advocacy program, Drugs for Neglected Diseases, which has highlighted this gap (<http://www.accessmed-msf.org/>).

Access to effective medicines and vaccines requires a complex and coordinated system. It must encompass production that ensures good quality, selection, procurement, and distribution; correct prescription and dispensing and correct use by patients; adequate financing; and effective monitoring of the system. Multiple delivery systems involving public, private, and nongovernmental organization (NGO) sectors frequently coexist, and patients are very likely to use multiple systems to access these products.

DRUG POLICIES

In any country, many stakeholders are interested in the national policy on pharmaceuticals. In broad terms, they can be characterized as producers, importers, distributors, prescribers, finance providers, and consumers. Each has a different set of

interests, which in some cases are contradictory and in other cases congruent. To reconcile these disparate interests, many countries have developed a national drug policy. Managers of disease control programs need to be involved in these discussions at an early stage to prevent policy decisions from adversely affecting their programs. Any national drug policy broadly relates to three key objectives: increasing access, improving and ensuring quality, and ensuring rational prescription and use by providers and patients.

The primary components of a drug policy are selection of essential medicines; assurance of affordability, which includes issues of pricing, taxation, generic competition, and policies related to the Agreement on Trade-Related Aspects of Intellectual Property Rights (WHO 2001a); financing options; supply systems; regulation and quality assurance; rational use; operational research and drug development; clinical research, including clinical trials; human resource development for pharmaceutical policy and program management; and monitoring and evaluation. WHO has developed manuals and has provided technical support to countries to develop such national policies (WHO 2001b, 2003a).

VACCINE POLICIES

Every country has a national vaccine policy, usually laid down in a national health policy or through the establishment of well-defined elements of such a policy. WHO defines global frameworks and produces policy documents to advise developing countries (WHO 2002b). At the national level these guidelines may be adapted to fit national needs and capacities. Standards and norms for vaccines are also set by WHO and are generally adhered to worldwide (WHO 2003b).

WHO's creation of the Expanded Program on Immunization (EPI) in the 1970s established a policy for selection and use of vaccines that the vast majority of developing countries adopted. Only three vaccines—HepB, yellow fever (YF), and *Haemophilus influenzae* type B (Hib)—have been added since then, and the overall program directions remain largely intact.

In recent years, WHO has published a set of policy guidelines for vaccines not included in the global recommendations. These position papers are regularly updated. Three guiding principles provide the pillars for any national vaccine policy:

- Every eligible child must have equal access to nationally adopted vaccines regardless of religion, caste, or economic status.
- Vaccines require active government financial participation to ensure that they are provided and used in adequate quantities, thus ensuring the benefit of their considerable externalities. For example, the benefits to society of an individual's being vaccinated are greater than those to the indi-

vidual, because vaccination prevents transmission. It can also be argued that the elimination or eradication of a disease as a public health problem has public good characteristics: the benefits of the absence of disease are available to everyone, and all persons benefit at the same time. Therefore, governments must take an active role in ensuring that adequate vaccines of assured quality are available for comprehensive immunization programs within the country. The recent flu vaccine shortage and resulting rationing problems in the United States have illustrated this principle clearly.

- Countries should strive toward financial sustainability for the national immunization program.

A vaccine policy normally has six specific objectives:

- To provide a coordinated approach to national vaccines and equipment needs, including national vaccine production where applicable
- To provide criteria for vaccine selection and introduction, including burden-of-disease studies where relevant
- To develop a financial sustainability plan that ensures availability of vaccines in the longer term
- To define guidelines for private-public partnerships, including vaccine research
- To define national research priorities
- To support the implementation of the national immunization programs.

Policy setting is a continuous process that must keep up with global developments and changing national needs. Countries will normally formulate policies that are based on the technical work of a national committee of experts, who meet regularly under the auspices of the ministry of health. Bilateral donors and the Global Alliance for Vaccines and Immunization (GAVI) may influence policy setting, such as the timing for introduction of new vaccines, where they contribute significantly to the national immunization programs.

SELECTION OF DRUGS

Selection of a limited list of essential medicines that should always be available is necessary both for supply officials who work on procurement, storage, and distribution and for clinicians who aim to use medicines most effectively.

In 1977, WHO defined the first Model List of Essential Drugs (WHO 1977); since then it has updated the list 14 times. The latest list defines *essential medicine* as follows:

Essential medicines are those that satisfy the priority health care needs of the population. They are selected with due regard to public health relevance, evidence on efficacy and safety, and

comparative cost effectiveness. Essential medicines are intended to be available within the context of functioning health systems at all times in adequate amounts, in the appropriate dosage forms, with assured quality and adequate information, and at a price the individual and the community can afford. The implementation of the concept of essential medicines is intended to be flexible and adaptable to many different situations; exactly which medicines are regarded as essential remains a national responsibility.

In 2003, the WHO Expert Committee on Selection and Use of Essential Medicines decided to define the criteria for core and complementary lists, as follows:

The core list presents a list of minimum medicine needs for a basic health care system, listing the most efficacious, safe, and cost-effective medicine for priority conditions. Priority conditions are selected on the basis of current and estimated future public health relevance, and potential for safe and cost-effective treatment.

The complementary list presents essential medicines for priority diseases, for which specialized diagnostic or monitoring facilities, or specialist medical care, or specialist training, or all three are needed. In case of doubt, medicines may also be listed as complementary because of their consistently higher costs or less attractive cost effectiveness in a variety of settings (WHO 2003d, 28).

At its 2002 meeting, the WHO Expert Committee changed its attitude toward fixed-dose combinations (FDCs). The committee stated that most essential medicines should be formulated as single compounds. Fixed dose combination products are selected only when the combination has a proven advantage over single compounds administered separately in therapeutic effect, safety, adherence or in delaying the development of drug resistance in malaria, tuberculosis and HIV/AIDS (WHO 2002c). This change reflected the interest in preventing the development of resistance and in promoting adherence. Although controversial, these FDC products will very likely be the main form of treatment for AIDS, tuberculosis (TB), and malaria.

The number of medicines on the WHO list has increased over time. The 2003 WHO list has 320 drugs in 559 formulations (Laing and others 2003). At country level, the essential drugs list is used as a guide rather than as a template. A study of 17 national lists of essential drugs showed that 68 percent had fewer than 300 drugs. The number of drugs per list ranged from 108 in Liberia to 389 in Karnataka state, India. Nine of the drugs on the WHO list were not on any of the 17 national drug lists in the study (Laing and others 2003).

At the first stage of identifying common diseases and complaints, managers of disease control programs are in a strong position to provide epidemiological information about the incidence or prevalence of a condition. At the second stage, the

selection of treatments would ideally have already been undertaken on the basis of available evidence or clinical trial data from the country. The medicines identified within these guidelines would thus become the medicines on the essential medicines list. This list would then serve as the basis for procurement, storage, and distribution activities. The evidence-based treatment guidelines would define treatment practices and be the basis of training (including examinations and licensing) and supervision.

SELECTION OF VACCINES

Developing countries select vaccines used in national immunization programs primarily on the basis of WHO policy guidelines. Most countries have adhered strictly to the six original vaccines—Bacillus Calmette-Guérin (BCG), oral polio, diphtheria, pertussis, tetanus, and measles. On the recommendation of the WHO Global Advisory Group on Immunization, HepB vaccine was included in the global guidelines in 1987, and YF vaccine was added in 1988; Hib vaccine was added in 1994. These remain the only vaccines recommended by the WHO for national use, and the recommendation presupposes that a disease burden of public health importance is present (see table 72.1).

A few vaccines, such as YF and Japanese encephalitis (JE), have regional importance in accordance with the prevalence of the disease. These vaccines are used in only a small number of developing countries. WHO has not generally recommended JE, although no evidence indicates that the disease burden of

Table 72.1 Current Vaccines Recommended by the World Health Organization

Vaccine	Age				
	Birth	6 weeks	10 weeks	14 weeks	9 months
BCG	X				
Oral polio	X ^a	X	X	X	
Diphtheria-tetanus-pertussis		X	X	X	
Hepatitis B ^b		X	X	X	
<i>Haemophilus influenzae</i> type B ^b		X	X	X	
Yellow fever					X ^c
Measles					X ^d

Source: WHO 2002d, 88.

a. In endemic countries.

b. Only a few African countries have been able to introduce the vaccines to date.

c. In countries where yellow fever poses a risk.

d. In addition, a second opportunity to receive a dose of measles vaccine should be provided for all children.

YF is greater than the JE disease burden. However, a safety issue exists with mouse brain–derived vaccines such as JE.

Oral polio vaccine (OPV) is the vaccine of choice in developing countries, because it is easy to administer and the protective effect spreads to close contacts of vaccinees. It is suitable for mass campaigns, so the vaccine is used in poliomyelitis eradication programs. In 2005, the monovalent type 1 OPV, for which seroconversion rates are substantially higher than for trivalent OPV, has started to be used in areas where only type 1 wild poliovirus remains in circulation.

The selection of the original EPI vaccines was made on programmatic criteria rather than on considerations of disease burden. The need for consistent and standardized regimens determined the strategies selected by EPI. Adaptations over time, as new vaccines came along and local needs changed, were slow, and the uptake of newer vaccines remains a major constraint in most developing countries, although support provided through GAVI has improved the situation.

The term *vaccine gap* is used to describe the phenomenon whereby children in developing countries receive at most eight vaccines, if they are reached by immunization programs at all, whereas children in industrial countries normally receive 10 to 12 antigens, depending on national schedules. Furthermore, two vaccines in the routine schedule in the affluent world are less reactogenic than those given in developing countries: acellular pertussis vaccine (aP) and inactivated polio vaccine (IPV). The combination measles-mumps-rubella (MMR) vaccine is normally given twice, offering long-term protection against measles and rubella, important diseases in the developing world. The vaccine gap therefore consists mainly of three vaccines—aP, IPV, and MMR.

The pneumococcal vaccine, which is currently used in some countries, illustrates an additional aspect of the vaccine gap. Its composition is directed against the most prevalent strains, which cause otitis media in children. At the same time, millions of children die in the developing world from pneumonia caused by other strains of the bacteria, but no vaccine is currently available against those strains.

PROCUREMENT OF DRUGS

After the drugs have been selected, the next step is to decide how much to order. Usually this decision is based in part on past consumption, but it is also based on treatment guidelines and morbidity patterns. Concentrating on larger quantities of fewer drugs and dosage forms simplifies the process of ordering and reduces the chances of running out of stock. Ordering tablets or capsules rather than syrups or injections saves a great deal of money.

In 1997, when the second edition of *Managing Drug Supply* was published (Quick and others 1997), four methods of

procurement were recommended under different circumstances. These methods were open tender, restricted tender with performance monitoring, negotiated procurement, and direct procurement. At that time, the World Bank was a major funder, and many countries favored the use of open tender. However, a major shift has taken place to restricted tender based on prequalification and direct procurement from non-profit suppliers. The World Bank has produced a number of useful documents and resource materials that can be used for national procurement activities (World Bank 2000).

Another method of procurement that has been more widely used has been procurement from nonprofit suppliers, such as the United Nations Children’s Fund (UNICEF) or the International Dispensary Association (International Dispensary Association 2004; UNICEF 2004). These organizations produce price lists twice yearly, and products can be ordered directly. Management Sciences for Health (2004) publishes an international drug price indicator guide annually that reports these prices and other procurement prices. Interestingly, the trend in drug prices generally has been downward. Prices of some TB drugs fell by more than 90 percent when procurement managers opened intensive negotiations with suppliers. And since 2000, prices of many important first-line antiretroviral drugs have fallen considerably. This trend is attributable to “advocacy, corporate responsiveness, competition from generic manufacturers, sustained public pressure, and the growing political attention paid to the AIDS epidemic. In addition, originator companies began announcing discount offers for the benefit of the poorest countries or those where the HIV/AIDS prevalence is the highest” (WHO 2004d, 5). The influence of economies of scale, in which unit costs have fallen because of the increased consumption of needed pharmaceuticals, might also have played a role.

Generic drugs obtained in bulk are almost always 10 or more times less expensive than brand-name drugs. Bulk purchase of generic drugs is the single best way to make a given budget go farther to satisfy the drug needs of a population. For price comparison, international prices (ex-factory, free-on-board—that is, not including insurance, freight charges, or taxes) are available online from Management Sciences for Health (2004). Local prices must, of course, include transportation and freight, as well as any applicable local taxes. Organizations that procure drugs in bulk but then sell smaller quantities, usually to nonprofit organizations, can help smaller purchasers obtain the advantages of competitive tendering. Examples include the International Dispensary Association, which is based in the Netherlands, and the Copenhagen office of UNICEF, which is able to supply drugs at very low cost to government-supported institutions.

Recent studies have revealed just how much the local component of drug costs can be, particularly in the private sector. A survey of costs in nine countries found an average

markup of 68.6 percent, with retail markups of 16 to 50 percent comprising the largest single component in most cases. In countries that charge a value added tax on drugs, the tax can add 15 to 20 percent to the price of the drug (Levison and Laing 2003). Many of these cost elements are within the control of national policy makers.

Finally, when considering a change of standard therapy, managers of disease control programs need to take into account the long lead time between ordering a particular drug and having it arrive in the country ready for use—which can be a year or more. Time will also be required to prepare, print, and disseminate new guidelines, to train prescribers and dispensers, and to dispose of drugs used in the older therapy (Williams, Durrheim, and Shretta 2004).

PROCUREMENT OF VACCINES

Countries can be grouped into three categories according to the way they procure vaccines: procurement through United Nations (UN) agencies, direct procurement, and local production. Some countries procure their vaccines from a range of sources and may cut across all three categories. Over the past 25 years, UNICEF has been the main bulk procurer of traditional vaccines for most of the developing world, with the Pan American Health Organization Revolving Fund for Vaccine Procurement serving most Latin American countries. Because the fund takes advantage of large volume purchasing, it obtains prices comparable to those of UNICEF, which are available to all participating countries—regardless of their income level or size. The Gulf Cooperation Council also operates a purchasing program for its member states. That program includes 43 different vaccines and sera.

Some countries, where governments take on an increasing share of vaccine financing, purchase the vaccines directly from the producers or their representatives. Unfortunately, procurement is often being undertaken with little recognition that stringent quality assurance procedures must be in place to oversee the entire process. WHO is organizing workshops specifically targeted at vaccine procurement and has developed a vaccine procurement manual to guide such countries (WHO 2005a).

QUALITY ASSURANCE FOR PHARMACEUTICALS AND VACCINES

In an ideal world, all products to be imported into a country would be registered by a fully competent national drug regulatory authority to ensure quality. Unfortunately, this situation is not always the case. A study of antimalarial samples from seven African countries found that failures in ingredient content

ranging from 20 percent to 67 percent for chloroquine tablet (CQT) and 5 percent to 38 percent for sulphadoxine/pyrimethamine tablet (SPT) and dissolution failures ranging from 5 percent to 29 percent for CQT, and 75 percent to 100 percent for SPT (WHO 2003c). Good procurement practices of both brand-name and generic drugs require that suppliers be prequalified through the inspection of dossiers and factory inspections for good manufacturing practice (GMP) and that their performance be monitored.

Counterfeit medicines are a particularly difficult problem. Counterfeit medicines “are deliberately and fraudulently mislabeled with respect to identity and/or source. Counterfeiting can apply to both branded and generic products, and counterfeit medicines may include products with the correct ingredients but fake packaging, with the wrong ingredients, without active ingredients, or with insufficient active ingredients” (WHO 2005b, 1). In industrial countries, the newer brand-name medicines are counterfeited most often; Viagra is the frequent subject of counterfeiters. In poorer developing countries, the most commonly used antimalarials, antibiotics, and now antiretrovirals are the targets of the counterfeiters. The U.S. Food and Drug Administration estimates that up to 25 percent of medicines in developing countries are either counterfeit or otherwise substandard and that earnings from counterfeit drugs are more than US\$32 billion per year (WHO 2005b).

THE WHO PREQUALIFICATION SCHEMES

Because undertaking prequalification tasks may be beyond the capabilities of national authorities, WHO has, on behalf of all UN agencies, started a prequalification scheme (WHO 2004d) covering AIDS, TB, and artemisinin-containing malaria drugs. The prequalification process is rigorous but efficient. WHO provides a positive list of prequalified products and manufacturers that have applied for and received favorable product assessments and manufacturing site inspections. Since January 2005, the Global Fund to Fight AIDS, Tuberculosis, and Malaria has required recipients to use WHO-prequalified products.

Ensuring quality is also an important aspect of any immunization program. For countries receiving their vaccines through UN agencies, WHO advises on the quality, efficacy, and safety of vaccines on the market through a prequalification of vaccines that entails the following steps: (a) reliance on a fully functional national regulatory authority (NRA) in the country of production and (b) verification of compliance with specifications through a thorough process of independent dossier reviews, testing of samples, site visits, ongoing monitoring of quality, and follow-up of complaints.

For a successful prequalification process, the NRA of the country of production must be functional and empowered by

the government. A set of laws and structures must be in place that guarantee the NRA's authority and independence and that the NRA exercises the following functions: licensing, postmarketing surveillance, lot release, laboratory access, GMP inspections, and evaluation of clinical performance. These functions constitute the prerequisite for vaccines of assured quality and are the focus in vaccine regulation.

LOCAL PRODUCTION OF PHARMACEUTICALS

Large-scale production of pharmaceuticals in the developing world is limited to a few larger countries, most of which export primarily to other developing countries.

Whether local production of pharmaceuticals should be encouraged in low- and middle-income countries is a controversial issue. During the 1980s and early 1990s, the United Nations Industrial Development Organization encouraged the establishment of national production facilities. Recently, the World Bank and the executive board of WHO have reviewed this issue (Kaplan and others 2003; WHO 2004a). The more extensive World Bank report concluded:

In many parts of the world, there is no reason to produce medicines domestically, since it makes little economic sense. In the local pharmaceutical manufacturing sector, local production is often not reliable and, even if reliable, it does not necessarily mean that medicine prices are reduced for the end user. If local production is adopted by many countries, it may lead to less access to medicines, since there are no economies of scale in having a production facility in each country" (Kaplan and others 2003).

Profit margins on bulk generic drugs are low so that public production must be as efficient as private manufacturing. For many countries, technical expertise, raw materials, quality standards, and production and laboratory equipment all need to be imported, so foreign exchange savings may be small or nonexistent. Few developing countries have the capacity to produce active ingredients for pharmaceutical manufacture. Industrial investment to promote local manufacture of pharmaceuticals in most, but not all, developing countries could be better used to improve health infrastructure (Kaplan and others 2003).

In summary, a manager of a disease control program is likely to obtain quality-assured products by procuring them from prequalified suppliers at the lowest prices without considering whether the products are locally produced.

STORAGE AND DISTRIBUTION OF ESSENTIAL DRUGS AND VACCINES

In the past, essential drugs, vaccines, and contraceptives were for the most part distributed using separate logistics systems. For vaccines and contraceptives, such systems were organized

vertically to some extent, and because they were concerned with a far more limited range of products, the task was somewhat simpler.

A push has been made to integrate the distribution systems for drugs, vaccines, and contraceptives, although in most places separate systems are still operating, at least at the national level and often down to provincial levels. Vian and Bates (2003) noted a number of changes to the distribution systems in the past few years. In many countries, health sector reform programs included efforts to reform central medical stores to allow more autonomy and to introduce commercial incentives and improved management methods. In some cases, this reform has led to higher staff productivity, better performance, and more enforcement of payment policies. However, disruption in supply often occurs during central medical store transition phases. Increased integration of commodities, including contraceptives and vaccines, has also been noted. In some cases, it has decreased the amount and reliability of data collected on logistics, creating problems for needs estimation and for tracking of consumption (Vian and Bates 2003).

Another trend is the increasing use of private transporters and contracting out for transportation management; contracting transport can generate cost savings and improve services. Finally, a trend toward computerized systems exists, particularly involving the use of donor-financed software for improved management of logistics as well as a number of comprehensive assessment tools and indicator sets for evaluating drug supply systems. But the proliferation of software systems, with little coordination and not enough support and maintenance of complex and fragile computer systems, can be counterproductive, especially if paper-based systems that are difficult to reintroduce upon failure of the computer system are abandoned (Vian and Bates 2003).

Storage and Stocks Management

Drugs require secure storage in controlled climatic conditions and a reliable method of stock rotation. The FEFO rule (first expiry, first out) helps ensure that older stock is used up first. Security is another major consideration: access to the storehouse must be carefully controlled so that theft and embezzlement are minimized, and the persons who control access must themselves be trustworthy. Proper storage conditions, including minimizing exposure to heat, light, and humidity, are important for some drugs, but most drugs have proved remarkably resistant to poor conditions. Notable exceptions are tetracycline products, which become toxic when exposed to heat, and oxytocin and ergometrine, which lose their potency when exposed to light and heat; all should thus be stored in the refrigerator. The same applies to insulin and, of course, most vaccines. Correct FEFO stock rotation will ensure that exposure to harsh conditions is minimized and that potency is

preserved as much as possible. Ensuring good air circulation and preventing direct water contact are most important.

Management of Donated Drugs

Management of donated drugs is a major problem in some areas, particularly if an emergency has precipitated an influx of drug donations. The best strategy is to accept only invited donations of drugs that the facility has specifically asked for (WHO 1999a). Any drug that is neither vital nor essential, that is not labeled clearly with its generic name, that is expired, that is in a package that contains only a few days' dosage, or that is not on the national essential drugs list or on the facility's formulary should be discarded—and the pharmacist should feel no guilt and fear no sanctions about disposing of such materials. They take up space, require tracking like other drugs, and present a risk of being accidentally dispensed to a patient and causing the patient harm—a factor that must also be taken into account. Proper disposal can be a problem. These drugs constitute potential toxic waste, and they should be treated as such and disposed of so that they cannot be retrieved and sold (WHO 1999b).

Vaccine Management

Vaccines are delicate products that are destroyed if handled incorrectly. Vaccine management involves the use and distribution of vaccines, from the manufacturers to the end users. Aspects of vaccine management include inventory and forecasting, stock control, in-country distribution, storage and handling, equipment replacement plans, procedures for the use of the vaccine, monitoring of vaccine storage, transport management, and operational management.

Forecasting of vaccine needs is the first building block of an adequate management system. In 2002, 22 of 82 countries surveyed by UNICEF indicated that they had experienced a vaccine stockout. In addition to lack of resources, the main reasons cited included poor or late forecasting.

In recent years, attention has focused on avoiding heat exposure. The introduction of costly vaccines that are sensitive to freezing has drawn attention to the need to protect vaccines from excessive exposure to cold as well as heat. WHO guidelines for the international transport of vaccines now include specific recommendations for each category of vaccine, including freeze sensitivity. National cold stores are the next critical level of the vaccine management system. A failure there—where vaccines are received, stored, and distributed in bulk—can result in extensive losses. The WHO-UNICEF Effective Cold Store Management Initiative encourages countries to procure equipment and adopt management and training practices that fully protect vaccines in national and intermediate vaccine stores.

At the country level, emphasis is being put on the use of new tools, such as the vaccine vial monitor. This heat-sensitive label is a time-temperature indicator used to ensure that the vaccines have not been damaged by excessive exposure to heat, to identify weaknesses in the cold chain, and to take vaccines beyond the cold chain to children who have no access to fixed health facilities.

Together with the increased use of vaccine vial monitors, the gradual adoption of the multidose vial policy contributes to the reduction of wastage. This policy of using opened multidose vials of vaccine in subsequent immunization sessions applies to all multidose vials of liquid vaccine containing thimerosal (WHO 2000). The policy was formulated in 1996 but its adoption remains limited.

PRESCRIPTION AND RATIONAL USE OF DRUGS

Rational drug use involves the correct drug being given to the correct patient, for the correct indication, in the correct dosage, by the correct route of administration, for the correct duration of treatment. The dispenser must also correctly dispense and label the drug and counsel the patient, and the patient must take the drug correctly or comply with or adhere to treatment. An error at any stage of this complex process can prevent the drug from being effective. Usually, at least half of these errors are attributable to the failure of patients to adhere to treatment, but the other half of the errors occur before the patient actually begins taking the drug. Few of the recommended treatments for common diseases involve more than one or two drugs, yet in actual practice, multiple drugs are often prescribed, even for uncomplicated cases. Such overuse of drugs rapidly consumes stocks, does not add to the quality of care (although patients may believe that more drugs are better), and allows stockpiling by patients.

The use of injections instead of equally effective oral preparations is also common. Not only are risks associated with the injections themselves, but also the cost of these injections is far greater than for the equivalent oral preparations. If all the prescribers at a facility can agree on and adhere to standard treatment guidelines that can be used as the basis for procurement and storage, the problem of overprescription and stockouts can gradually be eliminated. Uncertainties about dosages, particularly pediatric dosages, can also be reduced by the use of standard guidelines by age or weight. Doctors often cite their mistrust or delay of laboratory results as a reason to “cover” the patient for a variety of conditions. Dealing with laboratory efficiency or accuracy issues may be a worthwhile way to improve prescription practices that would also yield great benefits in terms of quality of care. Regularly reviewing a sample of prescriptions or case records and comparing treatments given to the standard treatment guidelines is likely to have a dramatic

effect on the improvement of treatment practices (Laing, Hogerzeil, and Ross-Degnan 2001).

DISPENSING

Finally, the last step in the chain of the drug supply system is delivery to the patient. Often, dispensing is done by untrained staff members who know little about the drugs they are dispensing and are unable to communicate effectively with the patient. Anecdotal stories about patients receiving a handful of white pills and throwing them on the ground are discouraging to staff members but demonstrate that patients need explanations about the drugs they are getting. Increasing the use of dispensing materials—paper or plastic bags—may be worthwhile if it improves adherence to treatments. Brief training courses for dispensers can substantially improve the quality of dispensing.

Another major problem is the presence of dispensing doctors. A number of studies in both developed and developing countries have demonstrated that dispensing doctors prescribe more by value and not according to national or accepted guidelines (Trap, Hansen, and Hogerzeil 2002). The higher number of prescriptions is strongly associated with symptomatic treatment (that is, a drug was prescribed for every symptom); general overprescribing of antibiotics; overuse of injections; and prescription of medicines with lower clinical value. From a policy and safety perspective, the functions of prescribing and dispensing should be separated whenever possible (Nizami, Khan, and Bhutta 1996).

ADHERENCE

Delivering the drug to the patient is not the end of the story: the patient must adhere to the therapy. Failure to comply or adhere will result in poorer health outcomes; it may compromise the effectiveness of treatment, decrease the quality of life, increase preventable disability, and lead to premature death. It may also result in increased health care costs, more use of emergency rooms, more and longer hospitalizations, and potentially more use of intensive care units (Sabate 2003).

FINANCING ISSUES

The share of expenditures on health that goes to pharmaceuticals is presented in table 72.2.

Asking patients to pay part or all of the cost of their drugs can aid in holding down costs, reducing overuse, and replenishing the funds for drugs in the system. Drugs are often targeted for such fees because it is felt that patients will pay for them if they have no other choice. A substantial literature now

exists on the advantages and disadvantages of user fees. On the one hand, they do raise some revenue, but administrative costs have often taken a large proportion of it. Their net contribution has rarely exceeded 5 percent of a government's recurrent expenditure. On the other hand, they often accounted for as high as 100 percent of nonsalary recurrent expenditures. Moreover, where they have been retained at the facility level, they have allowed for improvements in infrastructure and staff income, as well as ensuring a more regular supply of drugs (Xu and others forthcoming).

However, from a public health perspective, the disadvantages are numerous. They are often applied inequitably, with exemptions provided to richer people—such as government workers, the military, and the police—while poorer people must pay. But the main problem is that user fees discourage some people, particularly the poor, from seeking care at all. And among those who do seek care, the resulting costs can be financially crippling, to the extent that households may sacrifice food, education, or other important purchases to pay for drugs. Some are forced into poverty as a direct result of user fees. A related issue of increasing importance with the advent of effective antiretroviral therapy for AIDS is that user fees discourage adherence to long-term treatment, resulting in treatment failure, increased disease transmission, and the development of drug resistance. Fees are, therefore, particularly problematic for transmissible diseases.

On the basis of similar evidence, Creese (1997, 203) concluded, "A range of policy options other than user fees exists for dealing with situations of both under financing and rapid growth in expenditure. As an instrument of health policy, user fees have proved to be blunt and of limited success and to have potentially serious side effects in terms of equity. They should be prescribed only after alternative interventions have been considered." In this respect, WHO is now advocating that fees should be minimized and that countries should be supported in attempts to channel a high proportion of health expenses through taxes or prepayment mechanisms such as forms of insurance.

Table 72.2 Measured World Pharmaceutical Spending, by per Capita Income Clusters, 1990–2000 (percent)

Income group	Share of world total		Share of expenditure on health	
	1990	2000	1990	2000
High income	80.2	78.7	13.0	13.8
Middle income	17.1	18.8	22.5	24.8
Low income	2.7	2.4	20.8	19.2

Note: Income groups refer to World Bank classifications as of July 2000.

SUSTAINABLE FINANCING OF VACCINES AND IMMUNIZATIONS

Immunization is now generally accepted as representing one of the “best buys” for the health sector that governments must play a lead role in financing, but sustainable financing mechanisms have been largely absent in poor countries (WHO 2004a). The cost of immunizing a child against the six basic diseases hovers between US\$15 and US\$20 at current levels of coverage, representing no more than US\$0.50 per capita, and on average 0.2 percent of the gross domestic product in most low-income countries. These costs suggest that immunizations are affordable for most developing countries from national budgets. However, immunization programs account for only 5 to 10 percent of total government health expenditures in many countries, which often rely heavily on donor funds.

Although the international community has recognized the important reasons that financing of vaccines cannot be left to individuals or households, donor support has often been quite erratic. The result is volatile financing that is vulnerable to shifts in donor priorities. In addition, recipient governments recognize that donors are more likely to fund vaccines than many other services, so they have taken the opportunity to spend their own resources on activities that are important to them but are less attractive to donors. This phenomenon can be seen in the apparent mismatch between data on disease burden, stated government priorities for health, and the allocation of government funds.

The challenge facing governments in poor countries is how best to finance vaccines, taking into account the variety of other health problems and the possible sources of funds. More funds could probably be raised from firms and households for health in general, but user fees for immunization, as for drugs, discourage people from seeking vaccination for their children. However, helping countries move to a system in which more prepayment exists for health services in general—either through taxes or the various possible forms of health insurance—would provide a pool of domestic funds that could be used for vaccines. If these funds were raised progressively, the rich could subsidize the poor.

A number of new issues relevant to immunization financing have arisen recently, including the evolving nature of the world market for vaccines, the growing divergence in vaccination schedules between developed and developing countries, the increasing diversity of products and presentations available to countries, the emergence of developing country manufacturers, and the importance of new global initiatives such as GAVI and the Vaccine Fund. The Vaccine Fund focuses on helping low-income countries introduce newer vaccines, such as HepB and Hib, which are generally more expensive than the older vaccines. In addition, the technology associated with the production of new combination vaccines has increased prices, with

the cost per fully immunized child now reaching US\$30 if HepB and Hib are included. This increased cost adds to the challenge. Governments in low-income countries and international development partners need to develop long-term strategies to ensure adequate financing for key health programs and interventions, including vaccines.

Since GAVI and the Vaccine Fund were established, renewed attention has been paid to financing issues as they relate to vaccine and immunization financing. GAVI has worked with WHO and countries to consider how much it would require to maintain existing levels of coverage after GAVI funding ends, whereas among the prerequisites for countries to obtain assistance from the Vaccine Fund is preparation of long-term financing plans for immunization programs. However, most low-income countries clearly will be unable to fund even a minimum set of essential interventions in the short to medium term without the assistance of international partners, thereby increasing the need to develop the long-term financing strategies described above. A mix of such strategies would include raising additional domestic funds, ensuring that funds are used effectively and efficiently, moving to greater reliance on prepayment mechanisms, and ensuring increased and stable flows of external funds. Table 72.3 summarizes and compares some recent trends in the financing of essential drugs, vaccines, and contraceptives.

ISSUES FOR THE FUTURE

As the world's population ages, health systems that formerly focused primarily on infectious disease are being asked to deliver new types of care, mostly for chronic illnesses and increasingly for mental illness. By 2020, the major causes of the burden of disease will shift from pneumonia, diarrhea, and perinatal conditions to heart disease, mental illness (particularly depression), and road traffic accidents. Tobacco will kill more people than any other cause of disease, including HIV. Unlike the United States and the countries of Western Europe, China and India will face the challenges of an aging population before they become high-income countries. Most health systems in the developing world are now prepared to deliver acute care, particularly for infectious disease, rather than chronic care. They are ill suited to long-term chronic care and follow-up; in general they lack recordkeeping, demonstrate little development of personal relationships with caregivers, and have little provision for enhancing patient adherence with medication. In many situations, the irregular and intermittent supply of medications for chronic disease means that the chronically ill suffer many interruptions of their treatment. The changing nature of health care will require changes in drug supply, which are only beginning to become visible. The (perceived) difference between “good” and “bad” care is often the availability of

Table 72.3 Trends and Developments in Financing and Procurement of Essential Drugs, Vaccines, and Contraceptives

Commodity	Trends and developments	Implications for logistics
Essential drugs	Use of loans and pooled or “basket” financing arrangements is increasing, leading to increased government involvement in procurement.	In the short term, procurement delays, shortages, emergency procurement requests, higher prices, and greater waste will result while governments develop internal capacity to procure. Also, increasing government involvement can mean less predictable results because of politics and governance issues.
	Procurement models adapted for health reforms such as decentralization and privatization proliferate.	Donors are more concerned about how procurement is done, translating into more technical assistance and emphasis on performance benchmarking. Difficulties in evaluating procurement systems are caused by a proliferation of models.
	Countries are moving toward restrictive tender and prequalification of suppliers.	In the longer term, prequalification may shorten the procurement cycle and lower costs. Similar effects from use of NGO suppliers are possible.
	Role of NGO suppliers continues in some countries as well as role of international NGO suppliers.	
	User fees represent a major trend for essential drugs, with many health facilities operating on a cash-and-carry basis.	Fee systems can decrease demand unless mechanisms exist to ensure service for those unable to pay.
	Private sector role is increasing as it becomes more apparent that public sector and NGO services cannot meet all needs.	Policy makers and managers will need to design and implement programs that promote appropriate use of the private sector
Vaccines	Donor contributions have been decreasing starting in 1990s.	Concerns are similar to those with essential drugs.
	Government financing and procurement of vaccines is increasing; a dependence on external resources persists.	GAVI supplies may require logistics changes because of new vaccines and injection equipment.
	Some shift in financing from grants to loans, and more use of basket financing.	Pressure on governments to finance vaccine purchases may lead to less government funding for EPI operating expenses and other Ministry of Health programs.
	Use of pooled procurement mechanisms and revolving funds or other international financial mechanisms, some based on achievement of outcomes, is increasing.	Outcome-based support requires information systems resistant to manipulation.
	New vaccines and vaccine combinations (new with old) are supplied through GAVI.	
Contraceptives	Donor contributions have been flat or have decreased, starting in 1990s.	Concerns are similar to those with essential drugs.
	Despite efforts to increase government contributions, there is still a major dependence on external resources.	Demand is created without supply keeping up.
	Many governments continue to give contraceptives (as compared with drugs) low priority for procurement with their own funds.	Constraints of Mexico City policy (“global gag rule”) have limited funding for contraceptives.
	Financing through loans and basket financing are increasing, and governments are increasingly involved in procurement.

drugs and supplies. Programs and funding agencies that are planning improvements in health care—for example, increasing coverage or case detection rates—often overlook the fact that such improvements will increase drug needs and costs.

Drug Resistance

Although the burden of chronic and noninfectious disease is increasing rapidly in the developing world, infectious diseases still account for nearly half of deaths in low-income countries. Most of these deaths are caused by six diseases: acute respira-

tory infections (mainly pneumonia), diarrheal disease, HIV and AIDS, tuberculosis, malaria, and measles. Drug resistance complicates the effective treatment for nearly all of these acute infections. Furthermore, this trend is expected to accelerate in the coming decades. In the treatment of HIV and AIDS, the increase of retroviral drug resistance is becoming a serious problem, especially in view of the limited number of treatment regimens available to date.

Drug-resistant malaria is now widespread. Chloroquine—once a cheap and reliable first-line treatment for malaria—is

no longer effective in most countries. Newer drugs are significantly more expensive. Most recently, the trend has been toward multidrug combinations of products, and the addition of more than one drug is often to “protect” the component drugs from developing resistance as well as to improve the therapeutic effect (WHO 2002a).

Drug resistance in tuberculosis control—in particular, multidrug resistance—is a growing problem. Multidrug-resistant TB has now appeared around the world, and in many places more than 20 percent of resistant new tuberculosis cases are resistant to several drugs. Furthermore, the emergence of multidrug-resistant bacilli means that medication that once cost US\$20 must now be replaced with drugs that are significantly more expensive and more difficult to use (WHO 2002a). Another major concern is the use of antimicrobials in farming, because about half of the antimicrobials produced each year are used in farm animals. Some of the new resistant bacteria are transmitted from food of animal origin or through direct contact with farm animals. Some reports indicate that as much as 50 percent of human antimicrobial resistance is caused by growth promoters in livestock, which are added to feed in subtherapeutic antibiotic doses (WHO 2002a).

HIV and AIDS

The HIV epidemic has had a tremendous impact on the pharmaceutical supply situation. First, it has highlighted weaknesses of drug supply and access around the world; the arrival of highly active antiretroviral therapy for the treatment of HIV/AIDS (HAART) means that HIV is to a large extent now a treatable condition, yet treatment is not available to the majority of those who suffer from HIV. Second, it has drawn the world’s attention to the growing gap between rich and poor in terms of pharmaceutical provision. Unlike many other highly prevalent illnesses in the developing world, HIV and AIDS are also of major concern in the wealthier countries, and thus significant research has been undertaken and has yielded effective new medications (HAART, in particular).

A recent WHO report highlights the issue of the affordability of medications, pointing out that of the 23 countries that are estimated to make up 80 percent of the 2003 global need for HIV and AIDS treatment—estimated at about US\$300 per annum per patient—only 8 have pharmaceutical expenditure levels above US\$5 per capita, far short of the level of expenditure needed (WHO 2004c). Prices have fallen dramatically; WHO has continued to monitor the quality of AIDS drugs available on the world market for sale in developing countries and has removed substandard drugs from its list when necessary (WHO 2004e). Many high-profile initiatives to solve this problem have been started, most notably the WHO’s “3 × 5” program; the Global Fund to Fight AIDS, Tuberculosis, and Malaria; the Clinton Foundation’s efforts to lower prices for

HAART; and President George W. Bush’s Emergency Plan for AIDS Relief. A number of issues are raised by the delivery of a complex, lifelong, costly treatment to poorer communities, especially in rural areas, one of which will be how to ensure adequate adherence to treatment in different clinical settings, ranging from district hospitals to health centers or even home settings, for HAART delivery.

Aging and Chronic Diseases

One of the important results of the exercise to estimate the global burden of disease was to highlight the growing importance of chronic disease, particularly in the developing world. A large percentage of chronic illnesses are related to smoking and lifestyle, and thus attempts to reduce smoking—or the lethality of smoking—would have an important effect on the need for medication for chronic disease.

Although many cancers are not yet curable, many are treatable with the goal either of slowing the spread or of palliating the symptoms of the disease. As the burden of cancer increases, palliative care, which involves the treatment of the symptoms and especially the pain that accompanies most cancers, needs to be given much higher priority. At present, the vast majority of the millions of cancer patients in the developing world receive totally inadequate pain control and suffer needless agony, in part because of antiquated laws governing the use of opioid analgesics (particularly morphine) and attitudes of medical and nursing personnel toward pain control (as well as attitudes of family members in some settings). The myths about morphine need to be dispelled. When used appropriately, especially in oral form, morphine does not lead to addiction, tolerance, respiratory depression, cognitive impairment, or premature death. In fact, people live longer when their pain is controlled, and they can eat, sleep, and live normal lives (Merriman and others 2002).

In countries where palliative care is fairly well developed and available, the consumption of morphine per capita averages over 20 milligrams, but in most developing countries it is negligible, and most of the needs for pain relief are unmet (Joranson, Rajagopal, and Gilson 2002). The World Bank recognized the importance of alleviating pain, which it included in its package of “essential clinical services” (World Bank 1993). As the population ages, the ability of the health care system to provide palliative care must grow along with it.

The trend toward more sedentary lifestyles and toward consumption of diets with higher fat and sugar content is leading to a steep increase in the burden of diabetes, with 150 percent increases in prevalence predicted for many countries by 2030; the absolute numbers will grow from 171 million in 2000 to about 366 million in 2030. The greatest increases in diabetes prevalence are predicted for the Middle East, Sub-Saharan Africa, and India (Wild and others 2004). Most of these

Table 72.4 New Vaccines Needed

Priority vaccines	Close to licensure vaccines	Vaccines for neglected diseases	Other vaccines of importance	Vaccines for new threats
HIV, TB, malaria	Meningococcus, streptococcus pneumoniae, rotavirus	Shigella, dengue, Japanese encephalitis, leishmaniasis, schistosomiasis, cholera	Human papilloma virus, respiratory syncytial virus, herpes simplex, enterotoxigenic, <i>Escherichia coli</i>	SARS, anthrax, smallpox, pandemic influenza

SARS = Severe acute respiratory syndrome.

new cases will be type 2 and, thus, most will not be insulin dependent, but they will require oral diabetic medications. For those who do require insulin, given the current state of technology, the main barrier (other than cost) is the need for storage of the insulin in a cold or cool location and for sterile injection equipment. In either case, to meet the predicted rise in cases and to treat them with current drugs, a major expansion of drug supply for diabetes must be anticipated. Many diabetics currently do not receive adequate treatment. The pressure to provide adequate treatment will increase as the population ages and begins to demand treatment of its chronic afflictions—and in that case the increase in demand for diabetes medications would potentially be much more than 150 percent.

Another important finding of the global burden-of-disease exercise was the high number of DALYs lost to mental illness, depression in particular. In 2020, unipolar depression is projected to be the leading cause of morbidity and disability among females worldwide and in developing countries. Whereas in the industrial countries a pharmacological solution is often used, this approach may not be feasible in the developing world, at least not at present price levels. Recent research in the developing world has shown good results with weekly group interpersonal therapy, without the use of antidepressants. Trained laypersons ran the therapy sessions, not psychiatrists or medical personnel (Bolton and others 2003).

VACCINE RESEARCH PRIORITIES

In the past two decades new advances in biotechnology have resulted in the licensure of new vaccines, such as Hib, acellular pertussis, HepB, and attenuated varicella. Research institutions in the public sector have generated most of the basic scientific breakthroughs, whereas the large pharmaceutical companies have borne the cost for clinical development. Because such development requires heavy investments that need to be recouped from profits, new vaccines are expensive and therefore out of reach for poor populations.

Of all the vaccines currently under development, the three most needed today are vaccines to prevent the three big diseases—AIDS, TB, and malaria—which jointly account for

more than 5 million deaths per year, or about 50 percent of all infectious disease deaths (see table 72.4). The total investment in vaccine against these diseases is not impressive, and it will probably take at least 5 to 10 years before a vaccine against any of them is available.

GAVI has selected three vaccines for accelerated development: meningococcal meningitis, rotavirus, and pneumococcal vaccines. They have been selected because they are considered close to licensure, or “near term.” Other important diseases are considered neglected in terms of vaccine development, among them shigella dysentery and dengue fever.

New diseases emerge and old ones reemerge, influencing priorities in vaccine research. The severe acute respiratory syndrome (SARS) epidemic, the outbreak of avian influenza, and the emergence of bioterrorism threats such as anthrax have led to a new search for vaccines against these infections. The threat of a pandemic of a reassorted influenza virus strain has recently highlighted the need for much greater resources and attention to be devoted to the development and distribution of effective flu vaccines.

New Vaccine Technologies

Alternative routes of administration would improve program safety, avoiding needle transmission of bloodborne pathogens. The ability of nonprofessionals to administer vaccines would also ease vaccine delivery strategies. New administration routes, such as oral, nasal, and transcutaneous routes, are being explored. An interesting project concentrates on the development of a nasal measles vaccine that would greatly enhance the feasibility of eliminating this disease by facilitating the administration during mass campaigns.

The concept of using plant-derived or edible vaccines involves encoding protective antigens from pathogens into transgenic plants. The plants are processed so that they can deliver a uniform dose of vaccines. Human clinical trials have been conducted with, for example, bananas and raw potatoes, which have shown encouraging antibody responses. The potential advantages of this technology could include thermostability, low investment needs, multivalency, and oral administration.

New Immunization Technologies

Priority is given to new delivery technologies that will expand access, improve safety, and cut the cost of immunization programs. They include the following technologies:

- The reuse of disposable syringes and needles is widespread and contributes significantly to the transmission of hepatitis B and C and HIV. The autodisable syringe prevents reuse, and disposal in safety boxes reduces the risk to health staff and the general public from contaminated syringes and needles.
- Four different technologies are being explored to minimize the risk of infection from accidental exposure to sharps: corrosive disinfectants, thermoprocessing, needle destruction, and plastic melting. However, none of these options will soon be put into use in the field.
- Although the adoption of the multidose vial policy will contribute to the reduction of wastage, the ultimate aim is to provide all immunizations as monodose preparations. Injection devices prefilled with a monodose increase quality and safety at the point of use. Uniject is one such device that has been tested with HepB and tetanus toxoid. Village health workers or traditional birth attendants can use such devices. Currently, the cost of the device and the need for additional cold storage space when multidose presentation is exchanged for monodose pose obstacles to implementation.
- Needle-free injection devices deliver vaccine at high velocity into the skin without penetration of a needle, reducing the risk of transmission of bloodborne pathogens. Technologies are being developed for both mono- and multidose presentations. Available multidose injectors have not been found safe, and new models are under development. However, regulatory obstacles and high cost have rendered the monodose injector models that are currently available infeasible for large-scale programs.
- Vaccine distribution and storage without a cold chain would considerably simplify the delivery system, reduce cost, and allow for an integrated supplies mechanism. Development of vaccines that do not need a cold chain should be the highest priority for technology research. Sugar glass drying is one such technology that has shown great promise. It can be used to produce multivalent vaccines that are completely heat stable except under extreme climatic conditions. The high cost of regulation and licensing and the uncertainty about market prospects in industrial countries have so far impeded the development and use of this technology.

Obstacles to Vaccine Research

A host of obstacles confront vaccine research, the most important being the low level of investment for vaccine development when there are limited market prospects in the industrial

world. Only a limited number of research centers have the capacity and experience required to conduct phase 2 and especially phase 3 trials of new vaccines, and they are mainly located in industrial countries. The capacity to conduct phase 3 trials in developing countries needs to be strengthened; the current situation impedes further development of vaccines needed in those countries.

Pilot lot production of vaccines is required for all phases of clinical trials. The global capacity to produce pilot lots is, however, inadequate to meet demand. Close public-private partnerships are necessary to ensure that the production capacity is available.

Manufacturers need markets to provide some assurance that the development cost for new products can be recouped. Such incentives require realistic forecasts of demands. Various mechanisms have recently been put in place to try to guarantee future markets, most notably the Vaccine Fund.

Last, disease burden data are needed for both selections of vaccines for national programs and for estimations of vaccine requirements, including market projections. However, such data are lacking in many countries and regions. Existing data are especially weak for respiratory disease of both bacterial and viral origin.

PRIORITIES FOR PHARMACEUTICAL RESEARCH

The WHO Priority Medicines Project, a recent exercise that used evidence-based methods to outline the priorities for public funding of pharmaceutical research, has recently been published (WHO 2004b). It incorporated data from the burden-of-disease rankings and from the Cochrane Database of Systematic Reviews of data on clinical efficacy. It also incorporated the use of criteria of social justice, social solidarity, and equity, so that neglected diseases and the needs of special patient groups (the elderly, women, and children) were also taken into account. The research identified 20 major diseases that account for 60 percent of the total DALY burden both in Europe and in the rest of the world—diseases that are common to both groups included unipolar depression, ischemic heart disease, cerebrovascular disease, chronic obstructive pulmonary disease, and digestive diseases (excluding diarrheal diseases).

The authors also mention the important contributions of various cancers, lower respiratory tract infections, and diabetes to the burden of disease, which is common to both developed European countries and to the developing world (WHO 2004b). Smoking is clearly a major contributing risk factor, and the authors caution that expenditure on pharmaceuticals for smoking cessation must not divert resources from other efforts to reduce smoking. The priority areas identified by this exercise are presented in table 72.5.

Table 72.5 Preliminary List of 16 Priority Areas for Pharmaceutical Research

Rank	Condition
1	Infections caused by antibacterial resistance
2	Pandemic influenza
3	Cardiovascular disease
4	Diabetes (types 1 and 2)
5	Cancer
6	Acute stroke
7	HIV/AIDS
8	Tuberculosis
9	Neglected diseases ^a
10	Malaria
11	Alzheimer's disease
12	Osteoarthritis
13	Chronic obstructive pulmonary disease
14	Alcohol use disorders: alcoholic liver disease and alcohol dependency
15	Depression in the elderly and adolescents
16	Postpartum hemorrhage

Source: WHO 2004b.

a. Neglected diseases include, but are not limited to, trypanosomiasis (sleeping sickness), Buruli ulcer, leishmaniasis, and Chagas disease.

CONCLUSION

Ensuring that needed essential medicines and vaccines are available is critical for the success of any disease control program. A great deal is known about what works and what does not work. Careful selection, procurement from prequalified suppliers, proper storage and distribution using secure reliable channels, and assurance of rational use and correct dispensing are all critical components of any drug and vaccine supply system. Ensuring that adequate funds are available to pay for the procurement, distribution, and quality assurance of all medicines and vaccines is equally critical. Depending on the circumstances, either the public or the private sector or a combination of both can efficiently deliver quality-assured medicines and vaccines. The experience of a number of countries and programs has demonstrated that essential medicines and vaccines can be reliably delivered to poor people using the approaches described in this chapter.

Strategic Management of Clinical Services

Alexander S. Preker, Martin McKee, Andrew Mitchell,
and Suwit Wilbulpolprasert

Financial resources alone are insufficient for individuals to benefit from the opportunities presented by modern health care systems. Some countries have achieved much better levels of health than would be expected given their financial resources (Mehotra 2000); many examples of poor-quality care in countries at all levels of development reflect not only scarce resources but also inadequate management of what resources are available (see chapter 70).

Many inputs must come together at the appropriate time and in the appropriate place to achieve maximum health gain. These inputs include human resources (in particular, trained staff); physical resources (such as pharmaceuticals and technology); and intellectual resources (in the form of evidence and the ability to apply it appropriately). This congruence requires that the production, distribution, and combination of these resources be actively managed and that the relations among the various elements that contribute to health care be optimized.

The challenge of bringing these diverse inputs together is becoming increasingly complex. Until the 1950s, providing basic care at low cost to large populations was relatively straightforward, given political will and sufficient resources. Relatively few effective drugs were available; even fewer drugs were effective in managing chronic disease. The available technology was limited to simple x-ray machines and chemistry tests that required few skills to administer. Consequently, scaling up the delivery of basic health care was relatively easy.

The situation in the former Soviet Union illustrates this state of affairs. Beginning in the 1930s, the Soviet Union implemented a vast system to provide basic health care where almost none had existed. The very simple care available was sufficient to produce significant reductions in maternal and childhood

mortality rates. What such a system could not do, however, was respond effectively to the possibilities opened up by the explosion in diagnostic and therapeutic knowledge that began in the mid 1960s with the availability of new and easily tolerated treatments for many common chronic disorders. As individuals became able to survive with their chronic diseases, they aged and acquired other conditions, many of which could now be treated effectively, constantly increasing the complexity of the health care required. The inability to manage this increased complexity resulted in persistently high mortality rates from treatable conditions at a time when corresponding mortality rates were falling in Western countries (Andreev and others 2003).

This situation has certain parallels with that faced by many low- and middle-income countries today. Through a variety of mechanisms, a political commitment to the health sector is manifest in the increased availability of funding, such as through the Global Fund for AIDS, Tuberculosis, and Malaria (<http://www.theglobalfund.org/en/>). Much discussion has focused on one of the elements of health care that these initiatives will support: the supply of drugs that target the microbiological agents responsible for these three diseases. Yet improved outcomes will be achieved only if such agents are linked to the many other elements required to diagnose and treat these patients. Most obviously, the supply of drugs such as antiretroviral agents must be coupled with those used to treat the opportunistic infections that exacerbate AIDS. Care for the acute episode of illness should be linked to general support for patients and family members as well as to activities designed to prevent further spread of the disease. Furthermore, as drugs to combat infections become more widely available, it is

probable—unless highly developed prevention systems have been put in place—that drug resistance will increase; this outcome has been evidenced with tuberculosis in those parts of the world where treatment has been available but poorly managed, such as the former Soviet Union and Peru (Farmer, Reichman, and Iseman 1999). The resulting resistant infections are much more complicated and expensive to treat. The rise in antibiotic resistance provides one of the most graphic examples of the consequence of the failure to manage the delivery of health care (see chapter 55).

Yet even where the financial resources and the political will exist to deliver effective health care, many health care systems contain numerous constraints to success (Hanson and others 2003):

- At the first level, that of the community or household, there may be inadequate demand for services or physical, financial, or social obstacles to their use. This situation calls for action to increase access and affordability, including health care financing reforms (see chapter 12). It also requires policies to ensure that services are culturally appropriate, that they address the particular needs of underserved populations, and that they provide dignity and privacy. Moreover, services should be physically accessible, both in terms of distance from population settlements and in terms of their construction—that is, facilities must be responsive to the needs of persons with disabilities.
- At the second level, the delivery of health care, there may be a shortage of resources, such as staff members, drugs, and equipment. However, to bring these resources together would require actions at the third level that anticipate future needs, as well as actions that ensure that the needed drugs and equipment are purchased at the best price possible, are subject to appropriate quality controls, and are distributed where needed.
- The third level includes health sector policy and strategic management. Effective action may be constrained by weak systems of management that are unable to take into account the changing health needs of the population and the changing demands on health care providers. Management weaknesses include inadequate pharmaceutical regulation and supply, ineffective training of health professionals, inability to engage with civil society, and a failure to put in place incentive systems to facilitate effective health care. Constraints at this level may originate outside the country, as governments are faced with demands by donors to follow paths that either undermine their policy goals or remove the flexibility needed to achieve them. Constraints acting at this level also arise when policies in other areas affect the health sector, such as when a weak, overly bureaucratic, and unreformed civil service system implements obsolete regulations; when there are inadequacies in infrastructure, such

as poor communication and transportation links; or when there are weaknesses in the banking system.

- The fourth level refers to the environmental and contextual constraints on effective policies. The delivery of effective care may be affected by the physical environment, including climate and population dispersion. However, an equally important constraint is weak governance working within unsupportive policy frameworks, which may be compromised further by corruption, weak rule of law, political instability, weak public accountability, and lack of a free press. For example, de Soto (2000) has shown that, in many middle-income countries, it is almost impossible even to create a simple garment repair business because of a failure of legislative reform, in particular a lack of clearly defined property rights. As a result, much of the economic activity in those countries is informal or even marginally illegal, a response that is of particular concern in health care, given the scope for unlicensed and incompetent providers to endanger the public.

This framework underscores the importance of coordinating action at multiple levels. Health services can operate effectively only if policies are in place at the community level to ensure that those in need have access to services, and only if policies are in place at higher levels to ensure that the resources are available to provide those services.

This analysis of different levels demonstrates the importance of taking a systemwide approach to the management of health services. However, because of limited space, this chapter focuses primarily on the third level, that of strategic management. It first examines the nature of management in general and the specificities of management in the health system. It then explores some issues that arise when managing health services in different settings. It concludes with an exploration of some of the strategies used in low- and middle-income countries to optimize the delivery of care, using a framework developed by Oliveira-Cruz, Hanson, and Mills (2003).

WHAT IS MANAGEMENT?

One of the earliest definitions of management was that of French mining engineer Henri Fayol. Writing at the beginning of the 20th century, he stated, “To manage is to forecast and plan, to organise, to command, to coordinate, and to control” (Fayol 1949). Put simply, managing is about assessing probable future scenarios, deciding how best to respond to them, bringing together the resources needed for that response, and deploying them as effectively as possible. Until relatively recently, most management research was concerned with industrial production, for which outputs could be measured relatively easily. Relatively less attention was given to management of

Box 73.1

Specificities of Health Care Organizations

Health care services differ from many other organizations in many ways:

- Defining and measuring outputs is difficult.
 - The work involved is more variable and more complex than in many other organizations.
 - Much of the work is of an emergency nature and cannot easily be deferred.
 - The consequences of error can be severe.
 - Activities by different groups of staff members are highly interdependent, requiring a high level of coordination.
- The work involves a high degree of specialization.
 - Workers are highly professional, with a primary loyalty to the profession rather than to the organization.
 - There is limited scope for effective organizational or managerial control over clinicians, the group most responsible for generating work and expenditure.
 - Dual lines of responsibility often create problems of coordination, accountability, and confusion of roles.

Source: Shortell and Kaluzny 1983.

service industries in general and health care services in particular. As Shortell and Kaluzny (1983) noted, health care services are different from many other organizations. Of course, many of the specificities shown in box 73.1 are differences of degree, with health services sharing many features with other service organizations. Yet important differences exist.

Managing Health Care Services

During the 1970s, health care services in many countries faced growing criticism for their perceived failure to articulate explicit goals or to develop the means to achieve them (Enthoven 1985; Griffiths 1984). This failure was contrasted with the perceived success of the private sector, which was seen as more capable of innovation and more responsive to demand.

These developments gave rise to what has been termed *new public management* (Hood 1991), which is characterized by the following:

- greater role for professional management in the public sector
- closer scrutiny of the work of professionals, involving performance measurement and target setting
- link between resource allocation and measurable outputs
- “unbundling” of previously integrated units, with contracting for previously integrated services
- shift to competition as a key to reducing costs and an emphasis on a private-sector management style
- careful use of resources to drive down the cost of labor and other inputs, where possible.

Recognizing the many reasons for market failure in health care (Arrow 1963), new public management builds on several

concepts that arise from new institutional economics. Included in these is contestability (Baumol, Panzar, and Willig 1982), in which the benefits that competition is thought to bring can arise even when competition is absent, thus ensuring that the barriers to market entry are sufficiently low to allow other providers to emerge. User choice is given priority over most other goals, including equity.

The enthusiasm for new public management was largely ideological, reflecting the contemporary rejection of an expanded role for the state; the extent to which this model was actually able to achieve what was claimed for it remains highly contested (Le Grand and Bartlett 1993; Stewart 1998). In particular, critics drew attention to the high transaction costs involved (Evans 1997) and the lack of evidence that competition can actually bring about the intended improvements in quality of care (Maynard 1998).

One feature of the new public management is its emphasis on general management, with managers possessing skills and expertise that can be applied to any sector. These managerial attributes are considered to be of greater importance than technical or professional knowledge. As a consequence, in some countries, the balance of power has begun to shift away from health professionals and toward general managers. In many places, the initial enthusiasm has given way to disillusionment and subsequently to a more balanced view that, though the precise solution will reflect the particular circumstances of the health care system, what is needed is a partnership between these two groups.

In some countries, this development will mean that managers must assume a greater role in relation to the delivery of clinical care. Such an expanded role will extend from their traditional responsibilities, such as financial controls, hotel services, and payroll management, to active participation in

setting and monitoring standards for care delivery, linked to a responsibility for ensuring that the resources needed for care delivery are available.

In other countries, this role may involve stepping back a little. In an analysis of the British National Health Service, in which the degree of managerial control over the delivery of health care has proceeded further than in many other industrial countries, Harrison and Pollitt (1994) note how clinical decision making is increasingly driven by diagnostic and treatment protocols. Although often developed locally, working arrangements are increasingly specified, with the introduction of timetabled job plans for medical specialists and much greater measurement of outcomes. Yet Harrison and Pollitt argue that the growth of managerial control over professional activity is likely to be constrained by the increasing involvement of professionals in management, even if they do not fully adopt the managerial agenda. A further constraint is the persisting ability of professionals, because of their specialized knowledge, to resist managerial control and the related unwillingness of lay managers to extend their control into certain areas in which they do not feel competent.

Managing for Improved Quality of Care

An increasing volume of research in industrial countries has focused specifically on managerial and organizational responses to evidence that health systems often deliver suboptimal care (Institute of Medicine 2001). Quality of care is addressed in more detail in chapter 70. However, some of the key messages from this research are relevant here.

One message is that change must take place at all levels of the system. In this context, Ferlie and Shortell (2001) identify four such levels: the individual, the group or team, the organization, and the larger system or environment. They note the growing evidence that strategies that focus on individuals alone are unlikely to be successful, whereas those that are embedded within broader organizational change are more likely to be effective (Davis and others 1995). A second key message is the importance of teamwork, with evidence that well-functioning, multiprofessional teams provide better quality care (Aiken, Sochalski, and Lake 1997). However, change may be inhibited by barriers at the level of the organization, including lack of a consistent focus on quality, inadequate information, lack of physician involvement, and inadequate managerial support (Shortell, Bennett, and Byck 1998).

MANAGING CLINICAL SERVICES IN DIFFERENT SETTINGS

Clinical services are provided in a variety of settings, from the patient's home to ambulatory care facilities and hospitals providing inpatient care. They include those services that

involve direct contact between a patient and a health care professional, as well as indirect contact, such as when a pathologist provides a diagnosis on a biopsy or blood sample. Reflecting the focus of much existing research, this section is structured in terms of different settings of care: ambulatory care, hospitals, and community care. Unfortunately, rather less research transcends these often artificial and arbitrary divisions to look at the more important issue of the patient's journey through the health care system, given that one of the greatest managerial challenges facing those delivering clinical services is how to ensure that the journey is efficiently navigated (McKee and Nolte 2004). Furthermore, available research that focuses on health facilities is often difficult to generalize because of the different meanings attributed to common terms such as *hospital*, *health center*, or more prosaically, *hospital bed*. For example, a major teaching hospital in a capital city, such as the Kenyatta National Hospital in Nairobi (<http://www.kenyattanationalhospital.org/services.html>), which offers invasive cardiology, renal transplants, and radiotherapy, is very different from a rural hospital with perhaps 100 beds and a single operating theater that provides only the most basic surgical and obstetric care.

Hospitals

Although hospitals are rarely the first places of contact between patients and health systems, and although hospitals do not provide the greatest share of health care, it is appropriate to begin with them because they often account for the largest share of public health sector expenditure (OECD 2003). They are also particularly difficult to manage for several reasons:

- One reason is the diversity of tasks that a hospital must undertake (Healy and McKee 2002b). Many hospitals fulfill roles that go beyond the delivery of patient care to provide training and research, support to community-based facilities, and even local employment or civic identity symbols.
- A second reason is the blurring of boundaries between hospitals and the rest of the health care system, which has occurred as a result of the emergence of many innovative models of care that cross the boundary between secondary and either primary or social care. A related issue is the shift taking place in many countries to managing patients through a complex combination of short inpatient stays and visits as an outpatient to specialist clinics and diagnostic facilities (McKee and Healy 2001). This approach is vastly more complicated to manage than the traditional model in which patients were admitted to wards from which they were taken to undergo investigations and treatment at a time convenient for the specialist concerned, a process managed by senior nurses. The new model requires new health worker roles, which might be termed *case*

managers. These case managers help patients to navigate the system.

- A third reason is the contrast between the rapidly changing demands on hospitals and the structural rigidities of hospitals themselves (McKee and Healy 2000). The original justification for creating hospitals as institutions was the need to concentrate equipment such as operating theaters, x-ray machines, and laboratories, and expertise such as medical specialists. Yet changes in the nature of health care are raising questions about how hospitals of the future should be configured. Many laboratory functions are being replaced by testing kits that can be used at the bedside, diagnostic equipment such as ultrasound scanners is being used in primary care, and a new generation of primary care workers are acquiring greatly augmented skills. In this rapidly changing environment, managers may be faced with aging hospital buildings that may lack sufficient electrical sockets for the greatly increased amount of equipment now available, or managers may have staff members with deeply ingrained ways of working who pose a particularly acute managerial problem.

These issues can be seen in the Kenyatta National Hospital in Nairobi, where a new managerial approach was developed but faced problems because of an unclear understanding of the kind of services to be provided, weak managerial capacity, and a lack of focus in targeting services (Collins and others 1999). In Zambia, financial management and accountability improved when the hiring of hospital staff was delinked from the national civil service, yet the process has been derailed on a wider scale because of trade unions' resistance to the changes (Hanson and others 2002).

Ambulatory Care

Ambulatory care, delivered on an outpatient basis, is the commonest form of contact between patients and health care providers. Although it often receives relatively little attention from policy makers compared with the more resource-intensive inpatient hospital care, ambulatory care contributes substantially to health care system performance (Berman 2000). Good management of ambulatory services is essential because these services are often the entry and exit points for consumers; however, these services can be difficult to manage effectively (Waghorn and McKee 2000).

Effective coordination of ambulatory and inpatient services is needed to ensure that patients are cared for in the most appropriate settings, thereby reducing inefficiencies such as the overuse of hospitals for nonemergency care. Such coordination often involves developing shared protocols for referral and management. In Benin and Guinea, for example, diagnostic and treatment decision trees were developed collaboratively

with the local staff, leading to more efficient use of resources (Levy-Bruhl and others 1997). In Zambia and Tanzania, strengthening of management capacities in primary care facilities through a team-based approach to decision making that linked planning to budgeted action plans led to improved client perceptions of facilities and to a marked increase in utilization (Few and Harpham 2003). However, the challenges of management in the ambulatory care sector are great in many countries; this sector is often highly fragmented, with extensive and largely unregulated private provision and few levers to exert pressure for change.

Community and Social Care

A particular challenge is how best to link long-term management of medical conditions with community and social care in those cases in which an effective response to health needs spans the interface. Management of chronic physical or mental illness in the elderly, for example, can fall under the responsibility of home care and volunteer agencies, day centers, day hospitals, rehabilitation hospitals, and long-term care institutions, as well as community-based health teams (Bergman, Beland, and Perrault 2002). A systematic review of community-based care for elderly people in industrial countries concluded that such schemes can favorably affect rates of institutionalization and costs. However, comprehensive approaches involving program restructuring are often necessary, and cost-effectiveness depends on the characteristics of the health and social care systems. The review's authors identified as a critical challenge the expansion of those programs considered to be successful (Johri, Beland, and Bergman 2003).

Low-income countries face particular obstacles because they often lack effective alternatives to hospital care. As a result, patients are frequently cared for by their families but with little support, or they are consigned to large, poorly equipped, and poorly staffed institutions. This situation has stimulated the development of models of "community care," in which health care providers work with communities to deliver services. In the area of mental health, for example, the World Health Organization (WHO) has developed models of care that cover a range of care settings, including community centers and outreach services and residential homes, backed up by access to hospital outpatient and emergency care (WHO 2001). Similarly, the complexities of caring for people with disabilities in low-income countries have led to internationally developed guidelines that advocate a shared role for health care providers and local communities (Helander 2000). Accordingly, effective coordination of those services clearly depends in large part on effective management. Shifting from hospital-focused care to community care introduces many managerial challenges. One element of an effective response should be to heighten the autonomy of patients in managing their diseases, but this

response requires attitudinal changes among providers, who must commit to a real shift of power to patients, supported by effective information systems and safeguards for vulnerable patients (Litwin and Lightman 1996).

Health care systems are generally poor at addressing long-term illnesses, especially when those illnesses require integrated care spanning primary, secondary, and community providers (McKee and Nolte 2004; WHO 2001). The often low status accorded to these conditions in the hierarchy of priorities, coupled with fragmentation between health and social sectors (WHO 2002), will require greater commitment to managerial reforms that can improve the delivery of appropriate services.

THE SPECIFICS: WHAT WORKS?

This section turns to those policies that are designed to enhance the resources available to deliver health care and to combine them in ways that optimize the potential benefits. It looks, in turn, at the different elements required to deliver effective care: human resources, physical resources, intellectual resources, and the organizational or social resources that bind them together. The section begins with the most important resources for health care systems: the people who provide care.

Developing Human Resources

A key element in the delivery of effective health care is how to provide staff members with the appropriate combination of skills to do their jobs effectively.

Increasing Skills. In their review undertaken to inform the Commission on Macroeconomics and Health, Oliveira-Cruz, Hanson, and Mills (2003) identified 13 studies that assessed the effects of training to enhance skills. Though the results were

mixed, training programs were overall more likely to have positive rather than negative effects. Several studies focused on communication and counseling skills, which often lead to improved client satisfaction. A study from Zambia showed that training must be linked to other resources; although training was associated with improved transmission of information, there was no decline in the number of complaints from clients who remained unhappy about long waits and short contact time (Faxelid and others 1997).

Changing Skill Mix. The division of tasks among different health care workers reflects many considerations, but evidence about who would be best at doing these tasks is rarely considered. There may be regulations restricting tasks to one professional group, such as the right to prescribe, or there may be cultural norms, which while unwritten have just as great an effect. Underlying these factors is a set of issues that includes a difference in the power of different professions, itself often a reflection of gender relationships in society, with a predominantly male medical profession controlling a predominantly female nursing profession. However, increasing evidence suggests that traditional demarcations do not support the optimal ways to provide care, and there is considerable scope for changing the mix of skills involved in delivering many aspects of health care.

This topic has recently been reviewed systematically by Sibbald, Shen, and McBride (2004), who have developed a taxonomy of the types of change in skill mixes that are possible (table 73.1). Their review shows that many tasks undertaken by one professional group can yield comparable and often better results when performed by another group. In particular, they show how nurse-led clinics often achieve better outcomes than traditional doctor-led service (Connor, Wright, and Fegan 2002; Stromberg and others 2003; Vrijhoef, Diederiks, and Spreeuwenberg 2000; Vrijhoef and others 2001, 2003).

Table 73.1 A Taxonomy of Changes in Skill Mix in Health Care

<i>Changing roles</i>	
Enhancement	Increasing the depth of a job by extending the role or skills of a particular group of workers
Substitution	Expanding the breadth of a job, in particular by working across professional divides or exchanging one type of worker for another
Delegation	Moving a task down a traditional unidisciplinary ladder
Innovation	Creating new jobs by introducing a new type of worker
<i>Changing the interface between services</i>	
Transfer	Moving the provision of a service from one health care setting to another (for example, substituting community for hospital care)
Relocation	Shifting the venue from which a service is provided from one health care sector to another without changing the people who provide it (for example, running a hospital clinic in a primary care facility)
Liaison	Using specialists in one health care sector to educate and support staff members working in another (for example, hospital outreach facilitators in primary care)

Source: Sibbald, Shen, and McBride 2004.

Although Sibbald, Shen, and McBride focus their review on experience in industrial countries, by challenging many deeply held beliefs they indicate what could be done in other settings around the world, after taking into account local circumstances such as the skills and expertise of those involved, as well as any salient regulatory or training issues.

Strengthening Management

In their review of constraints to health service delivery, Oliveira-Cruz, Hanson, and Mills (2003) identified 10 studies that evaluated the effect of management strengthening. The activities in those studies included the following:

- workshops for identifying and prioritizing managerial programs
- introduction of regular planning and evaluation cycles
- quality assurance methods
- establishment of routine communication systems
- training activities.

They concluded that the results were generally positive, with more rational use of funds; greater availability of funds as a consequence of better planning; improved coordination and integration of programs; improved methods of working; better staff morale; enhanced data collection, reporting, and use; and increased community participation. WHO has developed an approach to strengthening management that has been successful in a variety of settings (Cassels and Janovsky 1995).

It is important to identify where specific managerial skills are lacking and to explore different ways of obtaining them, whether through training, recruitment, or links with related organizations. For example, improved financial management in district health teams in Ghana was made possible by integrating staff members from local government accounts offices (Kanlisi 1991); a similar initiative was successful in The Gambia (Conn, Jenkins, and Touray 1996). However, a word of caution is required. Although a management strengthening exercise undertaken in Tanzania was successful when implemented at the local level, it failed when scaled up because the same degree of involvement by the originating team was no longer possible (Barnett and Ndeki 1992).

Managing Physical Resources

Managing infrastructure and other capital assets such as hospitals and health centers requires investment planning in both the short term (for example, maintenance) and the long term (for example, new acquisitions). Historically, however, costs associated with capital consumption and maintenance have not been met through operating budgets, resulting in few incentives for public sector health planners to efficiently manage infrastructure or to respond to market demand and consumer

needs (England 2000; Preker, Harding, and Travis 2000). Capital charging—requiring managers to explicitly account for the value of physical assets out of funding allocation or contract revenues—has been developed as a response, successfully heightening public sector management of capital investments in the United Kingdom and New Zealand (Heald and Scott 1996). Capital charging has been proposed as a strategy to stimulate better capital management in developing countries as well. For example, in Malaysia a corporatized hospital has been required to reimburse invested capital through dividends, with the Malaysian government recouping one-third of its original investment within five years (Hussein and Al-Junid 2003). Similarly, the Kenyatta National Hospital in Nairobi was obliged to account for all accruals (for example, property and depreciation) when it was given greater autonomy. Though changes in accounting management have experienced some shortcomings, improvements have been seen in financial transparency, timeliness of reporting, donor satisfaction, and revenue collection (Collins and others 1999).

Within the public sector, changes in line management have facilitated the incorporation of more explicit infrastructure concerns into the planning process. The central authority in Hong Kong (China) has made capital acquisition decisions jointly with hospitals during annual planning processes (Yip and Hsiao 2003). The introduction of business planning to district-level planning in Turkmenistan heightened accountability for maintaining physical infrastructure: use of a global budgeting model (that is, increased autonomy in line management as well as performance monitoring) led to reduced resource allocation to personnel and a greater than fivefold increase in maintenance expenditures (Enzor and Amannyazova 2000). Explicitly managing capital investments in both the short and the long term may facilitate efficient resource allocation.

Although capital charging is a relatively straightforward technical solution, capital investment can be particularly susceptible to political derailment (Anell and Barnum 1998). In the hospital sector, for instance, many transition economy countries have had difficulty downsizing infrastructure because those with decision rights to manage capital (that is, local governments) are different from those who have incentives to do so, such as hospital managers (Jakab and Preker 2003).

Strengthening Drug Procurement, Regulation, and Distribution

Managing pharmaceutical resources is crucial for ensuring access to essential drugs and promoting their rational use (Mossialos, Mrazek, and Walley 2004). WHO defines the goals of rational use of drugs as delivering medications effectively—appropriate to patients' clinical needs and at dose levels and durations appropriate to their individual requirements—and

at an affordable cost (WHO 1985). The public sector plays a key role in providing the framework for rational use of drugs (Quick 1997) through measures ranging from drug regulation to clinical practice guidelines.

National drug policies (NDPs) can be effective in regulating private and public sector provision of essential medicines. The Lao People's Democratic Republic's NDP has been important in improving private pharmacy service quality (Stenson, Tomson, and Syhakhang 1997). In Burkina Faso, an NDP has enhanced the performance of rural pharmacies (Krause and others 1998). At the local and facility levels, increasing accountability can also lead to a more rational use of drugs. A simulation exercise in Tunisia that required physicians to relate pharmaceutical budgeting to involvement in the procurement process improved prescribing practices by containing costs while increasing the use of essential drugs (Garraoui, Le Feuvre, and Ledoux 1999). Enhanced management information systems, with corresponding supervision, monitoring, and top-level support, have improved contraceptive management in several countries (Kinzett and Bates 2000). The introduction of standard treatment guidelines and formularies has reduced overprescribing in several countries, and educational materials for consumers in Cameroon increased compliance with antibiotic regimens (Nabiswa, Makokha, and Godfrey 1993).

A comprehensive review of interventions used in Sub-Saharan Africa, where health systems are plagued by shortages of supplies, high costs, large-scale use of proprietary drugs, waste, and theft, provided considerable evidence to suggest what works in those countries (Foster 1991). Successful interventions included the following:

- selection and precise quantification of drug needs—in particular, the creation of essential drug lists
- improved procurement, with greater use of generics, competitive bidding, and international procurement agencies
- improved storage and distribution, with better storage conditions, inventory controls, security systems, and use of prepacked kits.

At the same time, several factors constrain better management of pharmaceuticals. Considerable resources are needed to adequately monitor NDPs, and implementation can be difficult (Petrova 2002). Furthermore, much of the pharmaceutical use is outside the control of the public sector: two-thirds or more of health problems are self-medicated. Though the public sector may strive to inform consumers, patients' nonadherence remains high (Le Grand, Hogerzeil, and Haaijer-Ruskamp 1999). As in management of other inputs, political considerations can thwart managerial responses. The Republic of Korea decided to divide its prescribing and dispensing functions precisely to address high levels of pharmaceutical overuse and misuse, but it subsequently faced strikes and stiff opposition

from those same stakeholders (Kwon 2003). Management of pharmaceuticals thus presents a complicated challenge, requiring significant investment and flexible responses.

Using Intellectual Resources

The process of generating, disseminating, and using knowledge is frequently imperfect. Pang and others (2003) have argued that a well-functioning health care system must have in place mechanisms that allow it to access and use research and the products of research. They highlight the weaknesses of much of the existing health care research, including fragmentation, overspecialization, and damaging competition among researchers, who are frequently isolated from other researchers and from the policy-making community. Drawing on concepts of the functions of a health system, they identify a series of four roles for a health *research* system:

- *stewardship*, which includes defining and articulating a vision for a national research system, identifying appropriate priorities, and setting and monitoring ethical standards
- *financing*, which includes obtaining research funds and allocating them accountably
- *creating and sustaining resources*, which includes the physical and human capacity to conduct, absorb, and use research
- *producing and using research*, which includes generating valid research outputs; translating research into formats that inform health policy, practices, and public opinion; and promoting the use of research to support innovation.

Such a system must be able to answer the many different questions requiring research, from basic laboratory science, such as new drug development, through health services research, such as comparisons of the cost-effectiveness of different drug regimens, to organizational research, such as the best way of delivering the most cost-effective drug regimen. Although the majority of health systems and services research continues to be undertaken in the industrial countries, a growing volume of research addresses the needs of low- and middle-income countries, such as that by the participants in the Effective Health Care Alliance Programme (EHCAP), an international research network that is undertaking systematic research within the framework of the Cochrane Collaboration (<http://www.liv.ac.uk/lstm/ehcap/introduction.htm>).

Establishing Relationships

The debate about the relative benefits of vertical (in which a single disorder is tackled by a program managed across levels from the Ministry of Health to the health care provider) and horizontal (in which health care for a wide range of disorders is delivered through a system that is integrated at each level)

systems of health care delivery has been examined in detail in a major review of relevant literature by Oliveira-Cruz, Kurowski, and Mills (2003). They note how many activities lie on a continuum between the two extremes, with the Global Polio Eradication Initiative more vertical than the Expanded Programme on Immunization, which in turn is more vertical than the integrated management of childhood illness approach. They identify certain features that are often associated with vertical programs and that promote success: specific objectives, clear work schedules, well-defined techniques, and frequent supervision. They also identify characteristics that are often associated with horizontal programs and that can hamper effectiveness: shortage of essential drugs, lack of adequate staff training, intermittent supervision, and limited backup. However, they note that horizontal programs have considerable potential to deliver effective services if they are adequately funded, staffed, and managed, largely because of their economies of scale and scope.

To some extent, the approach is determined by the nature of the program. Vertical programs are most effective when the technology involved is very sophisticated or when it includes procedures different from the usual tasks and thus requires specialist skills. Vertical programs may be more appropriate when there is a need to rapidly achieve major reductions in the burden of a disease, although this situation does not preclude embedding the management of the program within existing organizations. These programs are often a response to weak management capacity in the existing system, although it is argued that they can perpetuate this problem or even undermine what does exist, diverting the attention of staff members from their usual tasks. Such programs often have a short time horizon, either being absorbed into existing systems or brought to an end. In part, their duration is linked to the source of their funding, which is often from donors who themselves have a short time horizon.

Integrating previously vertical programs into mainstream systems can be successful, as with schistosomiasis programs in Saudi Arabia (Ageel and Amin 1997) and Brazil (Coura Filho and others 1992). However, a systematic review of integration failed to identify consistent benefits, largely because of the very limited extent of the evidence available and the context-specific nature of this process (Briggs, Capdegelle, and Garner 2001). The authors of that review concluded that the question facing policy makers is not whether one approach is invariably better than the other; rather, it is how best to build on the synergies among them to maximize overall benefits. They note, for example, how the many successes of the Malaria Eradication Programme in the 1950s and 1960s were not sustained because active case surveillance was not integrated into routine health services (see also Bradley 1998).

Successful vertical programs are likely to involve community participation, but not to the extent that there is overdependence

and subsequent attrition of volunteers. The programs' developers will have learned lessons from other similar programs, in relation to both organizational and technical issues. Where several vertical programs coexist, the programs' developers should explore how they can share common elements.

Contracting for Services

The setting of contracts by public agencies to purchase health care services is increasingly common in a number of low- and middle-income countries. The theoretical case for contracting out identifies potential advantages from combining public finance with private provision. However, there may also be difficulties, such as ensuring that competition takes place among potential contractors, that competition leads to efficiency, and that contracts and the process of contracting are effectively managed; consequently, these advantages may not always be realized (McPake and Banda 1994).

Unfortunately, the question of whether the advantages outweigh the disadvantages has been the subject of relatively little empirical study in low- and middle-income countries, and what exists is often highly context specific. For example, in Zimbabwe, a comparison of a hospital owned by a colliery, from which services were purchased by the government, and a nearby government hospital found that the colliery hospital offered services of at least comparable quality at prices lower than the unit costs of the government hospital after capital costs were included (McPake and Hongoro 1995). However, failure to establish policies on thresholds for use meant that growth in expenditure on the colliery hospital was not controlled. The authors argue that contracted facilities can achieve powerful bargaining positions if there are no viable competitors and the government does not retain the ability to offer an alternative service. They also identify a need for specific skills to manage contracts at all levels. Where a policy of contracting is a response to crises arising from civil service retrenchment and public expenditure cuts, these skills are unlikely to be developed.

Another study examined the economic arguments for contracting for district hospital care in South Africa, by using private for-profit providers, and in Zimbabwe, by using non-governmental (mission) providers (Mills, Hongoro, and Broomberg 1997). In the South African setting, there were no significant differences in quality among three contractor hospitals and three government-run hospitals, but the contractor hospitals provided care at significantly lower unit costs. However, the overall cost to the government was similar for the two options because of the additional cost of contracting, with the efficiency gains captured almost entirely by the contractor. In Zimbabwe, two district-designated mission hospitals delivered similar quality care at lower cost than did two government hospitals. However, the contract between the government and

the missions was implicit, rather than explicit, and was of long standing. As in the other Zimbabwean example, the authors identified the importance of developing the government's capacity to design and negotiate contracts that allow the government to derive significant efficiency gains from contractual arrangements.

Increasing Provider Autonomy

A review of cross-country experiences with enhanced autonomy of hospitals found improvements in service delivery. The most successful cases—in Hong Kong (China) and Tunisia—applied private sector management techniques and training, with appropriate performance assessment systems for staff. In countries where reforms were considered less successful, managers had been granted greater autonomy without suitable performance-oriented incentives (New Zealand) or vice versa (Indonesia) (Hawkins and Ham 2003). In the Kenyatta National Hospital, greater autonomy led to the introduction of performance appraisal linked to incentives, enabling the dismissal of poor performers and increased benefits and greater responsibilities for good performers. This change was coupled with clarification of clinical management roles. Complementing increased salaries for staff nurses, these changes helped improve the hospital's strategic management, donor accountability, and performance reporting (Collins and others 1999).

Implementing such management strategies in a coherent fashion is not an easy task. Hospital governance in several Eastern European countries, which has been transferred to local governments to improve responsiveness, has included measures such as performance-based payment mechanisms. Performance did not improve as expected because of an “inconsistent incentive environment”; rewards and sanctions were not linked to performance. Important factors in that failure to improve were weak stewardship functions and an absence of effective governance at the regional level, which made it difficult to change the initial configuration of the hospital system. Instead, increased hospital autonomy was used to ensure the survival of the institution rather than to meet the needs of the population. Thus, a continuing excess of capacity, inefficiency, and poor responsiveness to patient expectations remains (Healy and McKee 2002a). A review of experience with programs that increased autonomy in Sub-Saharan Africa also identified only modest success in achieving the stated goals (McPake 1996).

Public or Private Provision?

Although there has been considerable enthusiasm for privatizing state facilities because of the supposed efficiency gains achieved in the private sector, in reality the evidence is

somewhat mixed. Thus, a study of dispensaries run by the government and by nongovernmental organizations in Tanzania found considerable variation in both sectors (Gilson 1995). This finding was consistent with another study in Tanzania of primary care providers in Dar es Salaam. In the latter, although the quality of care offered by private providers was, on average, better, much low-quality care was found in both types of facilities (Kanji and others 1995). Considerable variation in providers of both types, although with overall better quality in the private sector, was also reported in a study in Senegal (Bitran 1995). In summary, there is very little evidence to support the contention that private provision is better than public provision, and what evidence exists indicates considerable variations in both.

Strategic Purchasing

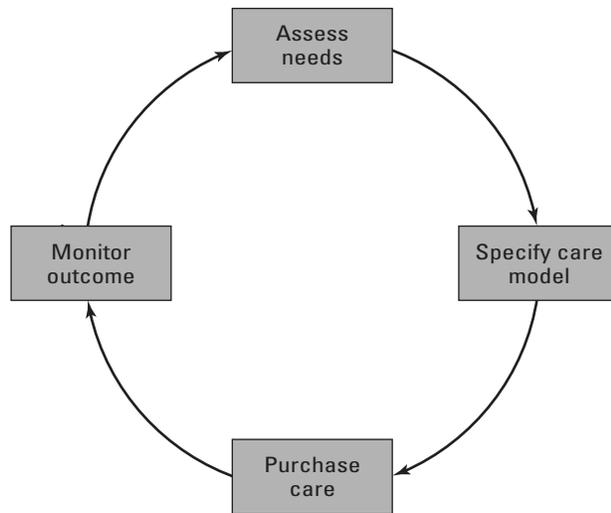

The quest to deliver effective health care is a dynamic process, adapting continually to changing health needs and the opportunities that arise that make it possible to respond in new and better ways. However, health systems that have failed in the past to respond to these changing circumstances face even greater problems. The pace of change is constantly increasing, with factors such as greater population mobility contributing to the reemergence of infectious diseases and with demographic changes and lifestyle changes giving rise to a new burden of chronic diseases.

Health care providers have faced difficulties in responding to this challenge on their own. Although they may possess a great deal of information about the patient sitting in front of them and, on the basis of their training and accumulated experience, about what might be done to help that patient, health care providers confront several important information gaps:

- First, they may know little about those who, despite being in need of health care, do not seek help. These people will often be the most disadvantaged in a society, with few means of making their voices heard.
- Second, they may have inadequate knowledge about newly emerging treatments or more effective ways of providing those treatments, especially if the treatments involve creating multidisciplinary teams with new sets of skills, working in ways outside their experience.
- Third, even if providers introduce changes, they may have inadequate knowledge of whether such changes have been effective.

These knowledge gaps provide the justification for action to improve the delivery of health care at several levels above that of the individual encounter between the patient and the health professional. Strategic purchasing brings together a series of interlinked activities: assessing health needs, using appropriate

Health strategy

Source: McKee and Brand 2005.

Figure 73.1 A Framework for Strategic Purchasing

evidence to develop models of care that meet priority needs, creating the appropriate combination of regulations and incentives to implement those models, and then evaluating the response and reassessing whether the need remains (Figure 73.1). All of these activities should take place within an overall health strategy that takes into account the goals of a health care system, such as those defined by WHO (2000), of increasing health attainment, providing services responsive to the population's needs and expectations, and financing those services equitably.

The development of a strategic purchasing function is complicated, requiring high levels of information resources, both on health needs and on effectiveness. Strategic purchasing involves using technical and political skills, determining the needs of the population, identifying evidence of the effectiveness of different care packages, and setting priorities within limited resources. The last of these components is arguably the most difficult, given the high level of need and the scarcity of resources in many places. This list of components highlights why, in addition to having skills in financial and personnel management, the effective health service manager needs at least a working knowledge of clinical epidemiology and economic evaluation.

Even in industrial countries, the strategic purchasing function is often poorly developed. Given its many interlinked components and the problem of isolating any benefits from wider changes in the health system, this function is very difficult to evaluate. Nonetheless, it is included here as a model from which concepts may be adopted in low- and middle-income settings.

SUMMARY

Health systems worldwide face unprecedented challenges in responding to the increasing complexity of health care. Systems that were capable of providing basic care to populations for whom diseases were either simple or complex but self-limiting confront a fatal struggle to keep up with the increasing opportunities that modern science has provided. The challenge is especially great for health systems in low- and middle-income countries because the global community is no longer willing to sit back while millions of people die from treatable diseases such as malaria and tuberculosis and fail to receive life-prolonging therapies for AIDS. As a consequence, some of the resources, primarily pharmaceuticals, are being made available to those who need them. However, the challenge that health systems face is not simply a lack of money to purchase pharmaceuticals; effective management systems are requisite as well to create the infrastructure to identify those in need, establish appropriate treatments, and ensure provision of these treatments as long as necessary. Emerging challenges must be identified, and the necessary resources to deal with them must be brought together and applied effectively.

Many countries have a clear need to invest in the development of human resources. Although in many cases this investment will require new and wide-ranging human resource strategies involving training, career progression, and retention, there seems to be scope for rapid gains from some shorter forms of training, particularly, in communications skills. Although the evidence for the effectiveness of current models of management strengthening is somewhat mixed, gains may be realized by identifying and filling key gaps, such as those in financial expertise. Changing the skill mix can do much to match available skills to tasks.

Much also can be done to manage the capital stock better or, in most cases, to manage it at all. For example, mechanisms such as capital charging can focus greater management attention on this issue, although this will work only if sufficient capacity can be focused. Important gains can be made from better management of pharmaceuticals, an issue of increasing importance because of the new funds made available for their purchase.

Modern health care is based on the growth of knowledge, and it is as important to manage intellectual resources as it is to manage people and equipment. Doing so means investing in a health research strategy that includes the generation, synthesis, and adoption of knowledge.

Finally, it is necessary to bring these resources together optimally, which raises issues of relationships between different levels of the system, between the public and private sectors, and between vertical and horizontal programs. Unfortunately, despite the large amount of rhetoric on these often highly ideological issues, there is surprisingly little research to inform

policy. More than ever, the issue of context specificity reemerges, leading once more to the answer “it depends.”

The delivery of optimal health care requires well-developed managerial skills to apply methods that are appropriate for the setting in which they are being applied. However, it also requires governments to provide oversight of their health systems and to anticipate changes and give managers the tools with which to respond to those changes.
