Dedication

This book is dedicated to Bill and Melinda Gates, whose vision, leadership, and financing over the past decade have catalyzed global support for transforming the lives of the world's poor through inexpensive but powerful health interventions.

Contents

Foreword by Jaime Sepúlveda	xiii
Preface	xvii
Editors	xix
Advisory Committee to the Editors	xxiii
Contributors	xxv
Disease Control Priorities Project Partners	xxxv
Acknowledgments	xxxvii
Abbreviations and Acronyms	xxxix
Part One Summary and Cross-Cutting Themes	1
<i>Summary</i>	
Chapter 1 Investing in Health	3
Dean T. Jamison	
Chapter 2 Intervention Cost-Effectiveness: Overview of Main Messages	35
Ramanan Laxminarayan, Jeffrey Chow, and Sonbol A. Shahid-Salles	
Chapter 3 Strengthening Health Systems	87
Anne Mills, Fawzia Rasheed, and Stephen Tollman	
<i>Cross-Cutting Themes</i>	
Chapter 4 Priorities for Global Research and Development of Interventions	103
Barry R. Bloom, Catherine M. Michaud, John R. La Montagne, and Lone Simonsen	
Chapter 5 Science and Technology for Disease Control: Past, Present, and Future	119
David Weatherall, Brian Greenwood, Heng Leng Chee, and Prawase Wasi	
Chapter 6 Product Development Priorities	139
Adel Mahmoud, Patricia M. Danzon, John H. Barton, and Roy D. Mugerwa	
Chapter 7 Economic Approaches to Valuing Global Health Research	157
David Meltzer	
Chapter 8 Improving the Health of Populations: Lessons of Experience	165
Carol Ann Medlin, Mushtaque Chowdhury, Dean T. Jamison, and Anthony R. Measham	

Chapter 9	Millennium Development Goals for Health: What Will It Take to Accelerate Progress?	181
	Adam Wagstaff, Mariam Claeson, Robert M. Hecht, Pablo Gottret, and Qiu Fang	
Chapter 10	Gender Differentials in Health	195
	Mayra Buvinić, André Médecin, Elisa Fernández, and Ana Cristina Torres	
Chapter 11	Fiscal Policies for Health Promotion and Disease Prevention	211
	Rachel Nugent and Felicia Knaul	
Chapter 12	Financing Health Systems in the 21st Century	225
	George Schieber, Cristian Baeza, Daniel Kress, and Margaret Maier	
Chapter 13	Recent Trends and Innovations in Development Assistance for Health	243
	Robert M. Hecht and Raj Shah	
Chapter 14	Ethical Issues in Resource Allocation, Research, and New Product Development	259
	Dan W. Brock and Daniel Wikler	
Chapter 15	Cost-Effectiveness Analysis for Priority Setting	271
	Philip Musgrove and Julia Fox-Rushby	
Part Two	Selecting Interventions	287
	<i>Infectious Disease, Reproductive Health, and Undernutrition</i>	
Chapter 16	Tuberculosis	289
	Christopher Dye and Katherine Floyd	
Chapter 17	Sexually Transmitted Infections	311
	Sevgi O. Aral and Mead Over, with Lisa Manhart and King K. Holmes	
Chapter 18	HIV/AIDS Prevention and Treatment	331
	Stefano Bertozzi, Nancy S. Padian, Jeny Wegbreit, Lisa M. DeMaria, Becca Feldman, Helene Gayle, Julian Gold, Robert Grant, and Michael T. Isbell	
Chapter 19	Diarrheal Diseases	371
	Gerald T. Keusch, Olivier Fontaine, Alok Bhargava, Cynthia Boschi-Pinto, Zulfiqar A. Bhutta, Eduardo Gotuzzo, Juan A. Rivera, Jeffrey Chow, Sonbol A. Shahid-Salles, and Ramanan Laxminarayan	
Chapter 20	Vaccine-Preventable Diseases	389
	Logan Brenzel, Lara J. Wolfson, Julia Fox-Rushby, Mark Miller, and Neal A. Halsey	
Chapter 21	Conquering Malaria	413
	Joel G. Breman, Anne Mills, Robert W. Snow, Jo-Ann Mulligan, Christian Lengeler, Kamini Mendis, Brian Sharp, Chantal Morel, Paola Marchesini, Nicholas J. White, Richard W. Steketee, and Ogobara K. Doumbo	
Chapter 22	Tropical Diseases Targeted for Elimination: Chagas Disease, Lymphatic Filariasis, Onchocerciasis, and Leprosy	433
	Jan H. F. Remme, Piet Feenstra, P. R. Lever, André Médecin, Carlos Morel, Mounkaila Noma, K. D. Ramaiah, Frank Richards, A. Seketeli, Gabriel Schmunis, W. H. van Brakel, and Anna Vassall	
Chapter 23	Tropical Diseases Lacking Adequate Control Measures: Dengue, Leishmaniasis, and African Trypanosomiasis	451
	Pierre Cattand, Phillippe Desjeux, M. G. Guzmán, Jean Jannin, A. Kroeger, André Médecin, Philip Musgrove, Mike B. Nathan, Alexandra Shaw, and C. J. Schofield	

Chapter 24	Helminth Infections: Soil-Transmitted Helminth Infections and Schistosomiasis	467
	Peter J. Hotez, Donald A. P. Bundy, Kathleen Beegle, Simon Brooker, Lesley Drake, Nilanathi de Silva, Antonio Montresor, Dirk Engels, Matthew Jukes, Lester Chitsulo, Jeffrey Chow, Ramanan Laxminarayan, Catherine M. Michaud, Jeff Bethony, Rodrigo Correa-Oliveira, Xiao Shu-Hua, Alan Fenwick, and Lorenzo Savioli	
Chapter 25	Acute Respiratory Infections in Children	483
	Eric A. F. Simoes, Thomas Cherian, Jeffrey Chow, Sonbol A. Shahid-Salles, Ramanan Laxminarayan, and T. Jacob John	
Chapter 26	Maternal and Perinatal Conditions	499
	Wendy J. Graham, John Cairns, Sohinee Bhattacharya, Colin H. W. Bullough, Zahidul Quayyum, and Khama Rogo	
Chapter 27	Newborn Survival	531
	Joy E. Lawn, Jelka Zupan, Geneviève Begkoyian, and Rudolf Knippenberg	
Chapter 28	Stunting, Wasting, and Micronutrient Deficiency Disorders	551
	Laura E. Caulfield, Stephanie A. Richard, Juan A. Rivera, Philip Musgrove, and Robert E. Black	
Chapter 29	Health Service Interventions for Cancer Control in Developing Countries	569
	Martin L. Brown, Sue J. Goldie, Gerrit Draisma, Joe Harford, and Joseph Lipscomb	
<i>Noncommunicable Disease and Injury</i>		
Chapter 30	Diabetes: The Pandemic and Potential Solutions	591
	K. M. Venkat Narayan, Ping Zhang, Alka M. Kanaya, Desmond E. Williams, Michael M. Engelgau, Giuseppina Imperatore, and Ambady Ramachandran	
Chapter 31	Mental Disorders	605
	Steven Hyman, Dan Chisholm, Ronald Kessler, Vikram Patel, and Harvey Whiteford	
Chapter 32	Neurological Disorders	627
	Vijay Chandra, Rajesh Pandav, Ramanan Laxminarayan, Caroline Tanner, Bala Manyam, Sadanand Rajkumar, Donald Silberberg, Carol Brayne, Jeffrey Chow, Susan Herman, Fleur Hourihan, Scott Kasner, Luis Morillo, Adesola Ogunniyi, William Theodore, and Zhen-Xin Zhang	
Chapter 33	Cardiovascular Disease	645
	Thomas A. Gaziano, K. Srinath Reddy, Fred Paccaud, Susan Horton, and Vivek Chaturvedi	
Chapter 34	Inherited Disorders of Hemoglobin	663
	David Weatherall, Olu Akinyanju, Suthat Fucharoen, Nancy Olivieri, and Philip Musgrove	
Chapter 35	Respiratory Diseases of Adults	681
	Frank E. Speizer, Susan Horton, Jane Batt, and Arthur S. Slutsky	
Chapter 36	Diseases of the Kidney and the Urinary System	695
	John Dirks, Giuseppe Remuzzi, Susan Horton, Arrigo Schieppati, and S. Adibul Hasan Rizvi	
Chapter 37	Skin Diseases	707
	Roderick Hay, Sandra E. Bendeck, Suephy Chen, Roberto Estrada, Anne Haddix, Tonya McLeod, and Antoine Mahé	
Chapter 38	Oral and Craniofacial Diseases and Disorders	723
	Douglas Bratthall, Poul Erik Petersen, Jayanthi Ramanathan Stjernswärd, and L. Jackson Brown	
Chapter 39	Unintentional Injuries	737
	Robyn Norton, Adnan A. Hyder, David Bishai, and Margie Peden	

Chapter 40	Interpersonal Violence	755
	Mark L. Rosenberg, Alexander Butchart, James Mercy, Vasant Narasimhan, Hugh Waters, and Maureen S. Marshall	
	<i>Risk Factors</i>	
Chapter 41	Water Supply, Sanitation, and Hygiene Promotion	771
	Sandy Cairncross and Vivian Valdmanis	
Chapter 42	Indoor Air Pollution	793
	Nigel Bruce, Eva Rehfuess, Sumi Mehta, Guy Hutton, and Kirk Smith	
Chapter 43	Air and Water Pollution: Burden and Strategies for Control	817
	Tord Kjellström, Madhumita Lodh, Tony McMichael, Geetha Ranmuthugala, Rupendra Shrestha, and Sally Kingsland	
Chapter 44	Prevention of Chronic Disease by Means of Diet and Lifestyle Changes	833
	Walter C. Willett, Jeffrey P. Koplan, Rachel Nugent, Courtenay Dusenbury, Pekka Puska, and Thomas A. Gaziano	
Chapter 45	The Growing Burden of Risk from High Blood Pressure, Cholesterol, and Bodyweight	851
	Anthony Rodgers, Carlene M. M. Lawes, Thomas A. Gaziano, and Theo Vos	
Chapter 46	Tobacco Addiction	869
	Prabhat Jha, Frank J. Chaloupka, James Moore, Vendhan Gajalakshmi, Prakash C. Gupta, Richard Peck, Samira Asma, and Witold Zatonski	
Chapter 47	Alcohol	887
	Jürgen Rehm, Dan Chisholm, Robin Room, and Alan D. Lopez	
Chapter 48	Illicit Opiate Abuse	907
	Wayne Hall, Chris Doran, Louisa Degenhardt, and Donald Shepard	
	<i>Consequences of Disease and Injury</i>	
Chapter 49	Learning and Developmental Disabilities	933
	Maureen S. Durkin, Helen Schneider, Vikram S. Pathania, Karin B. Nelson, Geoffrey C. Solarsh, Nicole Bellows, Richard M. Scheffler, and Karen J. Hofman	
Chapter 50	Loss of Vision and Hearing	953
	Joseph Cook, Kevin D. Frick, Rob Baltussen, Serge Resnikoff, Andrew Smith, Jeffrey Mecaskey, and Peter Kilima	
Chapter 51	Cost-Effectiveness of Interventions for Musculoskeletal Conditions	963
	Luke B. Connelly, Anthony Woolf, and Peter Brooks	
Chapter 52	Pain Control for People with Cancer and AIDS	981
	Kathleen M. Foley, Judith L. Wagner, David E. Joranson, and Hellen Gelband	
	Part Three Strengthening Health Systems	995
	<i>Strengthening Public Health Services</i>	
Chapter 53	Public Health Surveillance: A Tool for Targeting and Monitoring Interventions	997
	Peter Nsubuga, Mark E. White, Stephen B. Thacker, Mark A. Anderson, Stephen B. Blount, Claire V. Broome, Tom M. Chiller, Victoria Espitia, Rubina Imtiaz, Dan Sosin, Donna F. Stroup, Robert V. Tauxe, Maya Vijayaraghavan, and Murray Trostle	

Chapter 54	Information to Improve Decision Making for Health Sally K. Stansfield, Julia Walsh, Ndola Prata, and Timothy Evans	1017
Chapter 55	Drug Resistance Ramanan Laxminarayan, Zulfiqar A. Bhutta, Adriano Duse, Philip Jenkins, Thomas O'Brien, Iruka N. Okeke, Ariel Pablo-Mendez, and Keith P. Klugman	1031
Chapter 56	Community Health and Nutrition Programs John B. Mason, David Sanders, Philip Musgrove, Soekirman, and Rae Galloway	1053
Chapter 57	Contraception Ruth Levine, Ana Langer, Nancy Birdsall, Gaverick Matheny, Merrick Wright, and Angela Bayer	1075
Chapter 58	School-Based Health and Nutrition Programs Donald A. P. Bundy, Sheldon Shaeffer, Matthew Jukes, Kathleen Beegle, Amaya Gillespie, Lesley Drake, Seung-hee Frances Lee, Anna-Maria Hoffman, Jack Jones, Arlene Mitchell, Delia Barcelona, Balla Camara, Chuck Golmar, Lorenzo Savioli, Malick Sembene, Tsutomu Takeuchi, and Cream Wright	1091
Chapter 59	Adolescent Health Programs Elizabeth Lule, James E. Rosen, Susheela Singh, James C. Knowles, and Jere R. Behrman	1109
Chapter 60	Occupational Health Linda Rosenstock, Mark Cullen, and Marilyn Fingerhut	1127
Chapter 61	Natural Disaster Mitigation and Relief Claude de Ville de Goyet, Ricardo Zapata Marti, and Claudio Osorio	1147
Chapter 62	Control and Eradication Mark Miller, Scott Barrett, and D. A. Henderson	1163
<i>Strengthening Personal Health Services</i>		
Chapter 63	Integrated Management of the Sick Child Cesar G. Victora, Taghreed Adam, Jennifer Bryce, and David B. Evans	1177
Chapter 64	General Primary Care Stephen Tollman, Jane Doherty, and Jo-Ann Mulligan	1193
Chapter 65	The District Hospital Mike English, Claudio F. Lanata, Isaac Ngugi, and Peter C. Smith	1211
Chapter 66	Referral Hospitals Martin Hensher, Max Price, and Sarah Adomakoh	1229
Chapter 67	Surgery Haile T. Debas, Richard Gosselin, Colin McCord, and Amardeep Thind	1245
Chapter 68	Emergency Medical Services Olive C. Kobusingye, Adnan A. Hyder, David Bishai, Manjul Joshipura, Eduardo Romero Hicks, and Charles Mock	1261
Chapter 69	Complementary and Alternative Medicine Haile T. Debas, Ramanan Laxminarayan, and Stephen E. Straus	1281
<i>Capacity Strengthening and Management Reform</i>

Foreword

The 1993 publication of the now classic book, *Disease Control Priorities in Developing Countries*, by Oxford University Press and of its companion document, the *World Development Report 1993: Investing in Health*, published by the World Bank that same year, constitute a landmark in the public health literature. For the first time, decision makers and public health practitioners had a comprehensive review of the cost-effectiveness of available interventions to address the most common health problems in the developing world. They were also provided with the useful metric known as disability-adjusted life years to calculate the burden of disease and the cost-effectiveness of interventions more accurately than in the past.

As was the case with the first edition, this second edition of *Disease Control Priorities in Developing Countries* will serve an array of audiences. One primary audience consists of people working in the health sector, ranging from those who are responsible for making evidence-based decisions to those who practice medicine and public health under often suboptimal field conditions. A second audience consists of people working in finance and planning ministries, who will benefit from the solid recommendations for improving the health of populations through sound resource reallocation and cost-effective practices.

PURPOSE

The purpose of this book is to provide information about what works—specifically, the cost-effectiveness of health interventions in a variety of settings. Such information should influence the redesign of programs and the reallocation of resources, thereby helping to achieve the ultimate goal of reducing morbidity and mortality.

FUNDAMENTAL POLICY CONSIDERATIONS

Although economic and budgetary constraints are clearly important considerations, money is not the only limitation. Additional factors fundamental to improving outcomes are the

particular circumstances in each country, as well as the individual institutional capacities to deliver goods and services and to implement policies and processes.

Context-specific strategies and responses are essential, because application of the Disease Control Priorities Project's findings will vary according to each country's circumstances: one size does not fit all. Understanding that most health interventions require a minimum level of institutional capacity to deliver goods and services is equally important, and such capacity may have to be built up before money or physical inputs can yield any benefits. Accordingly, goals and priorities should be established and tailored to each country's context.

TRANSITION IN HEALTH

Every developing region is facing a transition in its epidemiological profile from an environment with high fertility rates and high mortality from preventable causes to one in which a combination of lower fertility rates and changing lifestyles has led to aging populations and epidemics of tobacco addiction, obesity, cardiovascular disease, cancers, diabetes, and other chronic ailments. The 20th century will be remembered for, among other things, witnessing the largest universal increase in life expectancy in history. While life expectancy is highest in the richest countries, the upward trend is apparent in almost every society. Moreover, in the past 50 years, variations in this health indicator across and within countries have decreased. This convergence of improved life expectancy and reduced variations, which has occurred even in the presence of widening income gaps in many regions, can be explained solely by the impact of knowledge expansion and direct public health interventions.

The increase in life expectancy worldwide will, however, soon reach a plateau, and a retraction has occurred in many countries. HIV/AIDS and civil unrest in Africa, vaccine-preventable diseases and alcoholism in Eastern Europe, and obesity in the United States have reduced—or will soon do so—the years of life their populations can expect.

SCALING UP EFFECTIVE INTERVENTIONS

The late Jim Grant, former executive director of the United Nations Children's Fund, was one of the first leaders with a vision for setting specific health goals and priorities within a time frame and on a global scale. He recognized the need to raise awareness of the dramatic disparities in children's health and to mobilize political will accordingly. His missionary zeal for universal child immunization and for organizing the first summit of world leaders for children's health and rights in 1990 permitted the scaling up of interventions of proven efficacy. The Millennium Development Goals are a natural consequence of that vision and an extremely useful instrument for maintaining both focus and social pressure. Achieving these ambitious goals will require not only the universal implementation of effective interventions that are currently available, but also the development of new interventions.

NEED FOR ONGOING RESEARCH

Today, most vaccines, medical devices, diagnostic tools, and drugs have been subjected to careful investigation in the laboratory, at the bedside, and in the field. However, not enough investment has gone into research to increase well-being and development globally. We need more epidemiological and health systems research to improve the efficiency of available interventions, technological research to reduce their costs, and biomedical research to develop new tools for dealing with as yet unsolved and emerging health problems.

OPPORTUNITIES AND CHALLENGES OF GLOBALIZATION

One of the greatest opportunities and challenges for international public health is globalization. We live in an era when the explosion of trade, travel, and communications is spreading new cultural influences and lifestyles faster than ever before, and the division between domestic and international health problems is becoming increasingly obsolete. At the same time, globalization also permits the spread of risks, pathogens, and other threats. The ever-increasing movement of people everywhere increases the potential for epidemics. Travelers, refugees, and displaced people are more vulnerable to infectious diseases, and their movement contributes to spreading pathogens into new areas. Overall, however, the positive consequences outweigh the negative ones, and cautious optimism about this irreversible trend is justified. Certainly, one of the most valuable contributions of globalization is the rapid accrual and spread of knowledge about useful tools for controlling disease and ways to implement those tools on a large scale.

In recent years, the huge advances in information technology have greatly boosted the globalization of knowledge.

Ideally, this should become a tide that lifts all boats to yield global benefits. The challenge is to harness the information technology revolution to foster the growth of economies. One step in the right direction is the open access movement, which promotes and permits free and immediate access to research results and other components of knowledge transfer.

SPENDING MORE AND SPENDING BETTER

It is indeed a paradox to observe that even though the money spent on health worldwide has reached 10 percent of overall global income, that amount is both insufficient and poorly allocated. The World Health Organization's Commission on Macroeconomics and Health and several other global initiatives make a persuasive plea for a larger investment in health. At the same time, this book is dedicated to making the case for better spending—that is, deriving more health benefits from every dollar spent. The aim should be to reduce inequalities in health investment between and within countries: a 100-fold difference between the rich and the poor in money spent on health services still persists in many places. Despite a lack of clarity about what constitutes the optimum balance of health spending, a larger share should go to prevention. This book looks at several prevention options and clinical interventions that are not being fully implemented.

SELECTING INTERVENTIONS

This book persuasively makes the case that both clinical and public health interventions depend on the capacity of a given country's health system to deliver, noting that some interventions are more demanding than others in terms of infrastructure and human resources. Therefore, both the costs and the likelihood of success of the more complex interventions are a function of the health capacity in place. In addition, decisions about which interventions should be given priority will depend on assessments of the local burden of disease, local health infrastructure, and other social factors as well as on cost-effectiveness analyses. The following chapters identify the health system capacity needed for scaling up a given intervention. Even middle-income countries with relatively better health infrastructure often pursue sophisticated approaches to medical care that result in fewer health gains per amount of money invested. Every country, regardless of level of development, could benefit from the recommendations presented here.

DIAGONAL APPROACH

The medical literature has long debated which approach to delivering health interventions is more effective: vertical programs or horizontal programs. *Vertical programs* refer to

focused, proactive, disease-specific interventions on a massive scale, whereas *horizontal programs* refer to more integrated, demand-driven, resource-sharing health services. This is a false dilemma, because both need to coexist in what could be called a *diagonal approach*—that is, the proactive, supply-driven provision of a set of highly cost-effective interventions on a large scale that bridges health clinics and homes. This approach often starts vertically (polio vaccination, for instance) but moves toward an increasing number of interventions (for example, oral rehydration, other vaccines, residual spraying and bednets for malaria control, micronutrient supplementation, and supervised tuberculosis treatment), making full use of field health workers and existing infrastructure. This could well be the equivalent of a public health polypill.

MULTIDISCIPLINARY ORIENTATION

What makes this book unique, in addition to its comprehensive scope, is its truly multidisciplinary approach to disease control, which merges the best of the medical and economic sciences. Every recommendation has been carefully researched and documented. Evidence-based approaches must be the foundation for allocating scarce resources. The poor cannot afford

anything but the most efficient methods for organizing and implementing health care. This book is a fundamental component for fostering equitable outcomes in health and development. It will inspire all those who seek the highly complex but attainable goal of universal good health for all members of the global community.

FACILITATING PROGRESS

We all share global responsibility: governments and international agencies, public and private sectors, and society and individuals all have specific tasks. We must all strive toward more equitable distribution of the benefits of new knowledge to reduce health and development gaps between rich and poor, between countries, and within countries. The second edition of *Disease Control Priorities in Developing Countries* is a new step in precisely the right direction. If we succeed in conveying the main lessons and messages of this book, public health in developing countries will progress farther and faster.

Jaime Sepúlveda, *Director, National Institutes of Health of Mexico, Mexico City, Mexico*
Chair, Advisory Committee to the Editors

Preface

In the late 1980s, the World Bank initiated a review of priorities for the control of specific diseases and used this information as input for comparative cost-effectiveness estimates of interventions addressing most conditions important in developing countries. The purpose of the comparative cost-effectiveness work was to inform decision making within the health sectors of highly resource-constrained low- and middle-income countries. This process resulted in the 1993 publication of the first edition of *Disease Control Priorities in Developing Countries (DCPI)* (Jamison and others 1993). That volume's preface stated its purpose as follows:

Between 1950 and 1990, life expectancy in developing countries increased from forty to sixty-three years with a concomitant rise in the incidence of the noncommunicable diseases of adults and the elderly. Yet there remains a huge unfinished agenda for dealing with undernutrition and the communicable childhood diseases. These trends lead to increasingly diverse and complicated epidemiological profiles in developing countries. At the same time, new epidemic diseases like AIDS are emerging; and the health of the poor during economic crisis is a source of growing concern. These developments have intensified the need for better information on the effectiveness and cost of health interventions. To assist countries to define essential health service packages, this book provides information on disease control interventions for the commonest diseases and injuries in developing countries.

To this end, *DCPI* aimed to provide systematic guidance on the selection of interventions to achieve rapid health improvements in an environment of highly constrained public sector budgets through the use of cost-effectiveness analysis.

DCPI provided limited discussion of investments in health system development. Other major efforts undertaken at the World Bank at about the same time, including the *World Development Report 1993: Investing in Health*, used the findings of *DCPI* and dealt more explicitly with the financial and health systems aspects of implementation (Feachem and others 1992;

World Bank 1993). Closely related efforts in collaboration with the World Health Organization led to the first global and regional estimates of numbers of deaths by age, sex, and cause and of the burden (including the disability burden) from more than 100 specific diseases and conditions (Murray, Lopez, and Jamison 1994; World Bank 1993).

This second edition of *Disease Control Priorities in Developing Countries (DCP2)* seeks to update and improve guidance on the “what to do” questions in *DCPI* and to address the institutional, organizational, financial, and research capacities essential for health systems to deliver the right interventions. *DCP2* is the principal product of the Disease Control Priorities Project, an alliance of organizations designed to review, generate, and disseminate information on how to improve population health in developing countries. In addition to *DCP2*, the project produced numerous background papers, an extensive range of interactive consultations held around the world, and several additional major publications. The other major publications are as follows:

- *Global Burden of Disease and Risk Factors* (Lopez and others 2006), undertaken in collaboration with the World Health Organization
- *Millions Saved: Proven Successes in Global Health* (Levine and the What Works Working Group 2004), undertaken in collaboration with the Center for Global Development
- “The Intolerable Burden of Malaria: II. What’s New, What’s Needed” (Bremner, Alilio, and Mills 2004), undertaken in collaboration with the Multilateral Initiative on Malaria
- *Priorities in Health* (Jamison and others 2006), a brief and nontechnical companion to this volume.

Each product of the Disease Control Priorities Project marries economic approaches with those of epidemiology, public health, and clinical medicine.

While general lessons emerge from the Disease Control Priorities Project, they result from careful consideration of individual cases. The diversity of health conditions necessitates specificity of analysis. Arrow clearly stated the need for

technical analyses to underpin health economics: “Another lesson of medical economics is the importance of recognizing the specific character of the disease under consideration. The policy challenges that arise in treating malaria are simply very different from those attached to other major infectious scourges (Arrow, Panosian, and Gelband 2004, xi–xii).” Chapters in this volume address this need for specificity, yet use cost-effectiveness analysis in a way that makes findings on the relative attractiveness of interventions comparable.

DCP2 goes beyond *DCP1* in a number of important ways as follows:

- While virtually all chapters of *DCP1* were structured around clusters of conditions, *DCP2* provides integrative chapters—for example, on school health systems, surgery, and integrated management of childhood illness—that draw together the implementation-related responses to a number of conditions. These and other chapters reflect *DCP2*'s inclusion of implementation and system issues.
- *DCP2* includes explicit discussions of research and product development opportunities.
- Although *DCP1* dealt with policy mechanisms to change behavior (or the environment), *DCP2* attempts to do so in a more systematic way. In particular, a number of chapters assess in depth the public sector instruments for influencing behavior change that were described briefly in *DCP1*: information, education, and communication; laws and regulations; taxes and subsidies; engineering design, such as speed bumps; and facility location and characteristics.
- Different interventions place different levels of demand on a country's health system capacity. *DCP2* builds on earlier work (Gericke and others 2005) in attempting, in some chapters, to identify which interventions require relatively less system capacity for scaling up and which require more.
- Although *DCP1* briefly discussed the nonhealth outcomes of interventions, *DCP2* does so in a more systematic way, including looking at the consequences of interventions (and intervention financing) for reducing financial risks at the household level. Other important nonhealth outcomes include, for example, the time-saving value of having piped water close to the home, the increased labor productivity of healthy workers, and the amenity value of clean air.
- An important element of *DCP1* was its assumption that to inform broad policy, major changes from the status quo need to be considered, not just marginal ones. For cost-effectiveness analysis, any major change needs to be informed by burden of disease assessments in a way not required for judging the attractiveness of marginal change, because the size of the burden affects total costs and the feasibility of extending the intervention to all who would benefit. This is particularly true when considering research and

development priorities, but also applies to control priorities. In this regard, *DCP2* continues in the spirit of *DCP1* in assessing cost-effectiveness analyses of major changes, but it does so more systematically for each of the six regional groupings of low- and middle-income countries used throughout this volume (see map 1, inside the front cover).

What was becoming clear in 1990 is clearer today: focusing health system attention on delivering efficacious and often relatively inexpensive health interventions can lead to dramatic reductions in mortality and disability at modest cost. A valuable dimension of globalization has been the diffusion of knowledge about what these interventions are and how to deliver them. The pace of this diffusion into a country determines the pace of health improvement in that country much more than its level of income. Our purpose is to help speed this diffusion of life-saving knowledge.

Editors

Dean T. Jamison is a professor of health economics in the School of Medicine at the University of California, San Francisco (UCSF), and an affiliate of UCSF Global Health Sciences. Dr. Jamison concurrently serves as an adjunct professor in both the Peking University Guanghua School of Management and in the University of Queensland School of Population Health.

Before joining UCSF, Dr. Jamison was on the faculty of the University of California, Los Angeles, and also spent many years at the World Bank, where he was a senior economist in the research department; division chief for education policy; and division chief for population, health, and nutrition. In 1992–93, he temporarily rejoined the World Bank to serve as director of the World Development Report Office and as lead author for the Bank's *World Development Report 1993: Investing in Health*.

His publications are in the areas of economic theory, public health, and education. Dr. Jamison studied at Stanford (B.A., philosophy; M.S., engineering sciences) and at Harvard (Ph.D., economics, under K. J. Arrow). In 1994, he was elected to membership in the Institute of Medicine of the U.S. National Academy of Sciences.

Joel G. Breman, M.D., D.T.P.H., is senior scientific adviser, Fogarty International Center of the National Institutes of Health, and co-managing editor of the Disease Control Priorities Project. He was educated at the University of California, Los Angeles; the Keck School of Medicine, the University of Southern California; and the London School of Hygiene and Tropical Medicine. Dr. Breman trained in medicine at the University of Southern California–Los Angeles County Medical Center; in infectious diseases at the Boston City Hospital, Harvard Medical School; and in epidemiology at the U.S. Centers for Disease Control and Prevention.

Dr. Breman worked in Guinea on smallpox eradication (1967–69); in Burkina Faso at the Organization for Coordination and Cooperation in the Control of the Major Endemic Diseases (1972–76); and at the World Health Organization, Geneva (1977–80), where he was responsible for orthopoxvirus research and the certification of smallpox

eradication. In 1976, in the Democratic Republic of Congo (formerly Zaire), Dr. Breman investigated the first outbreak of Ebola hemorrhagic fever.

Following the confirmation of smallpox eradication in 1980, Dr. Breman returned to the U.S. Centers for Disease Control, where he began work on the epidemiology and control of malaria. Dr. Breman joined the Fogarty International Center in 1995 and has been director of the International Training and Research Program in Emerging Infectious Diseases and senior scientific adviser. He has been a member of many advisory groups, including serving as chair of the World Health Organization's Technical Advisory Group on Human Monkeypox and as a member of the World Health Organization's International Commission for the Certification of *Dracunculiasis* (guinea worm) Eradication. Dr. Breman has written more than 100 publications on infectious diseases and research capacity strengthening in developing countries. He was guest editor of two supplements to the *American Journal of Tropical Medicine and Hygiene*: "The Intolerable Burden of Malaria: A New Look at the Numbers" (2001) and "The Intolerable Burden of Malaria: What's New, What's Needed" (2004).

Anthony R. Measham is co-managing editor of the Disease Control Priorities Project at the Fogarty International Center of the National Institutes of Health; deputy director of the Communicating Health Priorities Project at the Population Reference Bureau, Washington, DC; and a member of the Working Group of the Global Alliance for Vaccines and Immunization on behalf of the World Bank.

Born in the United Kingdom, Dr. Measham practiced family medicine in Dartmouth, Nova Scotia, before devoting the remainder of his career to date to international health. He spent 15 years living in developing countries on behalf of the Population Council (Colombia), the Ford Foundation (Bangladesh), and the World Bank (India). Early in his international health career (1975–77), he was deputy director of the Center for Population and Family Health at Columbia University, New York. He then served for 17 years on the staff

of the World Bank, as health adviser from 1984 until 1988 and as chief for policy and research of the Health, Nutrition, and Population Division from 1988 until 1993.

Dr. Measham has spent most of his career providing technical assistance, carrying out research and analysis, and helping to develop projects in more than 20 developing countries, primarily in the areas of maternal and child health, family planning, and nutrition. He was an editor of the first edition of *Disease Control Priorities in Developing Countries* and has authored approximately 60 monographs, book chapters, and journal articles.

Dr. Measham graduated in medicine from Dalhousie University, Halifax, Nova Scotia. He received a master of science and a doctorate in public health from the University of North Carolina in Chapel Hill and is a diplomat of the American Board of Preventive Medicine and Public Health. His honors include being elected to the Alpha Omega Alpha Honor Medical Society; being appointed as special professor of International Health, University of Nottingham Medical School, Nottingham, United Kingdom; and being named Dalhousie University Medical Alumnus of the Year in 2000–1.

George Alleyne, M.D., F.R.C.P., F.A.C.P. (Hon.), D.Sc. (Hon.), is director emeritus of the Pan American Health Organization, where he served as director from 1995 to 2003. Dr. Alleyne is a native of Barbados and graduated from the University of the West Indies in medicine in 1957. He completed his postgraduate training in internal medicine in the United Kingdom and did further postgraduate work in that country and in the United States. He entered academic medicine at the University of the West Indies in 1962, and his career included research in the Tropical Metabolism Research Unit for his doctorate in medicine. He was appointed professor of medicine at the University of the West Indies in 1972, and four years later he became chair of the Department of Medicine. He is an emeritus professor of the University of the West Indies. Dr. Alleyne joined the Pan American Health Organization in 1981, in 1983 he was appointed director of the Area of Health Programs, and in 1990 he was appointed assistant director.

Dr. Alleyne's scientific publications have dealt with his research in renal physiology and biochemistry and various aspects of clinical medicine. During his term as director of the Pan American Health Organization, he dealt with and published on issues such as equity in health, health and development, and international cooperation in health. He has also addressed several aspects of health in the Caribbean and the problems the area faces. He is a member of the Institute of Medicine and chancellor of the University of the West Indies.

Dr. Alleyne has received numerous awards in recognition of his work, including prestigious decorations and national honors from many countries of the Americas. In 1990, he was made Knight Bachelor by Her Majesty Queen Elizabeth II for

his services to medicine. In 2001, he was awarded the Order of the Caribbean Community, the highest honor that can be conferred on a Caribbean national.

Mariam Claeson, M.D., M.P.H., is the program coordinator for AIDS in the South Asia Region of the World Bank since January 2005. She was the lead public health specialist in the Health, Nutrition, and Population, Human Development Network, of the World Bank (1998–2004), managing the Health, Nutrition, and Population Millennium Development Goals work program to support accelerated progress in countries.

Dr. Claeson coauthored the call for action by the Bellagio study group on child survival in 2003, *Knowledge into Action for Child Survival*, and the World Bank's 2005 report on *The Millennium Development Goals for Health: Rising to the Challenges*. She was a member of the What Works Working group hosted by the Center for Global Development that resulted in the report *Millions Saved: Proven Successes in Global Health* (2005). Dr. Claeson coauthored the health chapter of the *Poverty Reduction Strategy* source book, promoting a life-cycle approach to maternal and child health and nutrition. As a coordinator of the public health thematic group (1998–2002), she led the development of the strategy note *Public Health and World Bank Operations* and promoted multisectoral approaches to child health within the World Bank and in Bank-supported country operations, analytical work, and lending.

Prior to joining the World Bank, Dr. Claeson worked with the World Health Organization from 1987 until 1995, in later years as program manager for the Global Program for the Control of Diarrheal Diseases. She has several years of field experience working in developing countries; in clinical practice at the rural district level in Bangladesh, Bhutan, and Tanzania; in national program management of immunization and diarrheal disease control programs in Ethiopia; and in health sector development projects in middle- and low-income countries.

David B. Evans, Ph.D., is an economist by training. Between 1980 and 1990, he was an academic, first in economics departments and then in a medical school, during which time he undertook consultancies for the World Bank, the World Health Organization, and governments. From 1990 until 1998, he sponsored and conducted research into social and economic aspects of tropical diseases and their control in the United Nations Children's Fund, United Nations Development Programme, World Bank, and World Health Organization Special Programme on Research and Training in Tropical Diseases. He subsequently became director of the Global Programme on Evidence for Health Policy and then the Department of Health Systems Financing of the World Health Organization, where he is now responsible for a range of activities relating to the development of appropriate health

financing strategies and policies. These activities include the World Health Organization's CHOICE project, which has assessed and reported the costs and effectiveness of more than 700 health interventions, the costs of scaling up interventions, the levels of health expenditures and accounts, and the extent of financial catastrophe and impoverishment caused by out-of-pocket payments for health and which has assessed the impact of different ways to raise funds for health, pool them, and use them to provide or purchase services and interventions. He has published widely in these areas.

Prabhat Jha is Canada research chair of health and development at the University of Toronto. He is also the founding director of the Centre for Global Health Research, St. Michael's Hospital; associate professor in the Department of Public Health Sciences, University of Toronto; research scholar at the McLaughlin Centre for Molecular Medicine; and professeur extraordinaire at the Université de Lausanne, Switzerland.

Dr. Jha is lead author of *Curbing the Epidemic: Governments and the Economics of Tobacco Control* and coeditor of *Tobacco Control in Developing Countries*. Both are among the most influential books on tobacco control. He is the principal investigator of a prospective study of 1 million deaths in India, researching mortality from smoking, alcohol use, fertility patterns, indoor air pollution, and other risk factors among 2.3 million homes and 15 million people. This work is currently the world's largest prospective study of health. He also conducts studies of HIV transmission in various countries, focusing on documenting the risk factors for the spread of HIV and interventions to prevent the spread of the HIV/AIDS epidemic. His studies have received more than \$5 million in peer-reviewed grants.

Dr. Jha has published widely on tobacco, HIV/AIDS, and health of the global poor. His awards include a Gold medal from the Poland Health Promotion Foundation (2000), the Top 40 Canadians under Age 40 Award (2004), and the Ontario Premier's Research Excellence Award (2004). Dr. Jha was a research scholar at the University of Toronto and McMaster University in Canada. He holds an M.D. from the University of Manitoba and a D. Phil. in epidemiology and public health from Oxford University, where he studied as a Rhodes Scholar at Magdalen College.

Anne Mills, Ph.D., is professor of health economics and policy at the London School of Hygiene and Tropical Medicine. She has more than 20 years of experience in research pertaining to health economics in developing countries and has published widely in the fields of health economics and health planning,

including books on the role of government in health in developing countries, health planning in the United Kingdom, decentralization, health economics research in developing countries, and the public-private mix. Her most recent research interests have been in the organization and financing of health systems, including the evaluation of contractual relationships between the public and private sectors and the application of economic evaluation techniques to improve the efficiency of disease control programs.

Dr. Mills has had extensive involvement in supporting the health economics research activities of the World Health Organization's Tropical Disease Research Programme. She founded, and is head of, the Health Economics and Financing Programme, which has become one of the world's leading groups in developing and applying theories and techniques of health economics to increase knowledge on how best to improve the equity and efficiency of developing countries' health systems. She has acted as adviser to a number of multi-lateral and bilateral agencies—notably, the United Kingdom Department for International Development and the World Health Organization. She guided the creation of the Alliance for Health Policy and Systems Research and chairs its board. Most recently, she has been a member of the Commission for Macroeconomics and Health and cochair of its working group on improving the health outcomes of the poor.

Philip Musgrove is deputy editor—global health for *Health Affairs*, which is published by Project HOPE in Bethesda, Maryland. He worked for the World Bank (1990–2002), including two years on secondment to the World Health Organization (1999–2001), retiring as a principal economist. He was previously an adviser in health economics at the Pan American Health Organization (1982–90) and a research associate at the Brookings Institution and at Resources for the Future (1964–81).

Dr. Musgrove is an adjunct professor at the School of Advanced International Studies, Johns Hopkins University, and has taught at George Washington University, American University, and the University of Florida. He holds degrees from Haverford College (B.A., 1962, summa cum laude); Princeton University (M.P.A., 1964); and Massachusetts Institute of Technology (Ph.D., 1974).

Dr. Musgrove has worked on health reform projects in Argentina, Brazil, Chile, and Colombia and has dealt with a variety of issues in health economics, financing, equity, and nutrition. His publications include more than 50 articles in economics and health journals and chapters in 20 books.

Disease Control Priorities Project Partners

The Disease Control Priorities Project is a joint enterprise of the Fogarty International Center of the National Institutes of Health, the World Health Organization, the World Bank, and the Population Reference Bureau.

The Fogarty International Center is the international component of the U.S. National Institutes of Health. It addresses global health challenges through innovative and collaborative research and training programs and supports and advances the mission of the U.S. National Institutes of Health through international partnerships.

The World Health Organization is the specialized agency for health of the United Nations. Its objective, as set out in its constitution, is the attainment by all peoples of the highest possible level of health, with *health* defined as a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.

The World Bank Group is one of the world's largest sources of development assistance. The Bank, which provides

US\$18 billion to US\$22 billion each year in loans to its client countries, provided US\$1.27 billion for health, nutrition, and population in 2004. The World Bank is working in more than 100 developing economies, bringing a mix of analytical work, policy dialogue, and lending to improve living standards—including health and education—and reduce poverty.

The Population Reference Bureau informs people around the world about health, population, and the environment and empowers them to use that information to advance the well-being of current and future generations. For 75 years, the bureau has analyzed complex data and research results to provide objective and timely information in a format easily understood by advocates, journalists, and decision makers; has conducted workshops around the world to give key audiences the tools they need to understand and communicate effectively about relevant issues; and has worked to ensure that policy makers in developing countries base policy decisions on sound evidence.

Acknowledgments

Preparation of this volume required efforts over four years by many institutions and almost 1,000 individuals: chapter coauthors, advisory committee members, peer reviewers, copy editors, and research and staff assistants. We have many contributions to acknowledge. We particularly thank our chapter authors, who worked extremely hard through a long and exacting process of writing, review, and revision. We also owe much gratitude to the institutional sponsors of this effort:

- *The Fogarty International Center (FIC) of the U.S. National Institutes of Health.* The FIC supported both the senior editor and one of the co-managing editors of this project, as well as support staff. Gerald Keusch, former director of the FIC, initiated and facilitated this effort, and FIC's acting director, Sharon Hrynkow, continued to provide support and counsel.
- *The World Bank.* Successive directors of the World Bank's Health, Nutrition, and Population Department, Christopher Lovelace and Jacques Baudouy, provided support, guidance, and critical reactions and facilitated the involvement of Bank staff as coauthors and reviewers.
- *The World Health Organization.* Successive leaders of the World Health Organization's Evidence and Information for Policy Cluster, Christopher Murray and Timothy Evans, coordinated the involvement of the World Health Organization, which had been agreed by Gro Harlem Brundtland, then the director-general.
- *The Bill & Melinda Gates Foundation.* Richard Klausner, Sally Stansfield, and Beth Peterman arranged for the foundation to provide major financial support and interacted closely with us throughout the past four years. Initial conversations with and encouragement from William Gates Senior are gratefully acknowledged.

In undertaking the work leading to this volume, we benefited from the close engagement of three institutions that helped organize and host consultations and arranged for background analyses to be undertaken. These institutions were the London School of Hygiene and Tropical Medicine (Anne Mills), the University of Toronto's Center for Global Health

(Prabhat Jha), and Resources for the Future (Ramanan Laxminarayan). The Center for Global Development (Ruth Levine) collaborated with the chapter authors in an effort to identify proven successes in global health, the results of which were used both in this book and in a separate publication. We are grateful to each of these institutions and individuals.

We were particularly fortunate to have the strong collaboration of the Inter-Academies Medical Panel (IAMP), an association of the medical academies or medical divisions of the scientific academies of 44 countries. David Challoner and Guy de Thé cochaired the Steering Committee of the IAMP and invested much time and effort into facilitating the collaboration. In particular, the IAMP helped establish the productive Advisory Committee to the Editors, chaired by Jaime Sepúlveda, on which many members of the IAMP Steering Committee served. The IAMP's second global meeting hosted the launch of this volume in Beijing in April 2006, and the IAMP also sponsored the peer review process for all the chapters. We are most grateful to David Challoner and Guy de Thé, as well as to Jaime Sepúlveda and other members of the Advisory Committee to the Editors. The U.S. member of the IAMP, the Institute of Medicine of the National Academy of Sciences, played a critical role in facilitating all aspects of the IAMP's collaboration. Patrick Kelley, Patricia Cuff, Dianne Stare, Stacey Knobler, and Leslie Baer at the Institute of Medicine and Mohamed Hassan and Muthoni Fanin at the IAMP managed this effort and provided critical, substantive inputs.

The Office of the Publisher at the World Bank provided outstanding assistance, enthusiastic advice, and support during every phase of production of this volume and helped coordinate publicity and initial distribution. We particularly wish to thank Dirk H. Koehler, the publisher; Carlos Rossel; Mary Fisk; Santiago Pombo-Bejarano; Nancy Lammers; Randi Park; Valentina Kalk; Alice Faintich; Joanne Ainsworth; Enid Zafran; Deepa Menon; and Janice Tuten for their timely, high-quality professionalism.

Donald Lindberg, director of the National Library of Medicine (NLM) of the U.S. National Institutes of Health, and Julia Royall, chief, International Programs, NLM, graciously

offered the competent services of the NLM's Information Engineering Branch of the National Center for Biotechnology Information to convert the text into an electronic product available to all visitors to the National Library of Medicine's PubMed Web site. We would like to extend our gratitude to the National Center for Biotechnology Information team members—David Lipman, Jo McEntyre, and Mohammad Al-Ubaydli, and Belinda Beck—for their technical expertise and commitment.

With this volume now in the dissemination phase, the Population Reference Bureau is charged to communicate its findings in formats likely to be of use to a range of audiences. We greatly value the work of the bureau's William P. Butz, president, and Nancy Yinger, director of international programs, in rapidly initiating this effort.

Multiple institutions from around the world contributed to organizing and hosting meetings that facilitated the preparation of this book and providing background for such meetings. We greatly appreciate the contributions and hospitality of these institutions, including the following:

- Chinese Academy of Engineering and Chinese Academy of Sciences, Disease Control Priorities Project Launch and Inter-Academies Medical Panel Global Meeting, Beijing, China (April 2006)
- Italian Ministry of Health, Veneto Region, consultation on child health and nutrition, Venice, Italy (January 2004)
- Instituto Nacional de Salud Pública, Advisory Committee to the Editors meeting, Cuernavaca, Mexico (June 2002)
- Institut Pasteur, Advisory Committee to the Editors meeting, Paris, France (March and December 2004)
- Johns Hopkins Bloomberg School of Public Health, consultation on maternal and child health, Annapolis, Maryland (May 2002)
- Johns Hopkins Paul H. Nitze School of Advanced International Studies, consultation on elimination and eradication of disease, and vaccinations, Washington, DC (October 2004)
- Merck & Company Inc., consultation on research and product development priorities, Whitehouse Station, New Jersey (September 2004)
- Multilateral Initiative on Malaria, consultations on the burden of malaria:
 - National Institute of Medical Research, Arusha, Tanzania (November 2002)
 - University of Yaoundé, Cameroon (November 2005)

- National Cancer Institute, National Institutes of Health, consultation on cancer prevention, treatment, and pain control, Bethesda, Maryland (June 2003)
- Oswaldo Cruz Foundation, World Health Organization, and Pan-American Health Organization, consultation on tropical infectious diseases, Rio de Janeiro, Brazil (April–May 2003)
- Université de Lausanne, consultation on cardiovascular disease, Lausanne, Switzerland (March 2002)
- University of California, Berkeley, consultation on learning and developmental disorders, Berkeley, California (August 2003)
- University of California, San Francisco, consultation on surgery, San Francisco, California (July 2003)
- University of Queensland, School of Population Health, authors' meeting on psychiatric disorders, neurology, and alcohol and other substance abuse, Brisbane, Australia (August 2003)
- University of Washington, consultation on sexually transmitted infections, Seattle, Washington (July 2003)
- University of the Witwatersrand, consultations on health systems and on capacity strengthening and management reform, Johannesburg, South Africa (July 2004)
- World Health Organization, Division of Mental Health, and National Institutes of Health, National Institute of Mental Health, consultation on mental health economics, Geneva, Switzerland (March 2004).

Coordination of the work leading to this publication and background research were undertaken by a small secretariat. Nancy Hancock, Pamela Maslen, and Sonbol A. Shahid-Salles provided outstanding research assistance; Andrew Marshall ably managed the budget and process; Candice Byrne provided key communications guidance, staff and editorial assistance; and Mantra Singh and Cherice Holloway provided staff assistance. Richard Miller, Lauren Sikes and Tommy Freeman of the FIC provided excellent administrative support to the Disease Control Priorities Project. Their work was absolutely essential in producing this book, and we are deeply grateful for their commitment and productivity. With so many authors and institutions involved, we are aware that many more people gave countless hours to this endeavor. We thank them also for their dedication.

The Editors

Abbreviations and Acronyms

ACE	angiotensin-converting enzyme	CBR	cost-benefit ratio

Chapter 1

Investing in Health

Dean T. Jamison

A girl born in Chile in 1910 could expect to live only to age 33. Since then, her life expectancy has more than doubled to its current level of 78 years. What has this increase meant for her? The probability that she will die before her fifth birthday has declined from 36 percent to less than 2 percent. Throughout middle age the likelihood that she will die is also far lower: death in childbearing or from tuberculosis (TB) as a young adult are no longer threats, and she is less likely to die in middle age from cancer. Mirroring this mortality reduction—but less easily quantified—are marked improvements in health-related quality of life. She will be able to choose to have fewer children and thus spend less time in pregnancy and child rearing. From an average of about 5.3 children at midcentury, Chilean women’s fertility rate has dropped to its current level of 2.3. She will have fewer infections, less anemia, greater strength and stature, and a quicker mind. Her life is not only much longer; it is much healthier as well.

Chile’s history of health improvements is unusually well documented but typifies changes that have occurred in much of the world. These dramatic improvements in health have, moreover, been possible without major increases in income. In the early 1900s, income levels in the United States were roughly the same as they are in Chile today, yet U.S. life expectancy then was 25 years shorter. New knowledge, new vaccines, and new drugs have inexpensively enabled major gains in health that were not possible before, even for those whose incomes were high. Although those gains are now *possible*, they do not occur unless health systems and policies effectively realize the available potential.

Although the magnitude of possible gains in health was clear by the early 1990s, it is even clearer today: focused attention by health systems on delivering powerful but often inexpensive interventions can lead to dramatic improvements in health at modest cost. Globalization has helped diffuse knowledge about what those interventions are and how health systems can deliver them. The pace of diffusion of such knowledge into a country—much more than its level of income—determines the pace of health improvement in that country. Our purpose in *Disease Control Priorities in Developing Countries*, 2nd edition (*DCP2*), is to help speed the diffusion of policy-relevant knowledge.

This introductory chapter to *DCP2* serves two purposes:

- First, it provides the context for the rest of the book by discussing broad trends in health conditions, by summarizing health conditions of the world at the dawn of the 21st century, and by pointing to recent research suggesting that the economic benefits from successful investments in health are likely to be exceptionally high.
- Second, it highlights some of the main messages for policy that emerge from the 37 chapters that deal with conditions and risk factors and the 21 chapters that deal with strengthening health systems. These highlights are deliberately brief because chapters 2 and 3 summarize the remainder of the book: chapter 2 summarizes findings about intervention cost-effectiveness from across the book, and chapter 3 synthesizes findings on strengthening health systems.

Box 1.1 summarizes the main messages of this chapter.

Box 1.1

Disease Control Priorities

Chapters in this volume convey compact distillations of current knowledge concerning interventions to improve health and the related delivery systems. Chapter 2 summarizes main messages of the chapters dealing with interventions, and chapter 3 summarizes the main messages concerning health systems. Chapter 1 provides context and conveys examples of the range of findings from across the volume. Here, in brief, are the main messages of chapter 1:

1. *Average life expectancy in low- and middle-income countries increased dramatically in the past half-century, while cross-country health inequalities decreased.* In the countries with the best health indicators, life expectancy increased a substantial two and one-half years per decade since 1960; low- and middle-income countries on average, with life expectancy gains of about five years per decade, have been converging toward the countries with the longest life expectancy. Improvement in average income and education levels contributed to these worldwide gains in health. Of much greater quantitative significance, however, have been the generation and diffusion of new knowledge and of low-cost, appropriate technologies. Increased access to knowledge and technology has accounted for perhaps as much as two-thirds of the impressive 2 percent per year rate of decline in under-five mortality rates.
 2. *Improved health has contributed significantly to economic welfare.* Per capita GNP rose rapidly in developing countries in the decades following 1960, and economic research suggests that health improvements led to perhaps 10 percent to 15 percent of that GNP growth. Although GNP includes the costs of providing medical care and reflects changes in health-related consumption, such as the quantity and quality of food, it omits altogether the value that mortality reduction represents for countries. Recent economic research has extended measurement to a broader indicator, known as *full income*, that reflects reasonable valuation of changes in mortality. For many countries, recent mortality changes exceed in value the growth of GNP. More widespread use of full-income measures to calculate the rate of return to investments in health—and health research—will almost certainly conclude that, today, most countries substantially undervalue those investments.
 3. *Although health improvements constituted an enormous success for human welfare in the 20th century, four critical challenges face developing countries (and the world) at the beginning of the 21st century:*
 - high levels and rapid growth (for mostly demographic reasons) of noncommunicable conditions in the disease profiles of developing countries
 - the still unchecked HIV/AIDS pandemic
 - the possibility of a successor to the influenza pandemic of 1918
 - the persistence in many countries and many population subgroups of high but preventable levels of mortality and disability from diseases such as malaria, TB, diarrhea, and pneumonia; from micronutrient malnutrition; and, for both mothers and infants, from childbirth.
- The main purpose of this volume is to facilitate diffusion of appropriate approaches for addressing those problems.
4. *The volume's conclusions concerning interventions include the following:*
 - Although 50 percent of deaths (including stillbirths) of children under age five occur at ages younger than 28 days, relatively little attention has been paid to this age group. Cost-effective interventions exist.
 - Treatment of HIV-positive mothers, treatment of sexually transmitted infections, free distribution of condoms, and other interventions can cost-effectively interrupt HIV transmission. These preventive interventions continue to receive inadequate attention from health systems and workers.
 - Controlling tobacco use, particularly through taxation, is feasible in developing countries and is the single most important intervention for reducing noncommunicable disease.
 - Lifelong medical management of risk factors in individuals at high risk for heart attacks or strokes, using aspirin and other drugs, is cost-effective and would benefit tens of millions of individuals.
 5. *This volume's findings concerning health services and systems include the following:*
 - Provider incentives matter. Financial or other recognition for timely, responsive service increases the likelihood of such services. Conversely, financial incentives for excessive or inappropriate use of

drugs or diagnostic tests is an all-too-common cause of high costs and poor health outcomes.

- Provider experience matters. Having providers do a few things frequently, rather than attempting to provide diverse services, facilitates quality improvement with potentially major improvements in health outcomes.
- Strengthening surgical capacity at district hospitals is likely to be cost-effective and would address broad needs.
- In low-income countries, targeting the very limited public sector resources for health to control of diseases—such as TB—that particularly affect the poor would be efficient.
- In middle-income countries, public finance—or publicly mandated finance—of a substantial package of clinical care for all would be not only equitable but also efficient in terms of meeting health needs, controlling costs, and providing financial protection to populations.

6. *The generation and diffusion of new knowledge and products underpinned the enormous improvements in*

health in the 20th century. Every reason exists to believe that continued progress—meeting the challenges of noncommunicable disease, HIV/AIDS, potential pandemics, and neglected populations—will also rely heavily on new knowledge. The rapidly growing commitment of high-income countries to providing development assistance for health would be more effectively used if a larger share were devoted to research and development. Public-private partnerships provide a promising institutional mechanism for new product development. A particularly important—and much neglected—type of knowledge results from tight evaluations of interventions and systems.

This volume represents an attempt to learn systematically from the enormous successes of the past half-century in improving human health. Knowledge that has been gained—and that this volume pulls together—creates a platform for addressing the problems that remain.

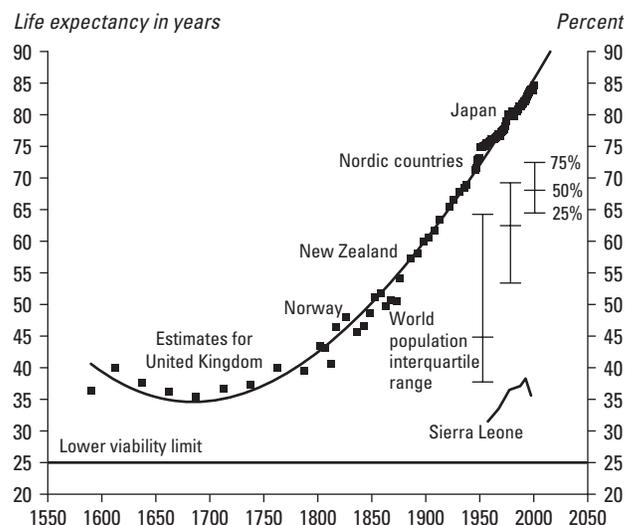

THE 20TH CENTURY TAKEOFF IN HUMAN HEALTH

The 20th century differed markedly from previous history in two critical domains:

- First, the rapid economic growth that had begun in the 19th century in countries of the North Atlantic diffused widely around the globe while continuing in the countries where it originated (DeLong 2000; Maddison 1999).
- Second, human mortality rates plummeted, and other dimensions of health improved dramatically. These changes also began in the North Atlantic countries in the 19th century but remained modest until the 20th century, during which the rate of improvement increased and spread to most of the rest of the world (Easterlin 1996, 1999; Oeppen and Vaupel 2002).

Improvements in Health

This section briefly documents the magnitude of health improvements and then points to the challenges that remain. For the past 160 years, life expectancy in the healthiest countries has increased steadily. At the same time, differences in life expectancy between those countries and much of the rest of the world have narrowed. Figure 1.1 depicts trends in female life expectancy in the country with the *highest* estimated level of

Source: Oeppen 1999.

Figure 1.1 Trends in Maximum Female Life Expectancy, 1600–2000

life expectancy. From about 1600 to about 1840, there is fluctuation but no clear trend; after 1840, the graph turns upward at a surprisingly uniform rate of improvement: maximum life expectancy increased by about two and one-half years per decade for 160 years.

Table 1.1 Levels and Changes in Life Expectancy, 1960–2002, by World Bank Region

Region	Life expectancy (years)			Rate of change (years per decade)	
	1960	1990	2002	1960–90	1990–2002
Low- and middle-income countries	44	63	65	6.3	1.7
East Asia and the Pacific	39	67	70	9.3	2.5
(China)	(36)	(69)	(71)	(11)	(1.7)
Europe and Central Asia	—	69	69	—	0.0
Latin America and the Caribbean	56	68	71	4.0	2.5
Middle East and North Africa	47	64	69	5.7	4.2
South Asia	44	58	63	4.7	4.2
(India)	(44)	(59)	(64)	(5)	(4.6)
Sub-Saharan Africa	40	50	46	3.3	–3.3
High-income countries	69	76	78	2.3	1.7
World	50	65	67	5.0	1.7

— = not available.

Note: Entries are the average of male and female life expectancies.

Table 1.1 shows progress in life expectancy by World Bank region between 1960 and 2002. (Map 1 on the inside front cover depicts the World Bank regions.) For the first three decades of this period, progress was remarkably fast—a gain of 6.3 years in life expectancy per decade on average, albeit with substantial regional variation. Progress continued between 1990 and 2002 in the low- and middle-income countries but at a much slower pace. This slower pace is due, in great part, to mortality increases from HIV/AIDS. Sub-Saharan Africa actually lost more than four years of life expectancy.

Since 1950, life expectancy in the median country has steadily converged toward the maximum and cross-country differences have decreased markedly. This reduction in inequality in health contrasts with long-term *increases* in income inequality between and within countries. Despite the magnitude of global improvements, many countries and populations have failed to share in the overall gains or have even fallen behind. Some countries—for example, Sierra Leone—remain far behind (figure 1.1). China's interior provinces lag behind the more advantaged coastal regions. Indigenous people everywhere probably lead far less healthy lives than do others in their respective countries, although confirmatory data are scant.

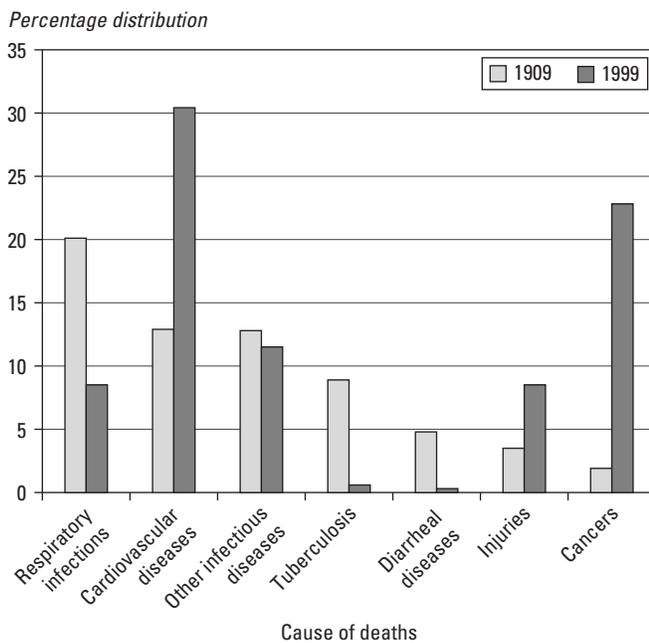

Reasons for remaining health inequalities lie only partially in income inequality: the experiences of China, Costa Rica, Cuba, Sri Lanka, and Kerala state in India, among many others, conclusively show that dramatic improvements in health can occur without high or rapidly growing incomes. The experiences of countries in Europe in the late 19th and early 20th centuries similarly show that health conditions can improve without prior or concomitant increases in income (Easterlin 1996). A recent review, undertaken in part as background for this volume,

identified many specific examples of low-cost interventions leading to large and carefully documented health improvements (Levine and others 2004). The public sector initiated and financed virtually all of these interventions. The goal of this book is to assist decision makers—particularly those in the public sector—to realize the potential for low-cost intervention to rapidly improve the health and welfare of their populations.

Remaining Challenges

Four central challenges for health policy ensue from the pace and unevenness of the progress just documented and from the evolving nature of microbial threats to human health.

Epidemiological Transition. First, the next two decades will see continuation of trends resulting from the dramatic mortality declines of recent decades. The key phenomenon is that the major noncommunicable diseases—circulatory system diseases, cancers, and major psychiatric disorders—are fast replacing (or adding to) the traditional scourges—particularly infectious diseases and undernutrition in children. This phenomenon results in substantial part from rapid relative population growth at the older ages, when noncommunicable diseases become manifest. Additionally, injuries resulting from road traffic are replacing more traditional forms of injury. Using data from Chile, figure 1.2 illustrates the huge increase in the relative importance of injuries, cancers, and cardiovascular disease between 1909 and 1999. Responding to this epidemiological transition with sharply constrained resources is a key challenge. Tables 1.A1 and 1.A2 (see annex 1.A) provide cause-specific summaries of death and disease burden, measured in DALYs, in 2001 for the world as a whole and for low- and

Source: WHO 1999, 13.

Note: For 1909, 35.1 percent of deaths were categorized as “other,” and for 1999, the corresponding percentage was 17.5. The cause-specific percentages shown in the figure are the number from the indicated cause as a percentage of the total number classified into a specific cause for that year.

Figure 1.2 Distribution of Deaths by Cause in Chile, 1909 and 1999

middle-income countries as a group as well as for high-income countries. Those summaries indicate that noncommunicable disease already accounts for over half of all deaths in the low- and middle-income countries, although nearly 40 percent of deaths continue to be from infection, undernutrition, and maternal conditions, creating a “dual burden” that Julio Frenk and colleagues have pointed to (Bobadilla and others 1993).

HIV/AIDS Epidemic. A second key challenge is the HIV/AIDS epidemic. Control efforts and successes have been very real but, with only a few exceptions, limited to upper-middle-income and high-income countries. Poorer countries remain in the epidemic’s deadly path.

New Pandemics. The global influenza pandemic of 1918 resulted in more than 40 million human deaths, exceeding the 20th-century toll of HIV/AIDS or of World Wars I and II. Continued evolution of the influenza virus leaves the world at risk of another such pandemic—as has been much discussed in the press as this book goes to print. If the H5N1 strain of avian influenza, for example, evolved so that (like the human flu) it could be efficiently transmitted from human to human, a major pandemic would be likely. Preparing for such an eventuality is the third great challenge to global health.

Unequal Progress. A fourth key challenge results from continued high levels of inequality in health conditions across

and within countries. Bourguignon and Morrisson (2002) have stressed that global inequalities are declining if one properly accounts for convergence across countries in health conditions, which more than compensates for income divergence. However, in far too many countries health conditions remain unacceptably—and unnecessarily—poor. This factor is a source of grief and misery, and it is a sharp brake on economic growth and poverty reduction. From 1990 to 2001, for example, the under-five mortality rate remained stagnant or increased in 23 countries. In another 53 countries (including China), the rate of decline in under-five mortality in this period was less than half of the 4.3 percent per year required to reach the fourth Millennium Development Goal (MDG-4) (see map 2 on the inside back cover of this book). Meeting the MDG for under-five mortality reduction by 2015 is not remotely possible for these countries. Yet the examples of many other countries, often quite poor, show that with the right policies dramatic reductions in mortality are possible. A major goal of this volume is to identify strategies for implementing interventions that are known to be highly cost-effective for dealing with the health problems of countries remaining behind—for example, treatment for diarrhea, pneumonia, TB, and malaria; immunization; and other preventive measures against a large proportion of those diseases.

THE ECONOMIC BENEFITS OF BETTER HEALTH

The dramatic health improvements globally during the 20th century arguably contributed as much or more to improvements in overall well-being as did the equally dramatic innovation in and expansion of the availability of material goods and services. To the substantial extent that appropriate investments in health can contribute to continued reductions in morbidity and mortality, the economic welfare returns to health investments are likely to be exceptional and positive—with previously unrecognized implications for public sector resource allocation. These returns go far beyond the contribution better health makes to per capita income, which itself appears substantial (see Bloom, Canning, and Jamison 2004; Lopez-Casasnovas, Rivera, and Currais 2005). This section first summarizes the evidence concerning health’s effect on per capita income and then turns to more recent literature concerning the effect of health changes on a broader measure of economic well-being than per capita gross domestic product (GDP).

Health and Income

How does health influence GDP per person? Healthy workers are more productive than workers who are similar but not healthy. Supporting evidence for this plausible observation comes from studies that link investments in health and nutrition of the young to adult wages (Strauss and Thomas 1998). Better

health also raises per capita income through a number of other channels. One involves altering decisions about expenditures and savings over the life cycle. The idea of planning for retirement occurs only when mortality rates become low enough for retirement to be a realistic prospect. Rising longevity in developing countries has opened a new incentive for the current generation to save—an incentive that can dramatically affect national saving rates. Although this saving boom lasts for only one generation and is offset by the needs of the elderly after population aging occurs, it can substantially boost investment and economic growth rates while it lasts.

Encouraging foreign direct investment is another channel: investors shun environments in which the labor force suffers a heavy disease burden. Endemic diseases can also deny humans access to land or other natural resources, as occurred in much of West Africa before the successful control of river blindness.

Boosting education is yet another channel. Healthier children attend school and learn more while they are there. A longer life span increases the returns on investment in education.

Demographic channels also play an important role. Lower infant mortality initially creates a “baby-boom” cohort and leads to a subsequent reduction in the birth rates as families choose to have fewer children in the new low-mortality regime. A baby-boom cohort thereby affects the economy profoundly as its members enter the educational system, find employment, save for retirement, and finally leave the labor market. The cohorts before and after a baby boom are much smaller; hence, for a substantial transition period, this cohort creates a large labor force relative to overall population size and the potential for accelerated economic growth (Bloom, Canning, and Malaney 2000).

If better health improves the productive potential of individuals, good health should accompany higher levels of national income in the long run. Countries that have high levels of health but low levels of income tend to experience relatively faster economic growth as their income adjusts. How big an overall contribution does better health make to economic growth? Evidence from cross-country growth regressions suggests the contribution is consistently substantial. Indeed, the initial health of a population has been identified as one of the most robust and potent drivers of economic growth—among such well-established influences as the initial level of income per capita, geographic location, institutional environment, economic policy, initial level of education, and investments in education. Bloom, Canning, and Sevilla (2004) found that one extra year of life expectancy raises GDP per person by about 4 percent in the long run. Jamison, Lau, and Wang (2005) estimated that reductions in adult mortality explain 10 to 15 percent of the economic growth that occurred from 1960 to 1990. Not all countries benefit equally from this link. Bhargava and others (2001) found that better health matters more for

income growth in low-income countries than in high-income ones. Although attribution of causality is never unequivocal in analyses like these, different types of evidence point consistently to a likely causal effect of health on growth.

Health declines can precipitate downward spirals, setting off impoverishment and further ill health. For example, the effect of HIV/AIDS on per capita GDP could prove devastating in the long run. An enormous waste of human capital occurs as prime-age workers die. A high-mortality environment deters the next generation from investing in education and creating human capital. The creation of a generation of orphans means that children may be forced to work to survive and may not get the education they need. High rates of mortality may reduce investment. Saving rates are likely to fall, and retirement becomes less likely. A foreign company is less likely to invest in a country with a high HIV prevalence rate because of the threat to the firm’s own workers, the prospect of high labor turnover, and the loss of workers who have gained specific skills by working for the firm. The International Monetary Fund recently published a collection of important studies of the multiple mechanisms through which a major AIDS epidemic can be expected to affect national economies (Haacker 2004).

Health and Economic Welfare

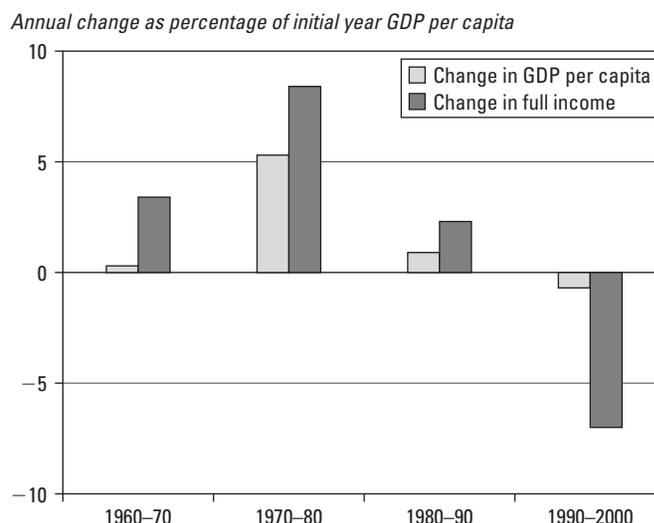

Judging countries’ economic performance by GDP per person fails to differentiate between situations in which health conditions differ: a country whose citizens enjoy long and healthy lives clearly outperforms another with the same GDP per person but whose citizens suffer much illness and die sooner. Individual willingness to forgo income to work in safer environments and social willingness to pay for health-enhancing safety and environmental regulations provide measures, albeit approximate, of the value of differences in mortality rates. Many such willingness-to-pay studies have been undertaken in recent decades, and their results are typically summarized as the *value of a statistical life* (VSL). Chapter 7 discusses these issues in the context of assessing the economic returns to investments in health research and development.

Although the national income and product accounts include the value of inputs into health care (such as drugs and physician time), standard procedures do not incorporate information on the value of changes in longevity. In a seminal paper, Usher (1973) first brought the value of mortality reduction into national income accounting. He did this by generating estimates of the growth in what Becker, Philipson, and Soares (2003) have called *full income*—a concept that captures the value of changes in life expectancy by including them in an assessment of economic welfare. Estimates of changes in full income are typically generated by adding the value of changes in annual mortality rates (calculated using VSL figures) to changes in annual GDP per person. These estimates of change

in full income are conservative in that they incorporate only the value of mortality changes and do not account for the total value of changes in health status. Valuation of changes in mortality, it should be noted, is only one element—albeit a quantitatively important one—of potentially feasible additions to national account to deal with nonmarket outcomes. The U.S. National Academy of Sciences has recently proposed broad changes for the United States that would include but go beyond valuation of mortality change (Abraham and Mackie 2005).

For many years, little further work was done on the effects of mortality change on full income although, as Viscusi and Aldy (2003) document, the number of carefully constructed estimates of VSLs increased enormously. Bourguignon and Morrisson (2002) address the long-term evolution of inequality among world citizens, starting from the premise that a “comprehensive definition of economic well-being would consider individuals over their lifetime.” Their conclusion is that rapid increases in life expectancy in poorer countries had resulted in declines in inequality (broadly defined) beginning sometime after 1950, even though income inequality had continued to rise. In another important paper, Nordhaus (2003) assessed the growth of full income per capita in the United States in the 20th century. He concludes that more than half of the growth in full income in the first half of the century—and less than half in the second half of the century—had resulted from mortality decline. In this period, real income in the United States increased sixfold and life expectancy increased by more than 25 years.

Three lines of more recent work extend those methods to the interpretation of the economic performance of developing countries. All reach conclusions that differ substantially from analyses based on GDP alone. Two of those studies—one undertaken for the Commission on Macroeconomics and Health (CMH) of the World Health Organization (WHO) (Jamison, Sachs, and Wang 2001) and the other at the International Monetary Fund (Crafts and Haacker 2004)—assessed the impact of the AIDS epidemic on full income. Both studies conclude that the AIDS epidemic in the 1990s had far more adverse economic consequences than previous estimates of effects on per person GDP growth would suggest. Accounting for mortality decline in Africa before the 1990s, on the other hand leads to estimates of much more favorable overall economic performance than does the trend in GDP per person. Figure 1.3 shows that in Kenya, for example, full income grew more rapidly in GDP per person before 1990 (and far more rapidly in the 1960s). After 1990 the mounting death toll from AIDS appears to have only a modest effect on GDP per person but a dramatically adverse impact on changes in full income. Becker, Philipson, and Soares (2003) extended the earlier work of Bourguignon and Morrisson (2002) in finding strong absolute convergence in full income across countries over time, in contrast to the standard finding of continued divergence (increased inequality) of GDP per person. Finally,

Source: Jamison, Sachs, and Wang 2001.

Figure 1.3 Changes in GDP and Full Income in Kenya, 1960–2000

Jamison, Jamison, and Sachs (2003) have adapted standard cross-country growth regressions to model determinants of full income (rather than GDP per person). Like Becker, Philipson, and Soares (2003), they conclude that inequalities have been decreasing.

The dramatic mortality declines of the past 150 years—and their reversal in Africa by AIDS subsequent to 1990—have had major economic consequences. The effect of health on GDP is substantial. The intrinsic value of mortality changes—measured in terms of VSL—is even more substantial. What are the implications of these findings for development strategy and for benefit-cost analyses of public sector investment options? Using full income in benefit-cost analyses of investments in health (and in health-related sectors such as education, water supply and sanitation, and targeted food transfers) would markedly increase estimates of net benefits or rates of return. A careful, quantitative reassessment of competing policies for improving a country’s living standards would probably conclude that development assistance and budgetary allocations to health deserve greater relative priority.

WHY HAS MORTALITY DECLINED AT SUCH DIFFERENT RATES IN DIFFERENT COUNTRIES?

This section explores some of the reasons mortality has declined so rapidly and at such different rates in different countries. It considers the question of whether income levels or growth rates play an important role in achieving better health or whether good policies can potentially lead to good health for low-income populations. The section concludes with a snapshot of health conditions in the world at the dawn of the 21st century.

The 20th century witnessed huge and unprecedented declines in mortality rates at all ages and in most parts of the world. Easterlin (1996) and Crafts (2000) place an emphasis on mortality transformation that is comparable to their emphasis on economic growth in their retrospectives on the unprecedented changes in the human condition during the 20th century. Understanding the sources of mortality changes is important for understanding one of the defining events of world history and also for devising policies to address the needs of the perhaps 25 percent of the world's population whose mortality rates remain far higher than those of the rest of humanity.

Several approaches shed light on the sources of mortality decline. Epidemiologists and demographers have carefully tracked specific communities for many years to assess levels of mortality and causes of death. In rural Senegal, rapid mortality decline followed introduction of interventions addressing specific conditions (Pison and others 1993).

Another approach is historical. Easterlin (1996, 1999) examined the interplay of economic growth, urbanization, and mortality in 19th- and 20th-century Europe. He concluded that although income growth in the 19th century probably did play a role in reducing mortality (through its influence on food availability and environmental conditions), the magnitude of the effect was small. Fogel (1997) stressed the importance of increases in food availability during this period. Positive effects of income growth were partially offset by increased infectious disease transmission resulting from urbanization. Easterlin (1999) concludes that 20th-century mortality decline, which was much more rapid than that of the 19th century, had its origin in technical progress, and Powles (2001) has pointed to the importance and nature of the institutional changes required to translate technical change and economic improvements into mortality reduction. Mosk and Johansson's (1986) assessment of the interplay between income and mortality in Japan illustrates the role that adoption of public health knowledge and institutional development played in mortality decline in the country that now has the world's lowest mortality rates.

Most analysts agree that advances in science and technology have underpinned the 20th-century transformations both of income and of mortality levels. Models of economic growth rely heavily on technological progress to account for economic change (Boskin and Lau 2000; Easterly and Levine 1997; Solow 1957). Preston (1975, 1980) and Fuchs (1974) provided early quantitative assessments of the central importance of technical progress in accounting for 20th-century increases in life expectancy. [Economists use the term *technical progress* to denote advances in knowledge that lead to new products, like vaccines, or that can inform behavior change, like knowledge of the germ theory of disease (Preston and Haines 1998).] Davis (1956) had already concluded that the unprecedented reduction in mortality in underdeveloped areas since 1940 is the result primarily of the discovery and dissemination of new

methods of disease treatment that can be applied at reasonable cost. The reduction was rapid because it did not depend on general economic development or social modernization (Davis 1956, 306–7, 314). Some strands of the literature, however, attribute the high correlation of income and life expectancy at any given time to a significant causal effect of income on health (see, for example, Pritchett and Summers 1996).

Background work for this volume (Jamison, Sandbu, and Wang 2004) attempted to provide a better sense of the importance of income as a determinant of mortality by exploring the relationships among income, technical progress (or diffusion), and mortality decline. Previous econometric research either has given little emphasis to technical progress—in part simply because much of the research is cross-sectional and therefore fails to address developments over time—or has assumed the rate of technical progress or technology adoption to be constant across countries. The background work for this volume relaxed the assumption that the rate of technology adoption is constant across countries. Allowing for cross-country variation in the rate of adapting new methods resulted in weaker estimated effects of income on infant mortality rates than previously found, although education's estimated effect was robust with respect to this change.

Much of the variation in country outcomes results from the very substantial cross-country variation in the rate of technical progress—from essentially no decline in infant mortality rate caused by technical progress to reductions of up to 5 percent per year from that source. Deaton (2004) provides a complementary and extended discussion of the importance of technological diffusion for improvements in health. Many factors from outside the health sector also affect the pace of health improvement; the education levels of populations are most important. Box 1.2 briefly discusses the multisectoral nature of health's determinants. The importance of technical progress and diffusion should be viewed in this larger context.

However technical progress or diffusion may be manifested, the large differences in its magnitude across countries suggest important effects of a country's health-related policies (Fuchs 1980; Oeppen 1999). This point bears reiterating in a slightly different way: income growth is neither necessary nor sufficient for sustained improvements in health. Today's tools for improving health are so powerful and inexpensive that health conditions can be reasonably good even in countries with low incomes.

CHILD HEALTH

A small number of conditions accounts for most of the (large) differences in health between the poor and the not so poor. Less than 1 percent of all deaths from AIDS, TB, and malaria, for example, occur in the high-income countries. Available technical options—exemplified by but going well beyond immunization—can address most of the conditions that affect

Box 1.2

The Multisectoral Determinants of Health

Malnourished children easily acquire diseases, and they easily die from the diseases that they acquire. Dwellings and neighborhoods without sanitation provide fertile environments for transmission of intestinal infections. Cooking with wood and coal results in air dense with particulates and gases, which destroy lungs and lives. Hopeless life circumstances thrust young girls (and boys) into commercial sex work with its attendant risks of violence and sexually transmitted infections, including HIV/AIDS. Manufacturers of tobacco and alcohol profit enormously from advertising and promotion that spread addiction. Rapid growth in vehicular traffic—often with untrained drivers on unsafe roads—generates a rising toll of injury. Poorly designed irrigation creates breeding grounds for vectors of disease. The point is clear: determinants of health are truly multisectoral.

WHO coordinated a group of more than 100 individuals to generate estimates of the percentage of deaths, by region and globally, associated with a range of 26 risk factors (Ezzati and others 2004). Those estimates were revised and updated for the Disease Control Priorities Project. The results give a sense of the extent to which multisectoral factors contributed to mortality and disease burden in low- and middle-income countries in 2001. The following, for example, are estimates of the percentage of disease burden (and, in parentheses, of deaths) in those countries attributable to the indicated risk factors:

- tobacco smoking—4.7 percent (8.5 percent)
- indoor air pollution—2.7 percent (3.2 percent)
- inadequate water and sanitation—3.4 percent (2.8 percent)

Source: Author.

Note: The estimates reported here of DALYs and deaths that are attributable to various risk factors come from Ezzati and others (2006).

- risky sexual activity—5.3 percent (5.1 percent)
- alcohol use—3.6 percent (3.4 percent).

Underlying most proximal risks are more general determinants of health, such as education and, to a lesser extent, income. The effects of income and education operate for the most part through influencing risk (and permitting effective use of health services). If an important fraction of ill health results from poverty and low educational levels—or from their consequences in inadequate food or sanitation or other specific risks—then ought the task of the health professional lie principally in addressing these underlying problems? In one sense, the answer is surely yes: the health community should measure the effects on health of actions outside the health sector. It should ensure that these findings are communicated and are considered by those making policy choices. The magnitude of the demonstrated effect of girls' education on health and fertility outcomes, for example, provides one powerful argument for investing in expansion of educational access to girls. Millions of premature deaths, to take another example, could be averted in Africa alone in the next quarter century with appropriate policies toward supply of energy for household use (Bailis, Ezzati, and Kammen 2005). It is essential that the health sector document and advocate opportunities such as these.

The health community has limited capacity for direct action outside the health sector, however. It will make more of a difference if it focuses its energy, expertise, and resources on ensuring that health systems efficiently deliver the powerful interventions provided by modern science.

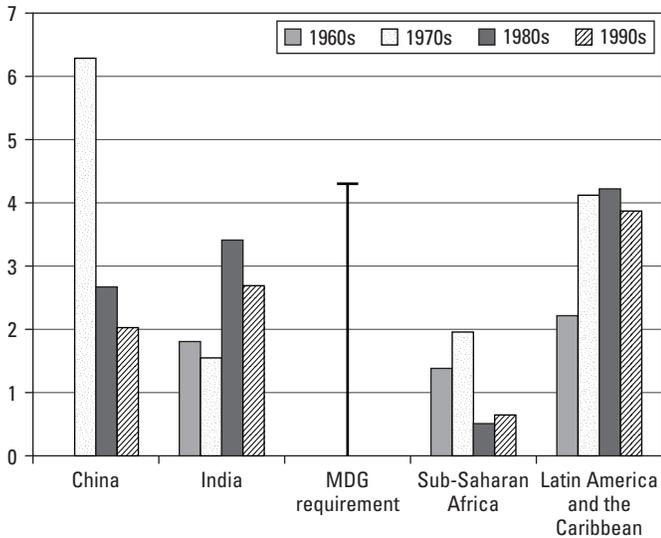

children, and can do so with great efficacy and at modest cost. That short list of conditions, including undernutrition, relates directly to achieving the MDGs for health. Public expenditures to address those conditions have, in the past, benefited the relatively well off, albeit within poor countries (although global inequities have decreased because many poor countries have made much progress).

Under-Five Health Problems and Intervention Priorities

MDG-4 for under-five mortality (reducing its level in 2015 by two-thirds relative to what it was in 1990) is highly

ambitious. Yet its implication of an average 4.3 percent per year decline is well within recent experience. In the first half of the MDG period (1990–2002), 46 countries achieved rates of decline in under-five mortality greater than 4.3 percent per year. Figure 1.4 displays trends in the rate of decline in under-five mortality relative to the requisite 4.3 percent per year for China, India, Latin America and the Caribbean, and Sub-Saharan Africa. Africa's slowed progress probably stems mostly from HIV/AIDS and the spread of resistance to previously effective and widely used antimalarial drugs. Map 2 (on the inside back cover of this

Rate of decline of under-five mortality rates (percent)

 Note: The black bar in the center shows the 4.3 percent per year rate of decline required for the period 1990–2015 to meet MDG-4 of reducing under-five mortality by two-thirds.

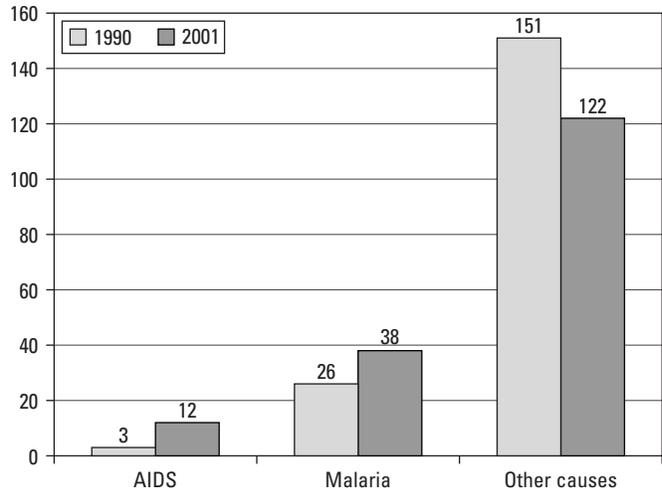

Figure 1.4 Rate of Progress in Reducing Under-Five Mortality, 1960–2000: China, India, Latin America and the Caribbean, and Sub-Saharan Africa

book) shows country-specific progress in reducing under-five mortality:

- Countries colored in green experienced annual rates of decline greater than 4.3 percent in the first half of the MDG period (1990–2002).
- Countries colored in red saw no decrease (or an increase) in their under-five mortality.
- Countries colored in yellow and orange depict countries in between—with yellow indicating performance in the top half of the range between 0 and 4.3 percent, and orange indicating poorer performance in the bottom half of the range.

Basic knowledge about the cost-effectiveness of interventions to address maternal and child health has been available from the 1980s. *DCP2*'s work provides a reassessment with few surprises but some additions. It makes two important relatively new points. The first results from noting that half of under-five deaths occur at ages less than 28 days, when the substantial but usually neglected problem of stillbirth is considered. *DCP2* identifies some highly cost-effective approaches to intervention against stillbirth and neonatal death (chapter 27). The second new point results from the rapid spread of resistance of the malaria parasite to chloroquine and sulfadoxine-pyrimethamine (SP). These inexpensive, highly effective, widely available drugs provided an important partial check on the high levels of malaria mortality in Africa. Their loss is

Under-five deaths per 1,000 births

Source: Lopez, Begg, and Bos 2006, table 2.4.

Figure 1.5 Under-Five Deaths from AIDS, Malaria, and Other Causes, per Thousand Births, 1990 and 2001, Sub-Saharan Africa

leading to an even greater rise in malaria mortality and morbidity that could be substantial. Figure 1.5 illustrates increases in malaria death rates in under-five children in Sub-Saharan Africa in the period from 1990 to 2001. The design of instruments for financing a rapid transition to effective new treatments—artemisinin combination therapies (ACTs)—is a high priority (chapter 21; Arrow, Gelband, and Jamison 2005).

The other intervention priorities for addressing under-five mortality are for the most part familiar:

- Expand immunization coverage.
- Expand the use of the simple and low cost but highly effective treatments for diarrhea and child pneumonia through integrated management of childhood illness or other mechanisms.
- Prevent transmission of and mortality from malaria by expanding coverage of insecticide-treated bednets, by expanding use of intermittent preventive treatment for pregnant women, and, particularly, by financing the adoption of ACTs to replace the now widely ineffective drugs chloroquine and SP.
- Ensure widespread distribution of key micronutrients.
- Expand the use of a package of measures to prevent mother-to-child transmission of HIV (further discussed in the next section on HIV/AIDS).

In addition to interventions to reduce under-five mortality, one other priority is clear. The world's most prevalent infections are intestinal helminth (worm) infections, and children of all ages are among the most heavily affected. Chapter 24 discusses these infections, which a low-cost drug (albendazole),

taken every six months to a year, can control effectively. Chapter 58 on school health services points to both the importance to children's school progress of taking albendazole where needed and the potential efficacy of school health programs as a vehicle for delivery. In the long run, improved sanitation and water supplies will prevent transmission. Use of albendazole is only an interim solution, but it is one that may be required for decades if the experience of the currently high-income countries is relevant.

Delivering Child Health Interventions

The list of potential interventions is far from exhaustive, and different regions, countries, and communities will face different mixes of the problems these interventions address. However, there can be little dispute that any short list of intervention priorities for under-five mortality in low- and middle-income countries would include many on the list in the preceding section. Why not, then, simply put money into scaling up these known interventions to a satisfactory level?

To greatly oversimplify—and these issues are discussed more substantially in chapter 3—two schools of thought exist. One line of thinking—often ascribed to macroeconomist Jeffrey Sachs and his work as chair of the WHO CMH—concludes that more money and focused effort *are* the solutions. Although acknowledging dual constraints—of money and of health system capacity—Sachs and his colleagues (WHO CMH 2001; Sachs 2005) contend that money can buy (or develop, or both) relevant system capacity even over a period as short as five years. Major gains are affordable and health system capacity constraints can be overcome. Immunization provides an example of where, even in the short term, money can substitute for system capacity. Adding antigens for *Haemophilus influenzae* type B (Hib) and hepatitis B (HepB) to the immunization schedule is costly (although still cost-effective). In some environments, however, it proves less demanding of system capacity than expanding coverage does. Money can be effectively spent by adding antigens at the same time as investing in the capacity to extend coverage.

A second school of thought acknowledges the need for more money but asserts that health system capacity is often a binding short- to medium-term constraint on substantial scaling up of interventions. Critical priorities are, therefore, system reform and strengthening while ensuring that such reforms focus clearly on achieving improved health outcomes and financial protection.

Chapter 3, as indicated, discusses these issues further in the context of all the problems facing a health system, and chapter 9 provides a thoughtful assessment of how to overcome the constraints facing achievement of the MDGs for health. From an individual country's perspective, however, if financial resources are available, the question is very much an empirical one: to what extent can those resources be effectively deployed

in buying interventions, in buying out of prevailing system constraints, and in investing in relevant system capacity for the future? What needs to be constantly borne in mind throughout this continued controversy is that *something* works: under-five mortality rates have plunged by more than half since 1960 in the low- and middle-income countries.

HIV/AIDS

For dozens of countries around the world—including several of the most populous—the AIDS epidemic threatens every aspect of development. No other threat comes close, with the possible exceptions of use of nuclear weapons in densely populated areas or a devastating global pandemic similar to the 1917–18 influenza episode. Most governments of affected low- and middle-income countries and most providers of development assistance have only recently begun to respond more than minimally. Creation of the Global Fund to Fight AIDS, Tuberculosis, and Malaria can be viewed as an attempt of the world's top political leaders to improve on the records of existing institutions. The Global Fund's initial years have seen substantial success, but that success is potentially undermined by sharp constraints on resource availability (Bezanson 2005).

Tools to Control the Epidemic

In contrast to the initially slow programmatic movement of most national leaders and international institutions, the research and development community—public and private—has made rapid progress in developing tools to control the HIV/AIDS epidemic, although both a vaccine and a curative drug remain distant objectives. Sensitive, specific, and inexpensive diagnostics are available; means of prevention have been developed and tested; modes of transmission are well understood; and increasingly powerful drugs for controlling viral load allow radical slowing of disease progression. Tools for dealing with HIV/AIDS are thus available: As emphasized in chapter 18, a number of countries show by example that those tools can be put to effective use. Most of the high-income countries have done so, and Brazil and Mexico provide examples of upper-middle-income countries that have forestalled potentially serious epidemics. Mexico succeeded, for example, with a policy of responding both early and forcefully to the epidemic (del Rio and Sepúlveda 2002). The major successes of Thailand and Uganda demonstrate that countries with fewer financial resources can also succeed—and succeed against more established epidemics that had already penetrated deeply into their populations.

Prevention and Management

Prevention underpins success. At the time the World Bank's *World Development Report: Investing in Health* (World Bank

1993) was being written in 1992 and 1993, the only tool for dealing with the epidemic was prevention. In collaboration with the then–Global Programme against AIDS at WHO, the *World Development Report* commissioned very approximate estimates of the consequence for the new infection rate of fully implementing available preventive measures (its optimistic case scenario) or of doing very little (worst case). Actual incidence numbers for 2000, unfortunately, fall very close to the worst-case projection, and chapter 18 points out that even by 2003 fewer than one in five people at high risk of infection had access to the most basic preventive services. In much of the world, little has been spent on prevention, and little has been achieved. In addition, the current U.S. administration may be partially responsible for discouraging condom use in some countries and in stigmatizing and alienating commercial sex workers who are particular priorities for prevention programs. Despite those problems, the potential for prevention is very real, and a number of successful countries have shown the possibility of using that potential well. Chapter 17 on sexually transmitted infections (STIs) and chapter 18 on AIDS discuss a broad menu of preventive measures and experiences with their implementation. Among them, treatment of STIs may be of particular salience both because the diseases are well worth treating in their own right and because the absence of STIs greatly reduces transmission of HIV.

In addition to prevention, better management of patients with AIDS could avert much misery, both by treating opportunistic infections and by ameliorating the often excruciating pain associated with many AIDS deaths. Medically inappropriate restrictions on the use of inexpensive but powerful opiates for pain control continue to deny dignity and comfort to millions of patients with AIDS and cancer in their final days (chapter 52).

Antiretroviral Treatment

Intensive research and development efforts have led in the past decade to the availability of well over a dozen antiretroviral drugs that can greatly reduce the quantity of HIV in an infected person. This reduction in viral load slows or halts progression of AIDS and can return individuals from serious illness to reasonable health. Available drugs leave a residual population of HIV in the body, however, and this population grows if the drugs are stopped. At present the drugs must be taken for life. Widespread use of these drugs in high-income (and some middle-income) countries has transformed the life prospects of HIV-infected individuals.

Early generation antiretroviral drugs suffered notable shortcomings: they were enormously costly; regimens for their use were complicated, making adherence difficult; their use generated unpleasant side effects; and rapid evolution of HIV led to

resistant mutants that undermined the efficacy of therapy. In a remarkably short time, scientific advances have substantially attenuated those problems, making feasible, at least in principle, antiretroviral therapy in low-income settings. WHO’s “3 by 5” program had as its objective, for example, to reach 3 million people in low- and middle-income countries with antiretroviral therapy by 2005. Although that goal was far from being met, the global effort to make treatment widely available is well under way.

Despite the indicated progress against the problems with antiretroviral drugs, challenges to their effective use in low-income environments remain formidable. The complexity of patient management is very real. Management requires high levels of human resources and other capacities in many of the countries where those capacities need to be most carefully rationed. Perhaps in consequence, achieving effective implementation has been difficult on even a limited scale. Chapter 18 reviews those problems and how they might be addressed.

Three points concerning widespread antiretroviral drug use are particularly noteworthy:

- Poor implementation (low adherence, development of resistance, interruptions in drug supplies) is likely to lead to very limited health gains, even for individuals on therapy. (This outcome is unlike that of a weak immunization program in which health gains still exist in the fraction of the population that is immunized.) Poorly implemented antiretroviral drug delivery programs could divert substantial resources from prevention or from other high-payoff activities in the health sector. Even worse, they could lead to a false sense of complacency in affected populations: evidence from some countries suggests that treatment availability has led to riskier sexual behavior and increased HIV transmission. The injunction to “do no harm” holds particular salience.
- Unless systematic efforts are made to acquire hard knowledge about which approaches work and which do not, the likelihood exists that unsuccessful implementation efforts will be continued without the appropriate reallocation of resources to successful approaches. Learning what works will require major variations in approach and careful evaluation of effects. Failing to learn will lead to large numbers of needless deaths. Most efforts to scale up antiretroviral therapy unconscionably fail to commit the substantial resources required for evaluation of effects. Such evaluations are essential if ineffective programs are to be halted or effective ones are to receive more resources.
- Many programs rely exclusively on the cheapest possible drugs, thereby risking problems with toxicity, adherence, and drug resistance. From the outset a broader range of drug regimens needs to be tested.

NONCOMMUNICABLE DISEASE AND INJURY

At the same time that most low- and middle-income countries need to address health problems that are now effectively controlled in high-income countries, they are increasingly sharing the high-income countries' heavy burdens of cardiovascular system disease (chapters 33, 44, and 45); cancers (chapter 29); psychiatric disorders (chapter 31); and automobile-related injuries (chapter 39). The public health research and policy community has been surprisingly silent about these epidemics even though, for example, cardiovascular disease (CVD) in low- and middle-income countries killed over twice as many people in 2001 as did AIDS, malaria, and TB combined (table 1.A1). An important early exception is Feachem and others (1992), who indicated approaches to treatment and prevention of these conditions that can be adapted to the tighter budget constraints of developing countries. The World Health Organization provides a valuable and more up-to-date discussion that emphasizes prevention (WHO 2005). In addition, low-cost but effective approaches to long-term management of chronic conditions need to be developed and implemented.

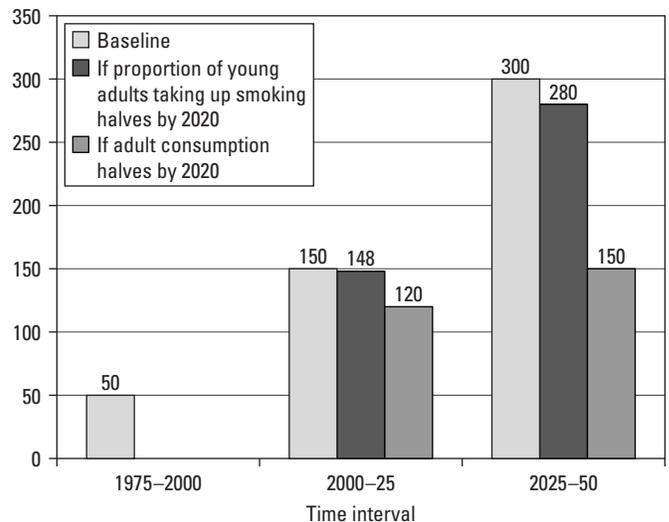

The remainder of this section briefly discusses, as examples, the prevention and management of cardiovascular diseases, psychiatric disorders, and injuries.

Cardiovascular Disease

Cardiovascular diseases in low- and middle-income countries result in about 13 million deaths each year, over a quarter of all deaths in those countries. Most cardiovascular deaths result from ischemic heart disease (5.7 million) or cerebrovascular disease (4.6 million). Because such deaths occur at older ages, they account for a substantially smaller fraction of total disease burden in disability-adjusted life years (DALYs)—12.9 percent—than they do of deaths (table 1.A2).

Growing tobacco use accounts for a substantial and avoidable fraction of CVD and of cancers. Reasonable projections show the number of tobacco-related deaths to be not only large but also growing, particularly in developing countries. In 2000, the number of tobacco-related deaths in developing countries about equaled the number in high-income countries; projections suggest that by 2030 developing countries will have more than twice as many. For those reasons, controlling smoking is a key element of any national strategy for preventing CVD or for promoting health more generally. Preventing the initiation of smoking is important because addiction to tobacco makes smoking cessation very difficult, even for the numerous individuals who would like to do so. However, helping people quit smoking is at least as important as preventing initiation. Figure 1.6 portrays estimates showing that far more lives could be saved between now and 2050 with successful efforts to help people stop smoking than with efforts to keep them from

Tobacco deaths worldwide in the indicated quarter century (millions)

Source: Chapter 46, figure 46.2. Adapted from Jha and Chaloupka 2000; Peto and Lopez 2001.

Figure 1.6 Increase in Tobacco-Related Deaths as Populations Age

starting. Reducing smoking levels is well demonstrated to be within the control of public policy. The principal instrument is through taxation: Complementary measures discussed in chapter 46 are important as well.

The main risk factors for CVD account for very large fractions of the deaths (and even more of the burden) from those diseases. For ischemic heart disease, they collectively account for 78 percent of deaths in low- and middle-income countries; for stroke, they account for 61 percent (Ezzati and others 2006). Measures to reduce the levels of those risk factors—high blood pressure, high cholesterol, smoking, obesity, excessive alcohol use, physical inactivity, and low fruit and vegetable consumption—are the goals for prevention. Unlike the favorable experience with controlling tobacco use, attempts to change the behaviors leading to obesity, hypertension, high cholesterol, or physical activity appear to have had little success at a population level. However, as chapter 44 documents, many promising approaches remain to be tried. Common sense suggests that they should be initiated even while more systematic efforts to develop and evaluate behavior-change packages are ramped up.

Pharmaceutical interventions to manage two major components of cardiovascular risk—hypertension and high cholesterol levels—are well established and are highly cost-effective for individuals at high risk of a stroke or heart attack. From at least the time of publication of *Disease Control Priorities in Developing Countries*, 1st edition (DCPI), researchers have recognized that the low cost and high effectiveness of drugs to prevent the reoccurrence of a cardiovascular event made their long-term use potentially cost-effective in low-income

environments (Pearson, Jamison, and Trejo-Gutierrez 1993). Even if sustained behavior change proves difficult to achieve, medications have the potential to reduce CVD risks by 50 percent or more. Chapters 33 and 45 develop the current evidence on that point. A key problem, however, concerns the health care personnel and systems requirements associated with the need for lifelong medication use, a problem also faced with antiretroviral therapy for AIDS and the use of medications to target several major psychiatric disorders. How to achieve effective long-term management of lifesaving drugs is a key delivery and research challenge for health system reformers.

In contrast to the lifelong requirement for drug use associated with CVD risk reduction in high-risk individuals, treatment of acute heart attacks with inexpensive drugs is both less demanding of system resources and highly cost-effective (chapter 45). Given the high incidence of these problems, systemwide efforts to achieve high rates of appropriate drug use in response to acute heart disease are a high priority.

Psychiatric Disorders

Although neurological and psychiatric disorders lead to only about 1.4 percent of deaths in low- and middle-income countries (1.8 percent in high-income countries), they cause suffering and disability far beyond what the mortality numbers suggest. About 10 percent of disease burden in DALYs in low- and middle-income countries results from these conditions; three major psychiatric diseases—unipolar major depression (3.1 percent of DALYs), bipolar disorder (0.6 percent), and schizophrenia (0.8 percent)—account for much of it (table 1.A2).

Chapter 31 provides a concise overview of advances made in recent years in treating these conditions (as well as panic disorder), summarizes information on their burden, and develops estimates of the cost-effectiveness of drug-based and cognitive behavioral therapies in different settings (hospital based and community based). Although the cost-effectiveness estimates reported in chapter 31 suggest interventions are only moderately cost-effective, the authors suggest that a fuller analysis of benefits than is captured by a health metric such as the DALY would justify substantial investments. They analyze a basic package of mental health services that could provide a practical vehicle for providing these interventions in environments with tightly constrained financial and implementation resources. A continuing theme in this volume—and one of particular relevance here—is that without careful evaluations of the effects of alternative approaches to large-scale intervention against psychiatric disorders, the world will fail to develop hard knowledge of what does—and does not—work. Without that knowledge, far less health and financial security will be gained than is potentially possible from the inevitably limited resources available.

Injuries

Injuries constitute an additional major and neglected component of disease burden in developing countries. This volume's chapters on injury (chapters 39 and 40) emphasize prevention. Timely treatment is also important, and chapters 67 (on surgery) and 68 (on emergency medical services) point to the potential, at low cost, for much better treatment of injury victims than is typical today.

The great diversity of both causes and consequences of injury precludes an attempt in this chapter to do more than highlight their importance. Chapter 2 and the injury-related chapters just mentioned provide a rich menu of practical options. It is worth pointing out here the central importance of two specific categories of injury—road-traffic injuries (1.07 million deaths in 2001 in low- and middle-income countries) and suicides (0.75 million deaths). Safer roads, safer driving, safer vehicles, and better emergency care have sharply reduced the toll from road-traffic injuries in high-income countries, but unless dramatic action is taken in developing countries, the toll will surely rise. Although there has been less success in reducing suicide rates, the improved treatments now available for psychiatric disorders are proving to be one important approach in suicide prevention.

This discussion of noncommunicable diseases and injury highlights the huge and growing burden from those conditions and conveys a consistent message that constructive action is feasible at relatively modest cost. No attempt has been made to be comprehensive (chapters 29 through 38 all deal with noncommunicable diseases); rather the discussion points to the need for health systems to systematically incorporate effective responses to noncommunicable diseases and injuries as their capacities grow.

HEALTH SYSTEM DEVELOPMENT AND FINANCE

DCPI focused principally on intervention priority. What mix of public health and clinical interventions would best respond to important disease conditions in highly resource constrained environments? Given the results of those assessments, where were the most important overall best buys? Where were resource commitments likely to be of low value? *DCP2* returns to those questions but goes beyond them in assessing the steps required for strengthening of health services and systems in ways that will allow the appropriate mix of interventions to be delivered equitably and well. De Savigny and others (2004) describe a specific example from Tanzania that links system reform to intervention selection.

Part 3 of the volume addresses strengthening of health systems. For valuable discussions of the goals of health systems, see WHO's *World Health Reports* for 1999 and 2000 (WHO 1999, 32–33; 2000, 23–25) and Roberts and others (2003).

Part 3 first reviews options for public health services with chapters on surveillance and information (chapters 53 and 54), drug resistance (chapter 55), community health and nutrition programs (chapter 56), contraception (chapter 57), school-based health (chapter 58), adolescent health (chapter 59), occupational health (chapter 60), natural disaster relief (chapter 61), and disease elimination and eradication (chapter 62). A major point implied by the simple number of chapters devoted to public health is that health system strengthening and reform efforts need to commit substantial financial resources and political and managerial attention to public health.

A second cluster of chapters in part 3 deals with strengthening personal health services. The first of those chapters deals with an important facet of community-level health services, the integrated management of the sick child (chapter 63). Chapters 64 to 66 deal with levels of care: general primary care, the district hospital, and the referral hospital, respectively. Three chapters address services offered at multiple levels of the system: surgery (chapter 67), emergency medical services (chapter 68), and complementary and alternative medicine (chapter 69). The final cluster of four chapters addresses capacity strengthening and management reform: quality of care (chapter 70), the health workforce (chapter 71), supplies of drugs and vaccines (chapter 72), and management of clinical services (chapter 73).

This overview of the topics on health systems provides a sense of the breadth of the issues considered. Chapter 3 provides a concise and integrated statement of the main findings. The remainder of this section deals briefly with assessing the performance of health systems and with the key issue of finance. Before we turn to those topics, however, it is worth highlighting several particular points.

First, in low-income countries, limited health system capacity has sometimes led governments (and development assistance agencies) to focus their capacity on a few high-priority items—such as immunization or control of HIV/AIDS. The objective may be a reasonable one: a greater reduction in disease burden in the population and more financial protection for it are likely to be achieved by doing a few important things well than by doing many things poorly. Yet if this focused effort is undertaken by establishing vertical structures outside the health system, then important opportunities for increasing capacity may be missed. Chapter 3 stresses a critical point: a focused program should be designed so that it contributes to, rather than detracts from, long-term system strengthening. Second, quality of care is important; it can be measured, and it can be improved (box 1.3). Third, providing basic surgical services, particularly at the district hospital level appears to offer major but neglected opportunities for addressing

Box 1.3

Tangible Approaches to Improving Quality of Care

A 2001 report from the Institute of Medicine of the U.S. National Academy of Sciences (Institute of Medicine 2001b) highlights great variation in the quality of clinical care in the United States. Its publication catalyzed reform efforts. In a recent evaluation, Leape and Berwick (2005) found that those reform efforts had a major effect on professional attitudes and organizational culture, although less effect, so far, on mortality. Chapter 70 on quality of care documents the similarly large variation in quality in low- and middle-income countries and the associated cost in lives and money. Improving quality of care amplifies the effect of investments in health. Promising approaches in improving the quality of care include the following:

- Invest in measuring quality and feeding that information back into the system. This approach has been shown to be possible (for example, clinical vignettes) and effective.

- Use evidence-based criteria to link quality of care to outcomes. This approach can be implemented by training and creating incentives for adapting clinical guidelines or by using the collaborative improvement model.
- Improve system-level and provider incentives. Minimally, do no harm with the structure of financial incentives facing providers, for example, by establishing a legal and ethical environment where care providers do not profit personally from sale of drugs, diagnostic procedures, or referrals to expensive specialized care.
- Emphasize high-volume care for selected surgical procedures and prevalent medical conditions. Such an approach can lead to higher quality and lower cost even while, in some cases (for example, cataract removal), allowing lower-level workers to substitute for more expensive and scarcer physicians.

Source: This box was prepared with input from John Peabody.

significant sources of disease burden. An important substantive component of health sector reforms should often involve strengthening surgical capacity.

Health System Performance

Since about 1940, the publication of economic performance indicators in national income and product accounts has made it possible to hold political leaders accountable for economic management. Additionally, measures of economic performance—such as GDP growth rates and unemployment rates—have allowed economists to move toward evidence-based assessments of which policies facilitate good economic performance and which do not.

In many ways, unfortunately, the assessment of health system performance remains where economic performance measures were before the development of national income and product accounts in the United Kingdom in the late 1930s. Chapter 3 observes, for example, that “The body of knowledge [on health systems] represents a largely ad hoc and disjointed collection of facts, figures, and points of view. Making confident recommendations relevant to strengthening health system capacity is thus difficult.” In its 2000 *World Health Report*, WHO made an ambitious effort to provide the performance measures for health systems that would enable progress toward more systematic knowledge of the policies to improve health systems (WHO 2000). Such knowledge could replace what is now frequently simply ideology and opinion. The 2000 *World Health Report* proved to be highly controversial, and its ranking of health system performance may in the end be judged as more of a first attempt than an initial approximation (Jamison and Sandbu 2001). WHO set an agenda that will certainly continue to be advanced.

Despite current inability to judge health system performance and the consequently ad hoc character of knowledge, much is in fact known that bears on health policy. Chapters 2 and 3 of this volume summarize very specific knowledge about intervention characteristics and system design that can inform policy. Although broad prescriptions may still elude us, particular knowledge is still important. Additionally, the perform-

ance of countries is better understood even though relating country performance to performance of its health systems may remain only judgmental for the moment. For example, Brazil and China had under-five mortality rates that were quite close in 2002: 37 per 1,000 for Brazil and 38 per 1,000 for China. In 1990, however, Brazil’s rate was 60 per 1,000 and China’s was 49 per 1,000: the rate of improvement in Brazil was far more rapid than in China. This measure is only one dimension of outcome, and many explanations are possible. Yet hard numbers on country perform do exist to initiate discussions of policy.

Financing Health Services

Chapters 12 and 13 in this volume discuss domestic and external financing of health systems. Different issues arise in low-income countries than in middle-income ones, and the discussion that follows is so divided. Table 1.2 provides context by conveying the level of health expenditures in 2001 in different income groupings of countries, the fraction of GDP spent on health, and the extent to which those expenditures are publicly financed. Almost 10 percent of the total product of the world pays for health services. In the low-income countries, about three-quarters of expenditures are from private, out-of-pocket payment. In the high-income European countries, only about one-quarter of expenditures is private. Middle-income countries spend about 5 times as much per capita on health services as do low-income ones and over 10 times as much through the public sector. Although available data sets (for example, from the World Bank or WHO) provide no direct evidence on trends over time in health expenditures (for more than very short periods), current levels of expenditure are likely to substantially exceed those of several decades ago, even as a percentage of growing incomes. The availability of physicians provides one indicator: in a large sample of countries the number of physicians per 100,000 population increased from 54 in the mid 1960s to 116 in the early 1990s, an annual rate of increase of 2.8 percent.

Before we turn to questions of financing health services (or insurance), briefly discussing related issues concerning the public sector’s financial role is worthwhile. Those issues address

Table 1.2 Health Expenditures by Country Income Level, Public and Total, 2001

Country group	Health expenditure per capita (2001 US\$)	Health expenditure (percentage of GDP)	Public sector expenditures (percentage of total health expenditures)
Low income	23	4.4	26.3
Middle income	118	6.0	51.1
High income (Countries in the European Monetary Union)	2,841 (1,856)	10.8 (9.3)	62.1 (73.5)
World	500	9.8	59.2

Source: World Bank 2004, table 2.14.

what chapter 11 calls “healthy fiscal policy and fiscal policy for health.” An example of unhealthy fiscal policy was the Polish government’s subsidy of fatty animal products. Elimination of that subsidy was a gain for the treasury and resulted in improved diets and health. Minimally, a healthy fiscal policy identifies and corrects such inappropriate subsidies. Fiscal policy for health is exemplified by tobacco taxation, which chapter 46 deals with at length and chapter 11 deals with more briefly. Fiscal policy for health involves taxes whose principal purposes lie more in changing health-related behaviors than in generating revenue (although the latter can be important as well).

Financing Health in Middle-Income Countries. A major cause of poverty (and economic insecurity more generally) results from highly uneven and unpredictable needs to finance health expenditures. In consequence, most societies have moved toward prepaid care as income rises. The current high-income countries, with only two exceptions, have decided in favor of universal public financing (rather than private voluntary insurance) as the principal means of meeting the demand for prepaid care. Taiwan (China) and the Republic of Korea, several years ago, and Mexico and Thailand more recently, have also taken the path toward universal public financing. The health sector is exceptional: no one in the mature capitalist democracies would contemplate substantial public financing for food or housing, and public subsidies and protection for agriculture result from unusually powerful interest groups.

Public financing for health, including for clinical services for well-off individuals, has been the result of the democratic process in all the major capitalist countries except Switzerland and the United States. (Public financing is, of course, consistent with private provision of services, and the countries of the Organisation for Economic Co-operation and Development (OECD) display substantial diversity in this regard.) Efficiency as well as equity concerns underlie this pattern. Barr (2001) examines in detail the efficiency rationales that have underpinned major public sector financial involvement in health, education, and social protection in the high-income countries.

Why do market economies choose public sector financing (either public spending or publicly mandated social insurance) for many of their personal clinical services? The case for publicly financing interventions that are shared by all (for example, antitobacco advertising or water fluoridation) or where significant externalities exist (such as interruption of transmission of TB by treatment of infections) is widely accepted. Providing personal clinical services, like hernia repair, has none of those attributes. Nonetheless, as Arrow (1963) articulated in a now-classic article, the pervasiveness of incomplete information for decision makers (patients, providers, insurers) dominates private health insurance and delivery of clinical services. These personal clinical services account for the bulk of health expenditure. The evidence is

increasingly clear that a strong government presence in finance is the least bad way of dealing with these problems. Such a presence is necessary to achieve universal access to health care and makes it easier to impose the hard budget constraints that impose discipline in resource allocation. Additional evidence indicates that introducing universal mandatory health coverage favorably affects both wages and employment levels. Gruber and Hanratty (1995) provide thorough documentation of these effects in Canada. Some combination of these factors likely underpins the choices of the high-income democracies to fund a large fraction of private clinical services with public resources.

Public financing of services for all does not imply that all services can be provided. Indeed, given their resource constraints, countries face hard choices about what to include (and exclude) in the universal benefits package—choices that this volume seeks to inform.

Middle-income countries vary substantially in the extent to which health care providers are financed on a fee-for-service basis—that is, by direct payment for specific services. Although that is traditionally the chief way to pay for *private* care, it is worth clarifying that *government* providers can also be financed (legally or illegally) on a fee-for-service basis—as is increasingly the case in China, for example. Similarly, providers are sometimes compensated through other means, such as capitation, and individual physicians in the private sector are sometimes on salary or a combination of salary plus capitation. Out-of-pocket payments to a public sector provider are usually called *user fees*, but they differ little from fee-for-service compensation of private providers.

What is the OECD experience with user fees? Basically, it is that both providers and patients respond strongly to the incentive environment. Indeed, a problem exists of providers being too responsive: much low-value or useless surgery, diagnosis, and drug use is, in some systems, highly profitable to the provider, and often the provider must, as agent for the patient, decide what to do. This conflict of interest has led to cost escalation and to inappropriate care. A case may be made for divorcing provider compensation from the delivery of individual services, drugs, or diagnostic tests unless a need exists to accelerate coverage of critical services by giving bonuses to providers for providing them, as the United Kingdom’s National Health Service has done with immunization.

If fee-for-service financing can generate a perverse incentive environment, does that imply that a system must forgo charging beneficiaries for services they receive? Not at all: other ways exist to ensure that funds are adequate for costs—ways that may be more effective. Earmarking payroll taxes to finance health care for workers and their dependents (usually called *social insurance*) is one approach for recovering costs that is consistent with provider compensation mechanisms relying principally on salaries or capitation rather than fee-for-service. It has been argued that cost recovery through payroll taxes

will generate more economic distortions than do income, consumption, or sin taxes—although recent evidence suggests that may not be true (Blanchard and Katz 1997). Nonetheless, when general revenue mechanisms are incapable of financing the nationally defined basic package of services for all, the option of cost recovery through payroll taxes for the privileged workers in the formal sector is clearly desirable on equity grounds. This form of taxation also links contributions to a specific service, which increases its acceptability.

Financing Health in Low-Income Countries. Approximately 2.5 billion people live in countries the World Bank classifies as low-income—that is, with a per capita gross national income in 2002 of less than US\$735 per year. These countries include India but not China. Table 1.2 reflects that the estimated average per capita health expenditure for these 2.5 billion people is about US\$23 per year, of which US\$5 or US\$6 comes from public sources. Chapter 12, on financing health systems, points to the severe challenges in setting priorities that these resource limitations imply. Not only are expenditure levels currently very low, but also the fiscal space needed to increase them is, in most low-income countries, sharply constrained. Fiscal space results from an excess of potential government revenues, including reasonable projections of official development assistance (ODA), over public expenditures. The concept of fiscal space combines both short-term fiscal balance and long-term debt sustainability. Grant ODA can help with short-term balance, and soft loans (such as International Development Association credits from the World Bank) can reduce the repayment burden from a given level of incurred debt. Health financing policy for low-income countries must focus heavily on mobilizing public sector resources and concentrating resources on true priorities (although the broader range of issues just discussed that middle-income countries must address is relevant to low-income countries with large formal sectors).

The chapters in this volume make clear that incremental resources for health, well spent, could have an enormous effect: resource mobilization is important. Increasing public sector expenditures in health by 0.5 percent or more of GDP will be possible in some countries, but not in all, and even where it is possible other investment priorities will also be pressing. However, increases of as much as 1 percent of GDP may be possible where the political will exists, as is now being attempted in India. Cost estimates for meeting just the health-related MDGs, as reported in chapter 9, can exceed that amount, and other estimates have run higher. Development assistance for health, discussed in chapter 13 and here, can expand the available resource envelope, but even multiples of current levels of development assistance would likely prove insufficient to finance attainment of the MDGs in some countries.

Achieving gains for health (and frequently concomitant gains in financial protection) requires that critical decisions be

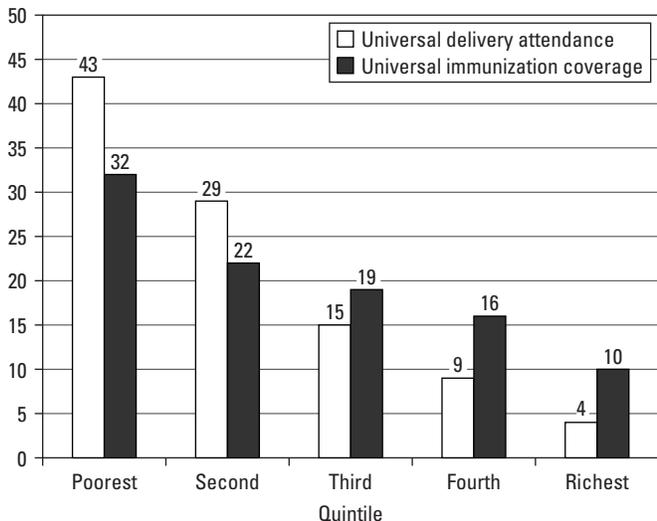

made on how to allocate highly limited public sector resources. Much of this volume deals with resource allocation across interventions. Public finance must address an additional set of decisions. Do interventions with substantial positive externalities have a particular claim on public resources—beyond the amount of health and financial protection they buy per million dollars spent? Should public resources be spent only on individuals with low income? Or should health systems provide universal public finance for the very limited range of interventions that can be afforded? Should public finance emphasize providing interventions that maximize financial protection or improvements in health? What patterns of public sector resource allocation are likely to prove politically sustainable? Fewer tradeoffs may exist among these criteria than at first seems to be the case.

A starting point for thinking about these criteria is the availability of an increasing number of good benefit incidence studies—that is, studies of how the benefits of a public intervention distribute across income (or asset) quintiles of the population. Those studies find that in a great majority of countries wealthier people are more likely to benefit from public programs than are the poor, at least where benefits are measured in expenditures. The World Bank's 1993 *World Development Report* pointed to that pattern some time ago (although noting a number of important exceptions), and more recent studies add support to that conclusion. The caveat “measured in expenditures” is important and insufficiently noted. The value or welfare benefit to the poor of a given level of transfer may well exceed the value received by the well off from the same level of transfer. A landmark benefit incidence study of the U.S. Medicare program, a mandatory health insurance for the elderly, found it to be regressive in dollar terms but pro-poor in welfare outcomes (McClellan and Skinner 1997).

Public programs that are not universal appear to systematically benefit the better off, and that pattern is understandable from a political perspective. It follows that if an immunization program, for example, is differentially benefiting the well off, then making immunization universal would be pro-poor in terms of incremental public expenditures. Figure 1.7 uses data from a careful benefit incidence assessment in the Philippines (Gwatkin and others 2000) to illustrate this point for immunization and for attended deliveries.

Making coverage universal for cost-effective interventions *for conditions important to the poor* is thus likely to prove to be an efficient way of both improving health outcomes and enhancing equity. Many of these interventions address infectious disease where control has significant externalities, and implementing universal coverage is likely to prove more politically sustainable than targeting population subgroups. Lindert (2004) extensively discusses the experience in high-income countries with universalization of public financing of education, health, and old-age pensions and concludes not only that

Percentage of incremental benefit received by each quintile

Source: Calculations based on data reprinted in Gwatkin and others (2000).

Notes: *Universal immunization coverage* means complete coverage with the standard immunization schedule. The Philippines achieved 75 percent coverage overall in 1998, and Gwatkin and others (2000) show the coverage level by quintile. The black bar shows what the percentage distribution of benefits by population quintile would be of moving from the 1998 status quo to universal coverage. *Universal delivery attendance* means that all births would be attended by a doctor, nurse, or nurse-midwife. The Philippines achieved 63 percent coverage overall, and the white bar shows what the percentage distribution of benefits by population quintile would be of moving from the current pattern of coverage to universal coverage.

Figure 1.7 Equity Implications of Providing Universal Coverage for Immunization and Attended Delivery in the Philippines, 1998

it is politically sustainable but also that no evidence indicates that the resulting higher taxes have harmed economic growth.

Two final points are worth stating about making coverage universal:

- First, early adoption of universalization of coverage for publicly financed interventions—even if only a few can be financed—sets the stage for expansion, in a middle-income environment, to universal public financing of health care, the overwhelming choice of the democratic process in high-income countries.
- Second, the implementation capacity of health systems in low-income countries will often be highly constrained. Capacity is likely to grow most rapidly by building on a base of doing a few things well rather than many things poorly. Universal coverage implies tight focus in highly resource-constrained environments.

RESEARCH AND DEVELOPMENT

Why has health improved so dramatically after controlling for income and, hence, the availability of commodities that, like food, are essential for health? Although no unambiguous

answer to this question exists, an important factor has been advance in scientific knowledge and its application both in creating powerful interventions and in guiding behavior. Acquisition and use of health research and development or its products becomes, then, an essential function of a country's health system. Moreover, it is important that research extend beyond development of new products to encompass knowledge generation on health system financing and performance.

Much knowledge is embodied in global public goods: once a vaccine against hepatitis B has been developed anywhere, it becomes, in some sense, available everywhere. Although monopoly pricing made possible by patents may slow the diffusion of some innovations, the temporary nature of patent-induced monopoly pricing limits that effect. However, an innovation's being cheap, powerful, and globally available in no way assures its global use. The implication is clear: globally available knowledge and products offer enormous opportunities to countries, but national policies and national health systems determine whether that knowledge is put to local use. Additionally, although some information for improving outcomes is principally local and must be locally produced, making the results available contributes to a growing evidence base. Chapter 4 on health research stresses the value of contributing to a global evidence base and summarizes with the observation that "all health care is national" and "all health research is global."

What are the implications for policy? One is that if knowledge gains prove even partially as important for future health improvements as they have in the past century—and chapters in this volume point to a number of reasons for expecting this to be so—then investments in health research and development will continue to have high payoffs in health status and economic productivity. Chapter 7 points to the potential for enormous economic returns. Ensuring an adequate level of research and development investment, therefore, holds strong claim on health budgets—a claim for more than the approximately 3 percent now committed. Equally important—or more important—is that the investments be efficient in generating useful new knowledge and products. Fauci (2005) discusses the need for greater efficiency in conducting research and development in an environment of tightening budgets in U.S. agencies, and he points to a number of specific directions for doing so.

In some cases, additional resources (probably from growth within national health budgets or health aid budgets) will be required to meet these research and development needs adequately. In many cases, institutional change will be necessary to create the information and incentives required for efficient resource allocation. At the international level, resource allocation has often lacked focus, failing to bring results to the point of application, and has neglected important conditions and issues while providing, often generously, for less important ones. Reform is needed. Successful models of competitively

driven international funding and experience-sharing networks should be applied to currently neglected clusters of conditions.

Just as the quality and productivity of research efforts vary dramatically from one institution to another within the high-income countries, they vary in the low- and middle-income countries. Exemplary work is done in a number of institutions and countries; but in general, the obstacles to high quality are greater when countries' incomes are lower. Inadequate training, insufficient staff motivation, and lack of competition prevent many institutions from attaining their potential. The instability of short-term funding, isolation from peers, and poor access to the research literature all compound the problem and prevent researchers from responding rapidly to ever-changing demands. Given the shortage of good researchers, an argument exists for the talent to move to countries (including low- and middle-income countries) whose policies are likely to facilitate productive research (WHO 1996). Donor funding should reflect this possibility.

Institutions are more likely to succeed not only if they receive stable core funding but also if a proportion of their work is funded competitively. Some institutions, such as the Oswaldo Cruz Foundation in Brazil, have already moved in these directions with great success—for example, by freeing up intramural resources for competitive allocation between groups and within the institution, with assessments being made by an external review group. Notable successes have occurred in assisting with capacity strengthening, such as the Special Programme for Research and Training in Tropical Diseases collaboratively supported by WHO, the World Bank, and the United Nations Development Programme.

The failure of current incentive structures, essentially the patent system, to produce health products for the lowest income groups demands remedial action (chapter 5). In essence, either the public sector must harness the skills, energy, and capacity of the private sector to develop and bring promptly to market products for the lowest income groups, or it must take responsibility for doing so itself. In reality, a combination of the two is likely, as is exemplified in successful public-private partnerships such as the Medicines for Malaria Venture or the International AIDS Vaccine Initiative. Recently proposed pre-commitments by the public sector to purchase specific new products are an additional potential instrument to generate incentives for private sector investment (Kremer and Glennerster 2004). Developing countries that participate in private sector innovation will be positioned to more quickly learn of and have access to the technical progress that is critical in driving health improvements.

Global challenges demand, in some sense, a global response. All nations share the fruits of research and development. Even though each country may invest a relatively modest sum toward collective goals, the aggregate effort potentially benefits all substantially. Collective action is the economically rational

approach to public goods such as research and development; here, responsibility for catalyzing collective action lies principally in the hands of the global community. Far from overshadowing action at the national level, global efforts help both to make national research and development efforts more productive and to lead to a global result that exceeds the sum of national ones. Thus, among the many competing demands on the funds allocated to international assistance for health, those contributing to generation of new knowledge, products, and interventions that can be shared by all have special merit.

DEVELOPMENT ASSISTANCE FOR HEALTH

Development assistance, wisely focused, has the potential for unusual effect. First, because health gains for the poor can be relatively inexpensive (compared to the cost of achieving significant effect in other sectors), development assistance itself can achieve much, particularly if it serves as a channel for diffusion of new technologies and best practices. Second, evidence suggests that development assistance in health can be more effective than other development assistance in poor policy and weak institutional environments. Third, the economic benefits of investing in health can be exceptionally high. Finally, because research and development have had high impact (chapter 7) and are an international public good, development assistance has a particular comparative advantage in ensuring their finance.

Those conclusions point to a proactive strategy within development assistance agencies and governments for achieving major shifts in staffing and budgetary allocations toward specific high-payoff investments in health. They also point to the need, in order to achieve the potential benefits, for a focused concentration of health system development on a limited set of priority health goals—for example, controlling AIDS, controlling smoking, meeting the health-related MDGs, and—for middle-income countries—implementing finance reforms that lead toward universal public financing. The section argues that although financial fungibility—the capacity to redirect government resources away from areas supported by external financing—can dilute the effect of development assistance in health, as in other sectors, designing development assistance for health that minimizes the fungibility problem is possible. Performance-based budget support will be one instrument.

In 2003, the world committed to ODA of almost US\$100 billion, and news reports in May 2005 suggested the possibility of substantial increases by European donors. Approximately 10 percent of ODA is spent for health, a percentage that has grown rapidly. Table 13.1 in chapter 13 shows recent trends in external financing for health, of which ODA (that is, grant or highly concessionary loans) is only a part: these numbers are

for commitments, not actual disbursements, which are smaller and lag behind commitments. (The Global Fund to Fight AIDS, Tuberculosis, and Malaria is one of the few providers of developmental finance that reports disbursements as well as commitments.) External financing for health has grown from about US\$6.7 billion in 1998 to US\$9.3 billion in 2002 (Michaud 2003). For some countries, development assistance constitutes a significant and growing fraction of health expenditures. Economists have recently returned to the question of the returns to expenditures on development assistance, and several recent trends have important potential implications for health.

Aid Effectiveness

Recent work has been reassessing aid effectiveness and has focused on the following questions: Is there any evidence that infusions of development assistance have affected economic growth rates? Is there any evidence that infusions of economic assistance have affected mortality rates or levels of poverty? These questions are clearly not easy to answer. Nonetheless, some data provide insights. Burnside and Dollar (2000) conclude, for example, that development assistance does seem to work in countries where a good policy environment and a good institutional environment exist, but not in countries lacking those elements. Recent work focuses on aid directed to economic development and greatly strengthens the inclusiveness of the conclusion that aid boosts growth (Clemens, Radelet, and Bhavnani 2004). The effect of development assistance on growth is quantitatively important even in countries with poor policies and institutions, although the effect is stronger in countries with better policies. Interestingly, aid's effect appears larger in countries with higher life expectancy. That development assistance contributes broadly to growth does not, of course, imply that development assistance for health will accelerate health improvements. However, it is certainly suggestive of the potential in health to know that development assistance works for growth.

Even if development assistance is viewed as working better in strong institutional and policy environments, a dilemma exists in that the countries that most need aid are often ones that have weak policies and weak institutions (Radelet 2003, 194). Experiences with ODA in health complement the recent research on aid for growth in suggesting that ODA can pay off despite limited institutional or absorptive capacity. Polio has certainly been eliminated in countries with good health systems, but it has also been eliminated from most countries with weak ones. No smallpox exists today in countries with bad policies and bad institutions. A number of those countries have immunization rates of 60 or 70 percent, or as high as in the United States. An important question concerns the extent to which other development assistance for health, particularly

highly targeted development assistance, can be as successfully implemented as immunization programs where health systems are weak.

Project Support versus Budget Support

Development assistance is tending to move away from project support—for example, of an immunization program, an AIDS control program, or an extension of a road network—and toward general budgetary support, often to be provided through pooling of donor assistance. There are many reasons for this tendency, some of which are good (Kanbur and Sandler 1999, 106). The usefulness (and even propriety) of budget support is contingent, however, on adequacy of the policy and institutional environments. Chapter 3 points to arguments that as health systems evolve, development assistance should move from project assistance toward program assistance. The Global Alliance for Vaccines and Immunization (GAVI) is pointing to ways that support for immunization programs can be advanced within the context of this tendency to move toward general budget support. GAVI's innovation is to support immunization programs based on performance—US\$20 for a fully immunized child. The country gets the US\$20 for immunizing the child in whatever way it decides; thus, GAVI provides general budget support that is conditioned on performance. GAVI's concern has been with transitional financing (rather than with sustained assistance), but its approach points the way for designing long-term budget support conditioned on measurable performance with respect to specific health goals. Jamison (2004) outlined design of long-term development assistance for health that could meet this objective, maintaining incentives for countries to increase coverage (or performance) while scaling back the volume of aid as a country's income increased. Adequate measurement underpins assessment of performance and can be difficult even for immunization coverage. Measurement requires resources that must be planned for and budgeted.

Macroeconomic Consequences of Aid

Another concern in the aid community—particularly in the International Monetary Fund—is that development assistance could have adverse domestic macroeconomic consequences—essentially inflationary consequences (see WHO 2002, chapter 8). This argument needs to be taken seriously. It is in essence an argument about the generation of domestic inflationary pressures—of projects chasing after those few good engineers or doctors with an increasing amount of foreign money and creating an inflationary spiral in that way. However, if the principal proposed use for the money is for drugs or vaccines—for example, the US\$10 increment for adding Hib and HepB vaccines to the Expanded Program on Immunization

schedule—that money is almost all foreign exchange, and the macroeconomic arguments about inflationary consequences simply would not apply. Careful project design can respond to what on the whole are serious concerns from the macroeconomic part of the development assistance community. Economic analysis can provide information—such as this volume attempts to provide—on getting the maximum health and financial protection outcomes from the development assistance available and for designing interventions (tradable and commodity intensive) that will minimize potentially adverse macroeconomic consequences.

The Millennium Development Goals

An additional and significant direction in thinking about ODA concerns achievement of the MDGs (chapter 9). The MDGs are very specific targets for improvement in education, health, and income-related poverty. Interestingly, focusing development assistance on achieving the MDGs stands in at least partial opposition to the move toward budget support.

These considerations point to several directions for the design of development assistance for health. Radelet (2003, 194) provides detailed quantitative examples to show that, even under very favorable circumstances, in a lower-middle-income country development assistance is likely to be needed for decades. Some conclusions follow that are drawn from the preceding discussion and from the need for predictability and long time horizons in donor behavior. ODA should move toward the following:

- providing aid over long-term perspectives (10 or more years)
- ensuring predictability in assistance commitments
- emphasizing demand-side support (with concomitant country control of resources)
- providing incentives for countries to maintain high coverage for cost-effective programs
- avoiding perverse incentives
- including a transparent exit strategy (for example, reduced grant support with per capita GDP growth).

There is a strong analogy to within-country programs like Mexico's *Progresa*, which provides cash transfers to poor households contingent on getting children immunized or into school. Gertler (2004) has reported evaluation results indicating a high degree of effectiveness. The effectiveness of coverage incentives is well exemplified by the Bill & Melinda Gates Foundation in its work on polio with both GAVI and the World Bank in providing a financial incentive for enhanced coverage (chapter 13). Although donors increasingly state a commitment to providing aid predictably and over long periods, the reality for many countries is that aid flows will be volatile and

of uncertain duration. Jamison and Radelet (2005) point to ways of using such aid that can be minimally disruptive.

CONCLUSIONS

A volume as large as this one can provide only a sampling of opportunities and potential pitfalls for investments in health. Indeed, the *International Statistical Classification of Diseases* (WHO 2003a) takes more than 1,500 pages simply to list the conditions that a health system must address. Yet the diseases accounting for most of the burden can be listed in perhaps half a dozen pages, and the diseases that account for most of the differences in outcome between high- and low-mortality countries can be listed on a page. Chapters in this volume assess 115 population interventions and 204 personal interventions that address most conditions of importance. The conclusions listed in this final section of the chapter simply highlight important conclusions for policy without attempting to summarize the volume as a whole. Chapters 2 and 3 complement this one with a fuller summary.

Table 1.3 provides a sense of the nature of the findings in much of the book, and box 1.4 provides a brief description of the methods. The table shows the number of DALYs that we estimate could be averted (or years of healthy life that could be bought) by spending a million dollars on a few of the interventions addressing major sources of disease burden. If we think of these numbers as the prices for buying health by different means, the price variation is enormous, ranging from one or two DALYs per million dollars up to well over 100,000. All the standard caveats more than apply to these numbers. Nonetheless, they do convey information relevant for policy. Expanding coverage of the currently used mix of vaccines, for example, appears more attractive than does adding new vaccines (except when the lower demands on system capacity of adding new vaccines are considered). Bypass surgery used even in the most appropriate circumstances is an expensive way to buy a year of healthy life, but for many common indications it is inordinately expensive. Findings from table 1.3 exemplify findings of the cost-effectiveness analyses from throughout the book that are summarized in chapter 2.

A general conclusion follows from the preceding discussion. There are many inexpensive ways to reduce mortality rates and improve health. A country that focuses on those interventions can expect to achieve major improvements—even with very limited resources. There are also ways to spend money on health that can dissipate even a substantial budget with almost no return—either for better health or for the financial protection of populations. Intervention selection matters. Many of the good and bad buys are now well known. Some are not, and our main purpose in this volume has been to assemble the evidence based on what is known.

We now turn to more specific conclusions. Different items on the list are relevant in different countries. (Chapter 2

Table 1.3 How Much Health Will a Million Dollars Buy?

Service or intervention	Cost per DALY (US\$)	Estimated DALYs averted per million US\$ spent
<i>Reducing under-five mortality</i>		
Improving care of children under 28 days old (including resuscitation of newborns)	10–400	2,500–100,000
Expanding immunization coverage with standard child vaccines	2–20	50,000–500,000
Adding vaccines against additional diseases to the standard child immunization program (particularly Hib and HepB)	40–250	4,000–24,000
Switching to the use of combination drugs (ACTs) against malaria where resistance exists to current inexpensive and previously highly effective drugs (Sub-Saharan Africa)	8–20	50,000–125,000
<i>Preventing and treating HIV/AIDS</i>		
Preventing mother-to-child transmission (antiretroviral-nevirapine prophylaxis of the mother; breastfeeding substitutes)	50–200	5,000–20,000
Treating STIs to interrupt HIV transmission	10–100	10,000–100,000
Using antiretroviral therapy that achieves high adherence for a large percentage of patients	350–500	2,000–3,000
Using antiretroviral therapy that achieves high adherence for only a small percentage of patients		Because of very limited gains by individual patients and the potential for adverse changes in population behavior, it is possible that more life years would be lost than saved.
<i>Preventing and treating noncommunicable disease</i>		
Taxing tobacco products	3–50	24,000–330,000
Treating AMI (heart attacks) with an inexpensive set of drugs	10–25	40,000–100,000
Treating AMI with inexpensive drugs plus streptokinase (costs and DALYs for this intervention are in addition to what would have occurred with inexpensive drugs only)	600–750	1,300–1,600
Treating heart attack and stroke survivors for life with a daily polypill combining four or five off-patent preventive medications	700–1,000	1,000–1,400
Performing coronary artery bypass grafting (bypass surgery) in specific identifiable high-risk cases—for example, disease of the left main coronary artery (incremental to treatment with polypill)	>25,000	<40
Using bypass surgery for less severe coronary artery disease (incremental to treatment with polypill)	Very high	Very small
<i>Other</i>		
Detecting and treating cervical cancer	15–50	20,000–60,000
Operating a basic surgical ward at the district hospital level that focuses on trauma, high-risk pregnancy, and other common surgically treatable conditions	70–250	4,000–15,000

AMI = acute myocardial infarction.

suggests, for example, major differences between the priorities for South Asia and those for Sub-Saharan Africa.) Many interventions or policy changes that are important are not on this list, but they are included in the more extensive discussions in chapters 2 and 3, which synthesize messages from the rest of the book on setting intervention priorities and strengthening health system capacity. Given often quite limited availability of

money or political leadership or health system capacity, it will often be necessary to focus the available resources on a few key priorities. Chapter 12 makes it disappointingly clear that, for the low-income countries, not only are financial resources sharply limited now, but prospects for more than modest increases seem unlikely for many years. (Financial constraints in the middle-income countries, although real, are less

Box 1.4

Cost-Effectiveness Analysis in This Volume

A starting point for cost-effectiveness analysis is to observe that health systems have two objectives: (a) to improve the level and distribution of health outcomes in the population and (b) to protect individuals from financial risks that are often very substantial and that are frequent causes of poverty. Financial risk results from illness-related loss of income as well as expenditures on care; the loss can be ameliorated by preventing illness or its progression and by using appropriate financial architecture for the system.

For the purposes of this book, we consider two classes of resources to be available: financial resources and health system capacity. To implement an intervention in a population, the system uses some of each resource. Just as some interventions have higher dollar costs than others, some interventions are more demanding of system capacity than others. In countries with limited health system capacity, it is clearly important to select interventions that require relatively little of such capacity. Human resource capacity constitutes a particularly important aspect of system capacity, discussed in chapter 71 and in a recent report of the Joint Learning Initiative (2004).

Although in the very short run little tradeoff may exist between dollars and human resources or system capacity more generally, investing in the development of such capacity can help make more of that resource available in the future. Chapter 3 discusses different types of health system capacity and intervention complexity, and it points to the importance of and potential for responding to low capacity by selecting interventions that are less demanding of capacity and by simplifying interventions. Chapter 3 also explores the extent to which financial resources can

Source: Author.

substitute for different aspects of system capacity (see also Gericke and others 2003). An important mechanism for strengthening capacity, inherent in highly outcome-oriented programs, may simply be to use it successfully—learning by doing. Several chapters discuss capacity strengthening at different levels of the clinical system, in public health, and in health research and development.

The literature on economic evaluation of health projects typically reports the cost per unit of achieving some measure of health outcome—quality-adjusted life years (QALYs) or DALYs or deaths averted—and at times addresses how that cost varies with the level of intervention and other factors. Pritchard (2004) provides a valuable introduction to this literature. *DCP1* reported such cost-effectiveness findings for a broad range of interventions; *DCP2* does so as well. *DCP2* authors were asked to use methods described in Jamison (2003); chapter 15 discusses actual implementation. Cost-effectiveness calculations provide important insights into the economic attractiveness of an intervention, but other considerations—such as consequences for financial protection and demands on health system capacity—are also relevant.

DCP2 also makes a preliminary attempt to accumulate information about the extent to which interventions place demands on health system capacity; this information is qualitative. *DCP2* provides only an initial effort, but qualitative information does provide helpful input to policy. Kim (2005) develops a more quantitative approach in an analysis dealing with cervical cancer. Much less has been done on the extent to which specific interventions provide financial protection for patients and their families.

binding.) Selecting priorities will be hard. This section provides a starting point for discussing which activities should be high priorities. The conclusions are grouped under four headings: interventions; health services, systems, and financing; research and development; and development assistance.

Interventions

1. Standard interventions for reducing under-five mortality have long been known to be highly cost-effective. The challenge is to scale up while conserving and strengthening scarce health system capacity. These interventions include immunization; micronutrient supplement delivery;
2. Cost-effective interventions exist to address the 50 percent of under-five deaths that occur under 28 days of age, including stillbirths. These are underused relative to interventions for older children, and correcting this neglect is a priority.

treatment for diarrhea, malaria, and acute respiratory infections; and improved prenatal and delivery care. In cases of sharply limited resources—financial or health system capacity—often the single highest priority will be expansion of immunization coverage with the basic antigens: poliomyelitis, measles, diphtheria, tetanus, pertussis, and perhaps BCG.

3. Standard interventions to treat TB are also known to be highly cost-effective, although probably more demanding of health system capacity than are some of the child health interventions. Scaling up by using already developed models for strengthening relevant health system capacity is a priority.
4. Many well-tested preventive interventions for AIDS are effective and cost-effective. Such interventions include treating STIs, promoting condom use, providing voluntary counseling and testing, promoting peer intervention, using antiretroviral therapies to prevent mother-to-child transmission, ensuring safe blood supplies, and encouraging the use of breast milk alternatives by HIV-positive mothers. Scaling up treatment for STIs may prove particularly important. Much more rapid implementation of these interventions is of highest priority and needs to be accompanied by effective mechanisms of surveillance and evaluation. The appropriate mix and distribution of interventions depends on the stage of the epidemic. In particular, limited financial and institutional resources imply focusing effort on populations at high risk early in an epidemic.
5. Antiretroviral drugs have been successful on a wide scale in high-income countries (and in some upper-middle-income countries—notably Brazil and Mexico) in sharply reducing viral load and extending the life expectancy of patients who are HIV positive. Health system capacity for achieving durable benefits from antiretroviral drug use at scale in resource-constrained environments, however, remains to be demonstrated. Failure to achieve good adherence in such an environment would provide minimal benefits to the patient, increase risks of drug resistance, and incur substantial costs: the financial and human losses could be enormous. Multiple approaches to successful maintenance on antiretroviral drugs should be tried and evaluated in large-scale pilots or as part of implementation scale-up. Given the magnitude of the AIDS problem, undertaking and evaluating variations in implementation (including possible variation in the choice of first-line drugs) in parallel rather than serially is important. This approach is not now being used. Similarly important is being rigorous in dropping unsuccessful implementation models before they consume substantial resources that could otherwise have greatly affected AIDS prevention or other priorities in the health sector.
6. Control of tobacco use is the cornerstone of proven approaches to primary prevention of heart disease, stroke, chronic pulmonary disease, and many types of cancer. Instruments for control of tobacco use centering on taxation and improved public information are well established.
7. A range of potential approaches to changing dietary and exercise patterns of populations would, if successful,

reduce problems of obesity, hypertension, and dyslipidemia and their consequences for vascular disease. Successes are rare but suggestive that large-scale efforts could be worthwhile. Careful impact evaluation will be essential to ascertain whether these investments deliver value for money.

8. Lifetime medical management—eventually using variants of the polypill—of individuals at high risk for stroke or ischemic heart disease is cost-effective and important for tens of millions of individuals. The clearest indications of high risk are a previous vascular event or diabetes.

Health Services, Systems, and Financing

9. Focused funding for particular diseases or programs—for example, TB or immunization—is a fact of life in many low-income countries. Using such funding to build health system capacity is feasible as well as desirable, but it is far from automatic. As capacity grows, the potential advantages of categorical programs are likely to fade while a more integrated (but still outcome-oriented) health system assumes responsibility for dealing with the relevant conditions.
10. Quality of clinical care makes an enormous difference, both to the cost of care and to health outcomes. Tangible actions can be taken to improve quality: important among them is having each provider do a few things well rather than many things poorly.
11. Strengthening capacity for surgery at the district hospital level is a frequently neglected priority. Major important uses of this capacity will be to deal with injuries and obstetrical emergencies.
12. In low-income countries public funding for health will remain highly constrained as a percentage of GDP for the foreseeable future. Targeting these funds to provide universal access to a limited number of interventions that are high priority for poor people is both efficient and equity enhancing, but it will require clear setting of priorities, particularly for incremental resources as they become available.
13. Middle-income countries can learn from the OECD experience that universal public financing of a substantial package of clinical care is both efficient and equity enhancing.

Research and Development

14. Impact evaluation of interventions in many domains is an essential priority and should be done around planned variations in implementation. One specific area of importance is evaluation of effective ways to manage lifelong drug use—for example, for AIDS, secondary prevention of vascular disease, diabetes, and major psychiatric disorders.
15. Public-private partnerships such as the Medicines for Malaria Venture and the International AIDS Vaccine

Initiative provide promising models for developing important new drugs, vaccines, and diagnostic products to deal with the major diseases of poverty as well as the problem of drug resistance and microbial evolution more generally.

Development Assistance

16. Development assistance for health has begun to become performance based, and this trend should accelerate, along with making development assistance more stable and long term (contingent on performance). This change may involve at least a partial shift away from the sectorwide approaches to development assistance that recent evidence suggests may lead to neglect of focus on outcomes. It will require renewed attention to outcome measurement.
17. Resistance of the malaria parasite that is responsible for most deaths to chloroquine and SP is now widespread and rapidly increasing. A particular challenge is overcoming financial and institutional barriers to virtually complete replacement of those drugs with ACTs, which minimize resistance and can decrease transmission. Absent such an effort, malaria mortality is likely to continue rising. A centralized procurement mechanism receiving subsidies from development assistance agencies and making low-cost ACTs available to public and private supply chains globally would address this problem.
18. Investing in global capacity to respond effectively to a new influenza pandemic, particularly within the resource constraints of low-income countries, is a priority for the international system. Such capacity would include effective surveillance, surge manufacturing capacity for drugs and vaccines, stockpiles of drugs that could be used to attempt to contain epidemics, and mass media messages and public policies prepared in advance to be deployed if needed.
19. Because research and development is so important for health and because it is a classic international public good, a substantial fraction of incremental development assistance for health should go to research and development.

The content of these specific recommendations, and of recommendations throughout this volume, point to the enormous potential we now have to reduce further the human and financial burden of ill health. Scientific advance created this potential. Its more widespread realization requires the focused attention of health systems to finance and deliver priority interventions.

ANNEX 1.A: THE BURDEN OF DISEASE IN 2001

This annex provides estimates of the burden of different diseases and injuries in 2001. Alan Lopez, Colin Mathers, Christopher Murray, and their colleagues at WHO generated the estimates, aggregated them by World Bank regions, and provided final updates. A companion volume (Lopez and

others 2006) will provide more comprehensive tables of results for a much finer disaggregation of conditions, a full exposition of methods and data sources, and sensitivity analyses (including assessments of the sensitivity of results to including still-birth). All numbers in this annex are consistent with those in the companion volume.

This annex first provides a brief background on assessments of deaths by cause and disease burden and then an overview of the uses of such measures for health policy. It concludes with aggregated tables on deaths and on disability-adjusted life years (DALYs) by selected causes or groups of causes. The tables present estimates both with and without stillbirths, which constituted approximately 5.5 percent of deaths globally in 2001. Estimates are provided separately for high-income countries and for the low- and middle-income countries as a group.

Background

Many countries, including all high-income ones, maintain vital registration systems that provide data (usually annual) on the number of deaths by cause, age, sex, and sometimes race. Some countries additionally compute years of life lost (or YLL) by cause, which assigns a number of years of life lost attributable to each cause that depends on the age of death and some relevant measure of life expectancy. As of the early 1990s, no similar estimates existed for many developing countries or for regional groupings of them. Experts on individual conditions or the relevant disease program at WHO generated estimates for the diseases of interest to them. When added up across diseases, however, such estimates exceeded, often by a factor of 2 or more, any plausible estimate of the total number of deaths occurring in each age group. *DCPI* and the *World Development Report 1993* (Lopez 1993 and World Bank 1993) generated estimates of the number of deaths by cause that were consistent with demographically determined death totals for eight regional groupings of countries. WHO collaborated closely on this work. The number of deaths from a disease is one measure of the magnitude of its burden, and YLL constitutes for many purposes a better measure. Neither takes account of the disability or suffering associated with a nonfatal disease.

The 1993 *World Development Report* also developed a variant of the quality-adjusted life year (QALY) from the health economics literature to add a disability dimension to YLLs in order to generate a more comprehensive measure of burden. The result, called a *disability-adjusted life year*, measures burden from a specific cause as the sum of years of life lost from that cause and the equivalent years of life lost (in a sense that is made quite specific) from the disability caused by the condition. Original publications on disease burden included estimates that discounted future events at 0 percent or at 3 percent per year. They also included estimates that weighted the value of a year of life uniformly across all age groups and estimates

that placed greater value on middle-aged groups. These are labeled DALYs (r,k) with the first number indicating the discount rate in percent per year and the second indicating whether uniform or nonuniform age weights were used. The most widely reported variant on the DALY is the DALY (3,1)—that is, one that uses a 3 percent discount rate and nonuniform age weighting. This chapter and the companion volume report DALYs (3,0)—that is, with discounting but uniform age weighting.

Estimates of DALYs by cause for 1990 first appeared as appendix B of the 1993 *World Development Report* and, in expanded form, in Murray, Lopez, and Jamison (1994). Christopher Murray, Alan Lopez, and colleagues later produced updated estimates for 1990 and a fuller account of the methods used (Murray and Lopez 1996a, 1996b). The relative burden of different conditions as measured by numbers of deaths correlates highly with DALYs, but important exceptions exist. The massive burden of major psychiatric conditions, for example, is captured by DALYs but missed in estimates of deaths by cause or YLLs. Table 1.A1 summarizes the current estimates of deaths by cause in 2001 from Mathers, Murray, and Lopez (2006). Table 1.A2 shows disease burden in DALYs. Additional columns in these tables show the effect of including stillbirths on the percentage distribution of burden across conditions while leaving unchanged the other numbers (see Jamison and others 2006).

Disease burden can be assessed by risk factor as well as by disease or condition. An initial assessment of risk factor burden appeared in the 1993 *World Development Report* and later in Murray and Lopez (1997) and WHO (1996). WHO published a much fuller set of estimates in its 2003 *World Health Report* (WHO 2003b). Ezzati and others (2006) provided a substantial update adjusted to the same methodological assumptions as for deaths and DALYs, including use of DALYs (3,0).

Uses of Disease Burden Measures

DALYs are useful for informing health policy in at least six ways. Estimates of deaths by cause or YLL serve these same purposes, but for some uses less well.

1. *Assessing performance.* A country-specific (or regional) assessment of the burden of disease provides an outcome indicator that can be used over time to judge progress or across countries or regions to judge relative performance. The most natural comparison is to the development of national income and product accounts (NIPAs) by Simon Kuznets and others in the 1930s, which culminated in 1939 with a complete NIPA for the United Kingdom prepared by James Meade and Richard Stone at the request of the U.K. Treasury. NIPAs have, in the subsequent decades, transformed the empirical underpinnings of economic policy analysis. One leading scholar has put it this way:

The national income and product accounts for the United States (NIPAs), and kindred accounts in other nations, have been among the major contributions to economic knowledge over the past half century. . . . Several generations of economists and practitioners have now been able to tie theoretical constructs of income, output, investment, consumption, and savings to the actual numbers of these remarkable accounts with all their fine detail and soundly meshed interrelations. (Eisner 1989, 1)
2. *Generating a forum for informed debate of values and priorities.* The assessment of disease burden in a country in practice involves participation of a broad range of national disease specialists, epidemiologists, and, often, policy makers. Debating the appropriate values, say, for disability weights or for years of life lost at different ages helps clarify values and objectives for national health policy. Discussing the interrelations among diseases and their risk factors in the light of local conditions sharpens consideration of priorities.
3. *Identifying national control priorities.* Many countries now identify a relatively short list of interventions, the full implementation of which becomes an explicit priority for national political and administrative attention. Examples include interventions to control TB, poliomyelitis, HIV infection, smoking, and specific micronutrient deficiencies. Because political attention and high-level administrative capacity are in relatively fixed and short supply, the benefits from using those resources will be maximized if they are directed to interventions that are both cost-effective and aimed at problems associated with a high burden. Thus, national assessments of disease burden are one input in establishing a potential short list of control priorities. In the summary of the cost-effectiveness analyses reported in this volume, chapter 2 pays particular attention to identifying cost-effective interventions capable of averting a large disease burden.
4. *Allocating training time for clinical and public health practitioners.* Medical schools offer a fixed number of instructional hours; training programs for other levels and types of practitioners are likewise limited. A major instrument for implementing policy priorities is allocating this fixed-time resource well. Again that means allocation of time to training in cost-effective interventions in which disease burden is high.
5. *Allocating research and development resources.* Whenever a fixed effort will have a benefit proportional not only to the size of the effort but also to the size of the problem being addressed, estimates of disease burden become essential for formulating policy. Developing a vaccine for a broad range

Sources: Mathers, Lopez, and Murray (2006) provide the reported estimates of DALYs. Jamison and others (2006) provide the estimates for DALYs_{SB}.

a. The burden of disease is measured in DALYs. DALYs form a class of measures that aggregate years of life lost from premature mortality with years of life lost due to disability. The DALYs reported here are calculated at a 3 percent per year discount rate with no age-weights, i.e. a year of life at any age is valued the same. These are referred to as DALYs (3,0) in the accompanying volume on burden of disease and risk factors (Lopez and others, 2006).

b. The DALYs_{SB} is analogous to the DALY except that it includes stillbirths in the estimates of burden and assumes a gradual “acquisition of life potential” that allows the burden associated with a death near the time of birth to grow gradually with age rather than instantaneously increasing from 0 to a high value at birth or some earlier time. Jamison and others (2006) provide the estimates used here, which they label DALYs_{SB} (3,0,0.54).

of viral pneumonias, for example, would have perhaps hundreds of times the effect of a vaccine against Hanta virus infection. Thus, information on disease or risk factor burden is one vital input (of several) to inform research and development resource allocation, as discussed in chapters 4 and 5.

6. *Allocating resources across health interventions.* Here disease burden assessment often plays a minor role; the task is to shift resources to interventions, which, at the margin, will generate the greatest reduction in DALY loss. When there are major fixed costs in mounting an intervention, as is the case with political and managerial attention for national control priorities, burden estimates are required to improve resource allocation. Likewise, major fixed costs may be associated with making the use of an intervention universal (or expanding it to cover a major percentage of the population), and if so, the cost-effectiveness of the expansion will depend in part on the size of the burden.

Results

Tables 1.A1 and 1.A2 convey summaries of deaths by cause and burden of disease in 2001, respectively.

ACKNOWLEDGMENTS

Sonbol Shahid-Salles provided invaluable research support and critical advice during preparation of this chapter. Mantra Singh expertly provided word-processing support. Candice Byrne provided valuable comments. The other editors of *Disease Control Priorities in Developing Countries*, 2nd edition, provided extensive critical reactions to the messages and text, and the chapter is consequently very different than it would have been. The Advisory Committee to the editors of this volume, chaired by Jaime Sepúlveda, provided invaluable comments and reaction during a meeting at the Institut Pasteur, Paris, in December 2004.

In the early 1990s, the World Bank initiated efforts to understand and disseminate policies to address the remaining large burden of disease affecting the world's poor. The World Bank's (1993) *World Development Report: Investing in Health* reported the results of that assessment, which drew on a second publication, *Disease Control Priorities in Developing Countries*, 1st edition (*DCP1*) (Jamison and others 1993). Enormous changes both in the world and in our knowledge base occurred during the subsequent decade, leading to the conclusion that a major revision, update, and expansion of *DCP1* would be of value. In a collaborative undertaking, the World Bank, the World Health Organization, and the Fogarty International Center of the U.S. National Institutes of Health sponsored this new effort (*DCP2*) with substantial financial support from the Bill & Melinda Gates Foundation. This book results from that collaboration.

Chapter 2

Intervention Cost-Effectiveness: Overview of Main Messages

Ramanan Laxminarayan, Jeffrey Chow, and Sonbol A. Shahid-Salles

Deeper understanding of the role of human health as a critical component of economic development has stimulated interest in improving the efficiency with which the modest health resources available in low- and middle-income countries (LMICs) are spent. In recent years, exponential growth in the number of economic evaluations of health interventions, spurred in part by the first edition of this volume (Jamison and others 1993), has created a wider knowledge base for evaluating the costs and benefits of interventions to enable better targeting of financial resources in the health sector (box 2.1). Although efficient spending on health has always been a desirable goal, it is particularly critical in the face of recent threats, such as HIV/AIDS and drug-resistant bacteria, as well as the problems presented by increasing prevalence of chronic diseases, such as diabetes and cardiovascular disease (CVD), that threaten to roll back the significant health gains achieved in the past two decades. This book is an opportunity to assess anew the costs associated with and the health gains attainable from specific interventions and thereby better inform the allocation of new health funding.

Drawing from the collective knowledge and analytical work of the many experts who have contributed to this volume, this chapter provides a broader perspective on the relative efficiency and effect on health of a number of interventions than is possible in a single, condition-specific chapter.¹ The objective is to provide information on the cost-effectiveness estimates for 319 interventions covering nearly every disease condition considered in the volume, and the resulting avertable burden

of disease.² This chapter provides broad conclusions on the economic efficiency of using these interventions to improve health.

PRIORITY SETTING

Information on the costs of purchasing health in conjunction with regional or national realities regarding disease priorities, private willingness to pay for health, and public budget constraints can be used to identify widely prevalent investments that are not cost-effective (shaded in figure 2.1) and highly cost-effective opportunities to improve health that policy makers are currently neglecting. Throughout the chapter, “not cost-effective” describes an intervention that has a relatively high ratio of costs to effectiveness. The information provided also may be helpful in identifying interventions that are not cost-effective and are rarely used and cost-effective interventions that are justifiably widely used (unshaded in figure 2.1). The broad objective of this exercise is to help improve global population health by improving understanding of the implications of investing in different interventions. Some of the interventions considered are widely prevalent, whereas others are less well known. Although some interventions are personal, others are population-based (see annex 2.A for definitions). They encompass the spectrum of disease conditions covered in this book but are by no means exhaustive of the universe of possible interventions.

Box 2.1

Use of Cost-Effectiveness to Set Policy: The Directly Observed Treatment Strategy

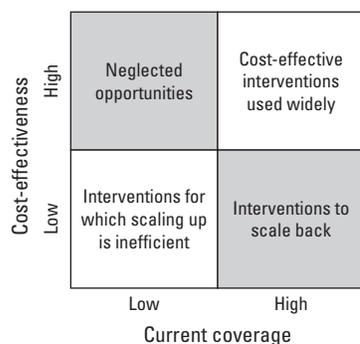

Nearly 2 million people die from tuberculosis (TB) each year, 98 percent of whom live in developing countries and most of whom are 15 to 49 years old. Meanwhile, anti-TB medicines are 95 percent effective in curing TB, even in low-income countries, and cost as little as US\$10 for a six-month course of treatment or directly observed therapy short course (DOTS). The TB chapter of the first edition of this book (Murray, Styblo, and Rouillon 1993) and studies by Joesoef, Remington, and Jiptoherijanto (1989) and Kamolratanakul and others (1993) describe treatment of smear-positive TB with short-course chemotherapy as an extremely cost-effective intervention for TB.

Since 1980, the World Health Organization (WHO) has collaborated closely with many countries in East Asia and the Pacific to introduce short-course chemotherapy and then the DOTS strategy to achieve global targets, with a cure rate of 85 percent and a case-detection rate of 70 percent. In 1990, 10 countries were using short-course chemotherapy. In 1993, as a result of growing TB prevalence rates, WHO's declaration of a global emergency,

and studies showing DOTS' cost-effectiveness, the DOTS strategy was established worldwide as the most effective response to TB. By 1995, DOTS had expanded to 73 countries, and by 2003, it had reached more than 180 countries worldwide (WHO 2004).

As of 1999, DOTS has been implemented with the collaboration of WHO in 13 provinces of China and has achieved a cure rate of 90 percent. The population in East Asia and the Pacific with access to DOTS increased from 44 percent in 1995 to 57 percent in 1997, with the proportion of registered TB patients who are enrolled in a DOTS program also increasing, from 30 percent in 1995 to 46 percent in 1997 (WHO 1999). The progress is mainly attributable to high-prevalence countries in the region, which include Cambodia, China, and the Philippines.

By 2002, national TB programs reported that 69 percent of the world's population lived in countries or parts of countries with DOTS coverage. DOTS programs treated a total of 13.3 million TB patients and 6.8 million smear-positive patients between 1995 and 2002.

Figure 2.1 Efficiency of Interventions

Cost-Effectiveness

The specific measure of cost-benefit analysis adopted in this volume is cost-effectiveness. Effectiveness is measured in natural units (deaths averted and years of life saved) and in disability-adjusted life years (DALYs), a composite measure that combines years lived with disability and years lost to premature death in a single metric (see chapter 15 for an explanation of how DALYs are calculated). Nevertheless, dollars per DALY averted can at best be only one consideration in the allocation of resources to different diseases and interventions. This

chapter also focuses on the total burden of disease avertable by expanding population coverage of an intervention. The delivery of many interventions, including those that are relatively cost-effective, may require a certain degree of institutional and organizational capacity on the part of a health system, and countries will have to pay attention to this important consideration.³ These factors, in combination with other considerations such as equity, social justice, medical suitability, and epidemiological appropriateness, should guide where money may be spent most effectively (Cookson and Dolan 1999, 2000).

Cost-effectiveness ratios can be used to set health priorities in two ways. One approach is to use a cutoff level of cost-effectiveness beyond which interventions are no longer used. This cutoff can vary from place to place depending on the availability of health resources, the disease burden, and the local preferences for health spending. The World Bank has described health interventions that cost less than US\$100 per year of life saved as highly cost-effective for poor countries, but this benchmark is arbitrary, as chapter 15 makes clear by noting the interaction with income, budget levels, and the disease burden (Jamison and others 1993).

An alternative approach to using cost-effectiveness data to set intervention priorities is to interpret the cost-effectiveness ratio as the "price" of equivalent units of health using different interventions (box 2.2 explains this approach). Reinterpreted

Box 2.2

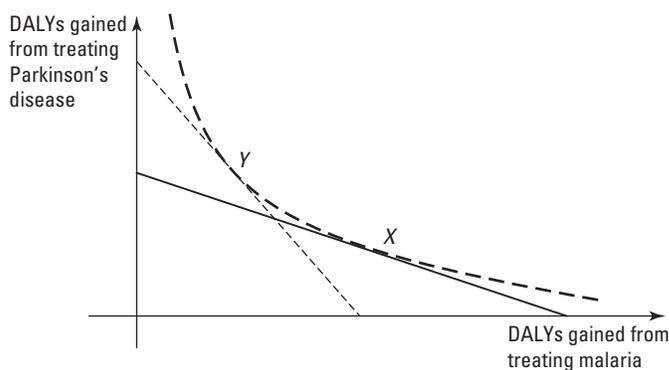

A Framework for Using Cost-Effectiveness Information to Set Health Priorities

A frequent, often justified, criticism of cost-effectiveness analyses is that they address only one of many criteria that could be used to evaluate health interventions. Epidemiological, medical, political, ethical, and cultural factors often also play important roles in the decision to allocate resources to a specific health condition or intervention; however, determining how one might weigh cost-effectiveness ratios alongside these other considerations when setting priorities for spending is difficult. Musgrove (1999) shows how to take some of these connections into account, including circumstances in which cost-effectiveness is an adequate criterion by itself. One approach is for the policy maker to think of cost-effectiveness ratios as the relative “price” of purchasing a unit of health (a DALY, for instance) using different interventions. These costs, along with the budget constraint, can help determine the optimal allocation of resources among a given set of interventions.

Consider, for instance, a policy maker in a country in Sub-Saharan Africa facing the choice between treating Parkinson’s disease and expanding malaria treatment programs while constrained by a fixed budget allocated by the ministry of finance. The cost per DALY averted of treating Parkinson’s disease using carbidopa is vastly greater than that for the malaria control program. A simplistic interpretation of the cost-effectiveness information would be to expand the malaria treatment program to the maximum extent possible before turning to the treatment of Parkinson’s disease. This solution could be desirable in some situations, particularly if the budget is large enough to deal fully with the malaria problem and still allow for some treatment of Parkinson’s. Emphasizing as complete coverage as possible of a particular problem may be especially appropriate in an epidemic situation, in which turning to another disease first can mean the epidemic will be worse in the future. Devoting some resources to each problem instead of concentrating on either may be more sensible when neither presents the threat of a growing epidemic.

Asking policy makers to make a binary choice between two sets of interventions on the basis of cost-effectiveness ratios alone may be unrealistic and misleading. Rather, policy makers should first determine their willingness to trade off health improvements in children (malaria) versus the elderly (Parkinson’s). Policy makers may want to avert at least some burden from Parkinson’s even if these cases are relatively expensive to treat for each unit of health gained because of such considerations as the target age group, the

socioeconomic status of target populations (including the extent to which they can obtain treatment from their own resources), and the ministry of health’s ability to deliver the program effectively. After the tradeoffs have been made and can be represented by an indifference curve (see the figure and explanation), the cost-effectiveness information is useful in determining how much of the policy makers’ fixed budget should be allocated to each intervention—that is, at what coverage of one problem should they start devoting resources to the other? The indifference curve represents health planners’ willingness to trade off between investment in antimalarial drugs and treatment for Parkinson’s based on all the relevant factors and independent of the budget constraint.

The solid line represents the budget, and its slope is the ratio of the cost-effectiveness ratios of the two interventions. The dashed line represents an alternative scenario in which the cost-effectiveness of treating Parkinson’s is better (more DALYs can be gained) than the ratio represented by the solid line. The axes show how many DALYs can be gained from each treatment, so a large number of DALYs corresponds to a low “price” of health or cost per DALY. The figure shows the simple case, in which these prices are constant for either budget line—that is, expanding either program does not raise the unit cost—although this case is unlikely when part of the population is difficult to reach, is harder to treat, or has more severe disease, in which case the rise in unit cost means that an intervention becomes relatively less cost-effective, giving a further reason to start devoting resources to an alternative intervention.

When the price of buying a unit of health to treat Parkinson’s is relatively high in terms of cost per DALY averted, the relatively flat (solid) budget line applies, and the optimal balance of investment in the two interventions is at

Box 2.2

Continued

point X. If the cost of buying a unit of health to treat Parkinson's is relatively low, then the steeper (dashed) budget line applies and the relative allocation of resources is represented by point Y. Therefore, policy makers would allocate relatively more resources to treating Parkinson's when the price of buying a unit of health through this intervention is relatively low, and they would allocate fewer resources when the price of health obtained through this intervention is relatively high. The figure shows the general likely shape of an indifference curve, but one possibility is

that policy makers' willingness to trade off between buying health from the two approaches is just a straight line, in which case they would want to invest the maximum amount possible in the lower-cost intervention (malaria) before turning to the higher-cost intervention (Parkinson's). The role of the cost-effectiveness information is to make policy makers aware of differences in the price of improving health using different interventions. Interventions with a high price should, all else being equal, be used less, whereas those with a low price should be used to a greater extent.

this way, there is no one-dimensional economic criterion that interventions must attain to be declared economically fit, and cost-effectiveness plays the more useful function of informing tradeoffs that policy makers are forced to make when investing in a portfolio of health interventions.

Target Audiences

The general notion of efficiency in how resources, both public and private, are spent on improving health is of interest not only to severely resource-constrained countries that each year spend only a few public dollars on health for each individual, but also to relatively wealthier nations with many competing priorities for public and private resources. The primary audiences for cost-effectiveness information are ministries of health and finance and policy makers in other branches of government in LMICs, both to help reallocate existing outlays in the health sector and to allocate new monies efficiently. Other audiences include aid agencies, international development lending institutions, nongovernmental organizations, and private health care providers.

Priority Setting in the Private Sector

The use of the efficiency criterion in priority setting should not be limited to public resources. A large proportion of health care in developing countries is paid for out of pocket, and greater clarity on interventions that are efficient from an economic perspective is no less urgent when the payer is private: inefficient private spending on health care in developing countries is wasteful as well. Much of this inefficiency may be attributed to significant differences in knowledge—termed *information*

asymmetries—between profit-making providers and patients. Private providers may encourage unnecessary procedures and excessively invasive procedures that, in some instances, can be more dangerous than no treatment at all. Governments have a role to play in lowering these information asymmetries, partly by providing information to populations, for instance, on the importance of childhood vaccinations. Moreover, even if government expenditures are not directly influenced by the lack of efficiency in privately delivered health care, they are affected by the inefficiency of private health systems if private patients seek public emergency care or require other state assistance. In their role as large purchasers of health care, governments—even in largely privately financed health care systems, such as in the United States—exercise enormous influence over the choices of drugs used and interventions provided and can play an important role in promoting policies to facilitate greater efficiency in health care systems.

The costs and efficacy of interventions may vary greatly, even within a single geographical region, depending on local health system capacity, cultural context, disease epidemiology, and a host of other factors. Greater efficiency in how countries spend their health care resources can have a tremendous effect on the health of their populations. Box 2.3 discusses gains from improved priority setting found in the lifesaving study by Harvard University (Tengs 1997; Tengs and others 1995).

METHODOLOGY

This chapter compares the cost-effectiveness of interventions that cover a broad spectrum of health conditions prevalent in developing countries. All results are presented in U.S. dollars discounted to the year 2001 using a 3 percent annual discount

Box 2.3

The Harvard Lifesaving Study

A study by Harvard University in the United States showed potential gains of life years saved by choosing interventions on the basis of their cost-effectiveness. The study's authors assessed more than 500 types of lifesaving interventions, defined as any behavioral or technological strategy that reduces the probability of premature death among a specified target population. The study focused on 185 interventions and the extent to which each intervention was currently being implemented, without taking its cost-effectiveness into account.

The authors estimated that the selected 185 interventions would cost US\$21.4 billion per year and would save

592,000 life years. The same amount of money could have saved another 636,000 life years had funds been redirected from less to more cost-effective interventions. Following an assessment of varying factors regarding interventions—those that affect the most people and are the most effective, least cost, and most cost-effective—the study reports that if the goal is to save the most life years, cost-effectiveness is a useful approach that will result in the most efficient allocation of resources. The study indicates that choosing the most cost-effective interventions could double the life years saved.

rate. Chapter 15 summarizes the general guidelines governing the analysis leading to the results reported for all LMICs.

Regional Variations

Where possible and appropriate, intervention cost-effectiveness ratios and other information have been disaggregated by World Bank region. In discussing the estimates, this chapter focuses on differences in the costs of interventions rather than on differences in their effectiveness in specific regional settings, although both contribute to differences in cost-effectiveness estimates across regions. Cost-effectiveness estimates also differ among regions because of variations in underlying mortality, age structure, disease prevalence, and efficiency with which interventions are implemented. The analyses take all but the last of these considerations into account.

Interregional cost differences are attributable to differences in the local costs of goods and services that are not easily tradable. For components that are tradable, such as patented drugs and specialized medical equipment typically imported from industrial nations, the analyses assume uniform international costs for all LMICs, usually adjusted for local transportation and distribution costs. By using a single composite set of resource costs for each region, the analyses mask intraregional differences in the costs of nontradable goods, such as physician time or hospitals, but this methodology is appropriate because results are presented only at the level of the region.⁴ Interventions may differ in cost-effectiveness because they are targeted more appropriately to some age groups rather than others, and important gender differences may also exist in cost-

effectiveness for some conditions, but data to estimate such differences are lacking.

Caveats

The findings in this chapter are subject to a number of caveats. First, despite efforts to ensure the consistency of cost-effectiveness numbers across chapters, the approaches taken in arriving at these numbers vary significantly. Although some chapters rely on cost-effectiveness numbers drawn from the literature, other chapters have analyzed these numbers afresh using the standardized resource costs described elsewhere. Table 2.1 contains definitions of indicators used to assess the

Table 2.1 Quality of Cost-Effectiveness Evidence for Interventions

Note: Standard region-specific age structures and underlying mortality rates were used to calculate DALYs. Nontradable inputs were converted into U.S. dollars at the market exchange rate. The costs of tradable inputs were assumed to be internationally consistent, as were the costs associated with surgical treatments.

quality of evidence on which the cost-effectiveness estimates are based. The tables in annex 2.B and annex 2.C indicate the quality of evidence associated with each intervention.

Second, almost without exception, the cost-effectiveness numbers do not vary with the scale at which the intervention is undertaken, and this is probably not the case in reality (Birch and Donaldson 1987; Johns and Torres 2005). Some interventions, such as vaccination programs, have large setup costs but marginal costs of extending coverage that decline at least initially. Other interventions, such as educational campaigns for condom use, may be easy to target to urban populations, but the marginal costs of expanding such interventions to relatively inaccessible populations increase with coverage. Therefore, many of the cost-effectiveness ratios presented here are useful only for modest increments in coverage, and separate analyses may have to be conducted to determine their applicability to program start-ups and larger-scale intervention changes.

Third, the cost-effectiveness numbers presented apply to countries whose institutional and technical capacity in relation to health is close to the average for the region. This evaluation is restricted to what countries could do more (or less) of, and clearly a more ambitious analysis would also cover what countries could do better. This issue is discussed in detail in chapters 3 and 70.

Finally, the estimates are based on the best available data, which in many cases are somewhat weak. Statistically derived confidence bounds for the cost-effectiveness estimates are not provided, and in most cases, uncertainty analysis has not been carried out. Readers are encouraged to pay attention to the order of magnitude of each estimate rather than to the specific number presented.

ASSESSING THE EVIDENCE ON THE COST-EFFECTIVENESS OF INTERVENTIONS

Figures 2.2 and 2.3 display results gathered from other chapters on cost-effectiveness ratios. In some cases, interventions are grouped on the basis of their similarity and whether they were personal interventions or population-based interventions. For instance, all population-based programs to prevent HIV transmission via contaminated blood and needles were grouped as a single intervention. Note that the cost-effectiveness ranges should not be interpreted as statistical confidence intervals but rather as a range of “best estimates” of cost-effectiveness incorporating variation across interventions included in the cluster. Ranges for the cost-effectiveness ratios are also attributable to variations in the epidemiological settings in which these interventions were evaluated. For example, a population-based primary intervention in an area of low prevalence is likely to be less cost-effective than the same intervention in a region of

high prevalence. Figure 2.2 reflects sets of interventions dealing with high-burden diseases, and figure 2.3 deals with relatively low-burden diseases.

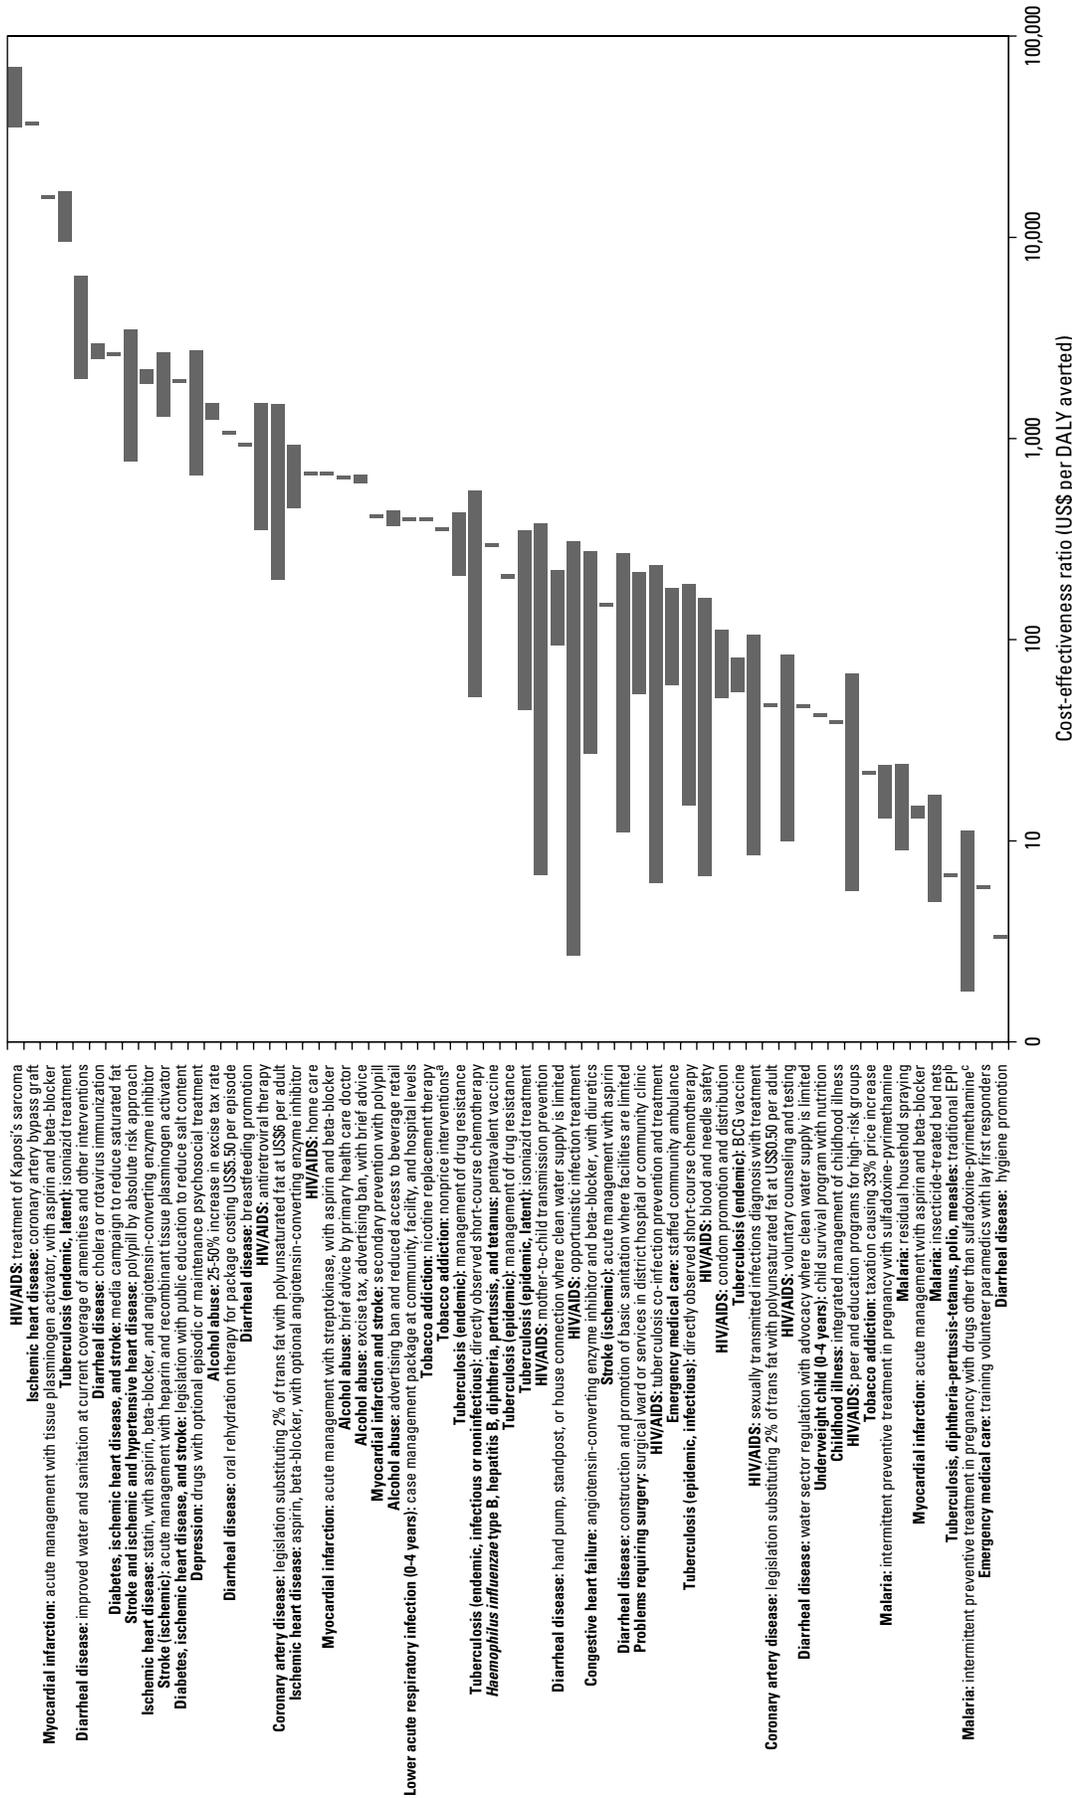

Within each figure, intervention clusters are displayed in the order of increasing cost-effectiveness. Additional information on the setting, objective, and target population of each intervention cluster for which cost-effectiveness has been calculated is provided in annex 2.B. The tables in annex 2.B also provide information on the quality of the evidence on which the data presented are based. Furthermore, the annex tables present information on potentially avertable deaths and DALYs if the coverage of these interventions were expanded by a further 20 percentage points of the relevant population (scaling up from 62 percent means reaching 82 percent, not 74 percent, of the pertinent population). Care should be taken not to confuse this information with the current burden of the underlying disease, on which basis interventions were divided into high-burden and low-burden diseases (figures 2.2 and 2.3, respectively).⁵ For example, a cost-effective treatment for CVD has only limited scope for increased scale of intervention in countries with a low burden of this disease. At the same time, in many parts of Asia and Sub-Saharan Africa, even though HIV treatment is not a highly cost-effective intervention, it deserves attention because of its sizable potential for lowering the disease burden.

The tables in annex 2.C summarize information on intervention clusters for which cost-effectiveness was evaluated with a metric other than DALYs. For these interventions too, details of setting, objective, target population, and quality of the evidence have been provided. Given the difficulty in comparing these intervention clusters with those evaluated using DALYs, they are excluded from figures 2.2–2.5.

Observations about specific interventions follow. Ranges of cost-effectiveness estimates shown reflect geographical variations across regions.

Prevention and Control of Tuberculosis

The treatment of all forms of active tuberculosis (TB) using the directly observed treatment strategy based on short-course chemotherapy is among the most cost-effective of all interventions available to improve health in LMICs (US\$5 to US\$35 per DALY averted except in Europe and Central Asia) (box 2.1). The bacillus Calmette-Guérin (BCG) vaccination for children is also cost-effective (US\$40 to US\$170 per DALY averted), but its main effect is to reduce the burden of severe TB in children (TB meningitis and miliary TB). Because BCG has relatively little effect on the huge burden of pulmonary TB in adults—which constitutes the major cause of ill health resulting from *Mycobacterium tuberculosis*—development of a new vaccine that targets adults is highly desirable. The treatment of latent TB in patients uninfected with HIV is relatively cost-ineffective (US\$4,000 to US\$25,000 per DALY averted), but it is more cost-effective for groups of patients who are coinfecting with TB

Note: Diseases were considered low burden for LMICs if their total avertable burden was less than 35 million DALYs. Bars represent the range in point estimates of cost-effectiveness ratios for specific interventions included in each intervention cluster and do not represent variation across regions or statistical confidence intervals. Point estimates for LMICs were obtained directly from the relevant chapters, calculated as the midpoint of range estimates reported in the chapters, or calculated from a population-weighted average of the region-specific estimates reported in the chapters. For details of these intervention clusters, including the specific interventions covered in each, see annex tables 2.B.1 and 2.B.2. Only interventions with cost-effectiveness reported in terms of DALYs are included in this figure. For interventions with cost-effectiveness reported in other units, see annex tables 2.C.1 and 2.C.2.

Figure 2.3 Cost-Effectiveness of Interventions Related to Low-Burden Diseases in LMICs

and HIV. In the context of TB control, antiretroviral therapy for HIV/AIDS is likely to be useful in extending the lives of patients successfully treated for TB.

Multidrug-resistant TB is much more expensive to treat than drug-susceptible TB—2 to 10 times the cost of standard first-line regimens for drug-susceptible TB—and this is one reason why priority should be given to preventing its emergence and spread. The management of drug resistance through the use of a standardized regimen that includes second-line drugs costs roughly US\$70 to US\$450 per DALY averted. Individualized treatment regimens for multidrug-resistant TB—that is, with drug combinations adjusted to the resistance pattern of each patient—are more costly but usually yield higher cure rates. Individualized treatment is harder to implement on a large scale but may not be less cost-effective than standardized treatment with regimens that include second-line drugs. The set of interventions needed to manage drug-resistant TB and TB associated with HIV requires higher levels of investment than the basic directly observed treatment strategy, but its cost is still typically less than US\$1 for each day of healthy life gained. Thus, a strong economic argument exists for integrating such interventions into an enhanced strategy for TB control.

Prevention and Treatment of HIV/AIDS

Despite the scale and relentless progression of the HIV/AIDS epidemic, important strides have been made in developing cost-effective interventions for both prevention and treatment.

Prevention. Although remarkably little rigorous evaluation has been conducted, population-based programs to prevent HIV/AIDS appear to be highly cost-effective approaches in countries with high HIV/AIDS prevalence where the epidemic is generalized. These programs include voluntary testing and counseling (US\$14 to US\$261 per DALY averted); peer-based programs to educate high-risk groups, including sex workers and injecting drug users (US\$1 to US\$74 per DALY averted); and social marketing, promotion, and distribution of condoms (US\$19 to US\$205 per DALY averted). Programs to improve blood and needle safety, while highly cost-effective (US\$4 to US\$51 per DALY averted), are limited in terms of the burden of disease they can avert.

Prevention of mother-to-child transmission using a single dose of nevirapine in generalized epidemic settings (US\$6 to US\$12 per DALY averted) stands out for its combination of well-documented high cost-effectiveness and significant avertable infections and deaths. Treatment of sexually transmitted infections to lower the risk of HIV transmission, although less well proven, also appears to be highly cost-effective (US\$16 to US\$105 per DALY averted).

Treatment. For care of people living with HIV/AIDS, treatment of most infectious opportunistic infections is cost-

effective (US\$10 to US\$500 per DALY averted), with treatment becoming significantly more cost-effective for patients who also have access to antiretroviral treatment. Few studies evaluate the cost-effectiveness of providing antiretroviral treatment, and even these are limited to clinical trial settings and are not directly applicable to the resource-poor settings in which antiretroviral treatment is being expanded. Economic evaluation of the cost-effectiveness of antiretroviral treatments based only on health outcomes for the treated patient is incomplete because of the large nonhealth impacts of HIV/AIDS and the effect of treatment on prevention of HIV transmission.

The cost-effectiveness of antiretroviral treatments is highly variable across settings as a function of drug prices and adherence rates. In low-cost settings with high adherence rates, antiretroviral treatment is moderately cost-effective (US\$350 to US\$500 per DALY averted); however, it can be a significantly poor value for resources spent in low-adherence settings if drug resistance is allowed to emerge and proliferate. Little is known about how to achieve necessary adherence levels (80 to 90 percent) at large scale at an affordable cost in low-income settings. To this end, research on effective, low-cost interventions to achieve long-term adherence to antiretroviral treatments (using support groups and other complementary interventions) in resource-poor settings is an urgent priority.

Childhood Illnesses and Mortality among Children under Five

Neonatal mortality rates and mortality rates for children under five can be reduced by large margins, at an affordable cost, by using interventions proven effective in low-income settings. Improvements are likely to come from increasing the coverage of preventive measures, such as breastfeeding, and from expanding the scope of existing childhood vaccines beyond the traditional six antigens in areas where existing coverage is relatively high and where new antigens address diseases of significant burden, particularly pneumococcal vaccines. Curative interventions—including case management of acute respiratory infections, malaria, and diarrhea—hold promise for lowering the 6 million preventable deaths each year in this age group.

Neonatal Mortality. An estimated 4 million deaths occur during the first 28 days of life, accounting for 38 percent of all deaths of children under five. Causes include infections (36 percent, including neonatal sepsis, pneumonia, diarrhea, and tetanus), preterm birth (27 percent), and asphyxia (23 percent). Intensive care is not required to save most of these babies. Developed countries and some low-income countries—for instance, Sri Lanka—have achieved neonatal mortality rates of 15 per 1,000 without intensive care, which is less than a third of current neonatal mortality rates in Sub-Saharan Africa.

Adding a set of community-based interventions—including promoting healthy behaviors, such as breastfeeding, and providing extra care of moderately small babies at home through cleanliness, warmth, and exclusive breastfeeding, plus community-based management of acute respiratory infections—to the standard maternal and child health package is likely to be highly effective. The cost of a year of life saved using this approach could be as low as US\$100 to US\$257 in India (US\$221 to US\$568 per DALY averted) and US\$100 to US\$270 in Sub-Saharan Africa (US\$183 to US\$493 per DALY averted). Use of these approaches is feasible now in most countries. Adding a clinical package that includes essential newborn care (warmth, cleanliness, and immediate breastfeeding); neonatal resuscitation; facility-based care of small newborns; and emergency care of ill newborns to the maternal and child health package has been shown to be highly cost-effective in India (US\$11 to US\$265 per year of life saved, or US\$24 to US\$585 per DALY averted) and Sub-Saharan Africa (US\$25 to US\$360 per year of life saved, or US\$46 to US\$657 per DALY averted); however, clinical care will require significant initial investment to raise coverage.

Basic resuscitation of newborns using a self-inflating bag that is available for as little as US\$5 in LMICs can save lives at low cost in areas where a midwife is available. Providing two tetanus toxoid immunizations costing less than US\$0.20 each to all pregnant women would avert more than 250,000 deaths at low cost and is eminently achievable. Improving maternal and child health services delivered through a combination of family- and community-level care, outreach, and clinical care will improve the survival of newborns and children and reduce stillbirths and maternal deaths.

Vaccinations. Childhood vaccinations, long recognized as among the most cost-effective uses of limited health resources in low-income countries, prevented more than 3 million deaths in 2001. National immunization programs traditionally have included vaccines against TB, diphtheria, tetanus, pertussis, poliomyelitis, and measles at a cost per fully immunized child of US\$13 to US\$24, depending on coverage levels and type of delivery strategy. The total cost in developing countries for national programs in 2001 ranged from US\$717 million to US\$1.4 billion, with an estimated cost per death averted ranging by region from under US\$275 (under US\$10 per DALY averted) in Sub-Saharan Africa and South Asia to US\$1,754 (US\$20 per DALY averted) in Europe and Central Asia.

The cost-effectiveness of scaling up immunization coverage with the traditional Expanded Program on Immunization (EPI) vaccines is highly dependent on the underlying prevalence of illness, starting coverage levels and trajectories, and mix of delivery strategies (whether facility-based strategies, campaigns, or mobile and outreach modalities). The cost per death averted varies by region, from US\$162 in Africa to more

than US\$1,600 in Eastern Europe. Cost-effectiveness ratios are less than US\$20 per DALY averted in all regions other than Europe and Central Asia. The cost-effectiveness of the tetanus toxoid vaccine also varies widely by region from under US\$400 per death averted and under US\$14 per DALY averted in Sub-Saharan Africa and South Asia to more than US\$190,000 per death averted and more than US\$15,000 per DALY averted in Europe and Central Asia.

Adding additional antigens to national programs has been successfully accomplished in many countries. Expanding the vaccination schedule to include a second opportunity for measles through either routine or campaign-based approaches costs between US\$23 and US\$228 per death averted and under US\$4 per DALY averted in regions other than Europe and Central Asia. Other new vaccines are less cost-effective because of their high unit costs per dose, but they may be worthwhile, especially in regions of high disease prevalence. For instance, the pentavalent vaccine (diphtheria, pertussis, tetanus, hepatitis B, and *Haemophilus influenzae* type B) was estimated to have a cost per death averted ranging from US\$1,433 to greater than US\$40,000 and cost-effectiveness of US\$42 per DALY averted in Sub-Saharan Africa and greater than US\$245 per DALY averted in other regions. The cost of adding a yellow fever vaccine ranges from US\$834 per death averted and US\$26 per DALY averted in Sub-Saharan Africa to US\$2,810 per death averted and US\$39 per DALY averted in Latin America and the Caribbean.

Because certain regions and countries contain the largest burden of disease, such as measles in India and Nigeria, targeting scarce public health resources to those geographic areas could potentially yield high returns to investment. Although immunization may have relatively low incremental cost-effective ratios, the total budget requirements for maintaining or increasing coverage rates, as well as for introducing new vaccines, can account for a large share of government health budgets.

The cost-effectiveness ratios of vaccination interventions presented here are based on estimates of their current costs and effectiveness; but they could change substantially with changing costs and the development of new interventions. For instance, multivalent pneumococcal conjugate vaccines have shown the potential to reduce the incidence of invasive pneumococcal disease while lowering the need for antibiotic use and the likelihood of drug resistance. The current price of these vaccines makes them expensive to most people in the developing world. However, with future price decreases, these vaccines could be adopted widely and could markedly lower the impact of the most common causes of morbidity and mortality in children under five (excluding the neonatal period). Moreover, new vaccines being developed could be included in the EPI schedule, including vaccines that protect against rotavirus, malaria, human papilloma virus associated with cervical

cancer, HIV/AIDS, and dengue. With future demonstrations of reasonable cost-effectiveness, these vaccines could become a component of the set of attractive interventions.

Acute Respiratory Infections. Even though vaccination strategies can be cost-effective in lowering the disease burden related to acute respiratory infections, case management may also be an efficient use of financial resources, although more demanding of health system capacity. Moreover, community case management and case management at a health care facility may be of comparable cost-effectiveness. In fact, treating nonsevere pneumonia at health care facilities using a combination of oral antimicrobials and acetaminophen (US\$24 to US\$424 per DALY averted) is more cost-effective than a similar treatment administered at home by a health care worker (US\$139 to US\$733 per DALY averted). Treating severe pneumonia in a hospital facility is more expensive (US\$1,486 to US\$14,719 per DALY averted).

Diarrheal Disease. Among interventions against diarrheal disease during the first year of life, breastfeeding promotion programs (US\$527 to US\$2,001 per DALY averted), measles immunization (US\$257 to US\$4,565 per DALY averted), and oral rehydration therapy (US\$132 to US\$2,570 per DALY averted) are relatively cost-effective compared with rotavirus immunizations (US\$1,402 to US\$8,357 per DALY averted) and cholera immunizations (US\$1,658 to US\$8,274 per DALY averted). The cost-effectiveness of oral rehydration therapy is extremely sensitive to the cost of the package. The cost-effectiveness of this intervention can be as low as US\$132 per DALY averted for an assumed cost per child of US\$0.70. An important reason for the relatively unfavorable cost-effectiveness ratios for diarrheal disease is that significant reductions in mortality from this condition have already been achieved and further gains are likely to be more expensive.

Further improvements in water and sanitation (US\$1,118 to US\$14,901 per DALY averted from diarrheal disease) are generally less cost-effective in regions where access to these amenities is adequate and other interventions against diarrheal disease exist. However, in areas with little access to water and sanitation facilities, improving access can be highly cost-effective (US\$94 per DALY averted for installation of hand pumps and US\$270 per DALY averted for provision and promotion of basic sanitation facilities).

Inherited Disorders of Hemoglobin. Inherited hemoglobin disorders, including sickle cell anemia and the thalassemias, affect roughly 500,000 babies born each year and cause early death for many of them. Prenatal screening for sickle cell disease, which is expensive, can be replaced by much cheaper newborn screening. Antibiotic prophylaxis is moderately cost-effective at preventing death in the first few years (US\$8,000 to

US\$12,000 per death averted, or US\$300 to US\$400 per DALY averted). Expensive interventions, such as bone marrow transplantation or repeated transfusions, are seldom needed. At US\$10,000 or more per DALY averted, treatment for transfusion-dependent thalassemias is expensive and probably unaffordable to all but the rich in LMICs. A feasible strategy to deal with the thalassemias is to screen couples to determine their risk of having an affected child, followed by prenatal testing—a relatively expensive proposition—of couples at high risk. Information is then available to parents to help them determine whether to terminate the pregnancy. Such strategies appear to have worked in Cyprus, Greece, and Italy, all countries that formerly had a high incidence of thalassemias.

Ongoing Challenges: Malaria and Other Tropical Diseases

Despite health researchers' relative neglect of diseases predominantly found in the tropics, interventions to control—and in some cases even eliminate—these diseases rank among the most cost-effective of all available options.

Malaria. In countries where malaria is prevalent, both prevention and effective treatment of this disease are highly cost-effective and can result in large health gains. Prevention tools include insecticide-treated bednets (US\$5 to US\$17 per DALY averted) and indoor residual spraying where DDT, malathion, deltamethrin, or lambda-cyhalothrin is applied to surfaces inside homes as a spray or deposit for prolonged action (US\$9 to US\$24 per DALY averted for Sub-Saharan Africa).

Intermittent preventive treatment of malaria during pregnancy using sulfadoxine-pyrimethamine is a highly cost-effective intervention (US\$13 to US\$24 per DALY averted) to decrease neonatal mortality and reduce severe maternal anemia. Changing first-line treatment for malaria from chloroquine, a drug that is ineffective in many parts of the world, to artemisinin-based combinations offers the advantage of faster cures and potential reductions in transmission, with cost-effectiveness ratios of less than US\$150 per DALY averted. Changing to sulfadoxine-pyrimethamine may be slightly more cost-effective initially because of the lower cost of this drug relative to artemisinin-based combinations; however, this advantage is likely to be eroded quickly because of the rapid expected growth of parasite resistance.

Lymphatic Filariasis, Onchocerciasis, and Chagas Disease. Annual mass drug administration to treat the entire population at risk for a period long enough to interrupt transmission is a cost-effective approach for eliminating lymphatic filariasis in areas of high prevalence (US\$4 to US\$8 per DALY averted). An alternative approach is to fortify salt with diethylcarbamazine (US\$1 to US\$3 per DALY averted) and to use ivermectin in

countries where onchocerciasis is coendemic. Onchocerciasis control programs have been highly successful in West Africa: investigators have estimated the cost-effectiveness of community-directed ivermectin treatment programs at roughly US\$6 per DALY averted when the drug has been provided free of charge. The cost of vector control to prevent—and perhaps eliminate—Chagas disease has been estimated at US\$260 per DALY averted.

Leishmaniasis and African Trypanosomiasis. Feasible intervention opportunities exist even for tropical diseases for which control measures are relatively less effective. Improved case management and immunization (currently undergoing clinical trials) for dengue (US\$587 to US\$1,440 per DALY averted) are relatively cost-effective compared with environmental vector control (more than US\$2,000 per DALY averted). Leishmaniasis treatment is also extremely cost-effective (US\$315 per death averted and US\$9 per DALY averted), as is treating African trypanosomiasis patients in the second stage of the disease using melarsoprol or eflornithine (US\$10 to US\$20 per DALY averted).

Helminthic Infections. Helminthic infections, although not a major contributor to deaths in tropical regions, have a significant effect on health, growth and physical fitness, school attendance, worker productivity, and earning potential. Mass school-based treatment of soil-transmitted helminths (*Ascaris*, *Trichuris*, and hookworm) using albendazole costs US\$2 to US\$9 per DALY averted. Although the cost of treating schistosomiasis with praziquantel is significantly greater (US\$336 to US\$692 per DALY averted), a combination of albendazole and praziquantel is extremely cost-effective (US\$8 to US\$19 per DALY averted).

Maternal and Neonatal Health

Given the hugely disproportionate burden of maternal and neonatal deaths in LMICs, identifying affordable, easy-to-implement interventions to prevent these deaths is a priority. Evidence from South Asia and Sub-Saharan Africa suggests that improved primary-level coverage with a package of interventions is extremely cost-effective (US\$3,337 to US\$6,129 per death averted and US\$92 to US\$148 per DALY averted). Improvements in the quality of prenatal and delivery care are of similar cost-effectiveness (US\$2,729 to US\$5,107 per death averted and US\$82 to US\$142 per DALY averted). An important finding is that improving the quality of care and expanding coverage are of comparable cost-effectiveness.

Improving Nutrition

The direct and indirect effects of undernutrition and micronutrient deficiencies account for a significant propor-

tion of the overall burden of disease in LMICs. For the most part, interventions to provide micronutrient supplementation can prevent malnutrition in children at a fairly low cost. They include breastfeeding support programs (US\$3 to US\$11 per DALY averted and US\$100 to US\$300 per death averted) and growth monitoring and counseling (US\$8 to US\$11 per DALY averted). Specific micronutrient supplementation programs can be implemented either by distributing capsules or by fortifying sugar, salt, water, or other essentials. In addressing vitamin A deficiencies, capsule distribution (US\$6 to US\$12 per DALY averted) is more cost-effective than sugar fortification (US\$33 to US\$35 per DALY averted), especially in countries where the prevalence of vitamin A deficiency is low. However, fortification of salt, sugar, and cereal in the case of iron deficiency and fortification of water and salt in the case of iodine deficiency is less expensive than distributing supplements for mild deficiency, though pregnant women and severely anemic or iodine-deficient people may still require supplementation. Overall cost-effectiveness is US\$66 to US\$70 per DALY averted for iron fortification programs and US\$34 to US\$36 per DALY averted for iodine fortification programs.

Cancer Prevention and Treatment

Screening for breast cancer using clinical breast examination (CBE) is estimated to be cost-effective at US\$552 per life year saved for biennial screening of women from age 40 to 60. This efficacy of CBE is related to the large percentage of tumors with a poor prognosis observed in developing countries. In this setting, CBE is estimated to be more cost-effective than mammography: mammograms every two years result in 10 percent more life years saved than annual CBE, but the cost is more than 100 percent greater. As with any screening program, cost-effectiveness is greater with higher underlying prevalence of disease.

In general, cancer prevention, when feasible, is far more cost-effective than treatment. The cost-effectiveness of initial treatment is between US\$1,300 and US\$6,200 per year of life saved for the more treatable cancers of the cervix, breast, oral cavity, colon, and rectum and between US\$53,000 and US\$163,000 per year of life saved for the less treatable cancers of the liver, lung, stomach, and esophagus. Postmastectomy radiation might be more cost-effective in developing countries, where the cost of radiation treatment can be relatively low compared to developed countries. Palliative care for terminally ill cancer patients can be a challenge in resource-constrained settings, where opioid drugs, a cost-effective option, may be in short supply. Studies from developed countries indicate that more advanced treatments to relieve pain and side effects of chemotherapy may be cost-effective under certain conditions.

Mental and Neurological Disorders

Mental disorders are a heterogeneous group of conditions with considerable variation in both the cost of the interventions and the burden reduction associated with such interventions. Interventions to treat depression, bipolar disorder, and schizophrenia rank among the least cost-effective of interventions considered in this volume. However, the potentially significant benefits to family members and to society as a whole are not captured by the DALY methodology and should be balanced against the relatively high cost of improving health of people with these disorders. For many disorders, drug treatment has been shown to be effective, especially when combined with psychosocial treatment that includes cognitive-behavioral approaches to managing symptoms and improving adherence to medications, group therapy, and family interventions.

Schizophrenia and Bipolar Disorder. Drug treatment accompanied by psychosocial treatment delivered through a community-based service was found to be the most cost-effective approach for severe mental disorders such as schizophrenia and bipolar disorder. Newer antipsychotic and mood-stabilizing drugs have recently become less expensive; even so, they are less cost-effective than drugs that have been available for many years. For example, family psychoeducation was much more cost-effective with haloperidol (US\$1,743 to US\$4,847 per DALY averted) compared with a newer antipsychotic drug (risperidone) in treating schizophrenia (US\$10,232 to US\$14,481 per DALY averted). For bipolar affective disorder, the combination of family psychoeducation with the older medication lithium (US\$1,587 to US\$4,928 per DALY averted) is more cost-effective than the combination of family psychoeducation with the newer sodium valproate (US\$2,765 to US\$5,908 per DALY averted).

Depression and Panic Disorder. Treating the more common depressive and anxiety disorders was more cost-effective than treating the more severe disorders; the interventions were less expensive, and the reduction in disability was greater. For depression, drug therapy with tricyclic antidepressants (imipramine or amitriptyline) costs US\$478 to US\$1,288 per DALY averted. Managing depression as a chronic illness with case management to reduce relapses did not greatly decrease the cost-effectiveness (US\$749 to US\$1,760 per DALY averted). Using newer medications with fewer side effects and potentially greater compliance (an advantage if medications need to be taken long term)—for example, a generic selective serotonin reuptake inhibitor (SSRI) such as fluoxetine—increased the cost somewhat (US\$1,229 to US\$2,459 per DALY averted). Finally, the treatment of panic disorder using tricyclic antidepressants (US\$305 to US\$619 per DALY averted) and SSRIs (US\$567 to US\$865 per DALY averted) was

more cost-effective than when combined with psychosocial treatment. Psychosocial treatment without drug treatment was of comparable cost-effectiveness (US\$338 to US\$927 per DALY averted).

The use of tricyclic antidepressants was more cost-effective than benzodiazepines, which are still commonly prescribed for anxiety disorders and produce dependence in many patients. Overall, the cost-effectiveness of a package of mental health interventions that addressed all four sets of disorders is between US\$1,429 and US\$2,902 per DALY averted, depending on the region.

Parkinson's Disease and Epilepsy. Ayurvedic treatment, a form of traditional medicine used in India, is relatively cost-effective in treating Parkinson's disease (US\$750 per DALY averted). Less cost-effective interventions include a combination of levodopa and carbidopa (US\$1,500 per DALY averted), which are used to treat the debilitating symptoms and delay the progress of the disease, and deep-brain stimulation (US\$31,000 per DALY averted).

Cost-effective options for treating epilepsy are available, especially the use of phenobarbital to help control seizures (US\$89 per DALY averted), but few eligible patients receive treatment. More expensive options, such as lamotrigine or surgery, are significantly less cost-effective than phenobarbital for first-line treatment; however, they are cost-effective for the small proportion of epilepsy patients who do not respond to phenobarbital.

Multipronged Strategy to Prevent and Treat CVD

CVD, including ischemic heart disease, congestive heart failure, and stroke, is the single most important cause of death worldwide; interventions to treat CVD are likely to account for increasingly greater proportions of health care expenditures in developing countries.

Population-Based Primary Prevention. Interventions to modify lifestyles can effectively lower the risk of coronary artery disease and stroke without expensive health infrastructure. They include lowering the fat composition of the diet, limiting sodium intake, avoiding tobacco use, and engaging in regular physical activity. The costs and the effectiveness of these approaches vary widely with the socioeconomic and cultural context in which they are contemplated.

Replacing dietary trans fat from partial hydrogenation with polyunsaturated fat is likely to be extremely effective in populations in South Asia, where the intake of trans fat is high. If such replacement is done during manufacture at a relatively low cost rather than through changes in individual behavior, a cost-effectiveness ratio of US\$25 to US\$73 per DALY averted can be attained. Replacing saturated fat with monounsaturated

fat in manufactured foods accompanied by a public education campaign is relatively expensive in the base case (US\$1,865 to US\$4,012 per DALY averted), although the cost per DALY averted is highly sensitive to both the relative risk reduction in CVD events as well as the cost per individual. Reducing salt in manufactured foods through a combination of legislation and education campaigns is also relatively expensive in the base case (US\$1,325 to US\$3,056 per DALY averted), but could be much more cost-effective in high-density populations with a high salt intake. Little evidence is available on the cost-effectiveness of programs to encourage exercise and other behavior changes by individuals.

Personal Interventions. Prevention strategies targeted at individuals at high risk for CVD—measured as a combination of nonoptimal blood pressure and cholesterol, lifestyle, and genetic risk factors—can be effective, especially when implemented in tandem with population-based measures. A previous cardiovascular event is a reliable predictor of a second event. The cost-effectiveness of primary prevention of CVD may vary greatly depending on the underlying risk factors, the age of the patient, and the cost of medications.

Single-pill combinations of blood pressure-lowering medications, statins, and aspirin offer the potential dual benefit of being highly effective at lowering the risk of CVD and facilitating patient compliance with the ongoing drug regimen. A hypothetical multidrug regimen that includes generic aspirin, a beta-blocker, a thiazide diuretic, an angiotensin-converting enzyme (ACE) inhibitor, and a statin may be implemented at a cost-effectiveness ratio of US\$721 to US\$1,065 per DALY averted compared with a baseline of no treatment in a population with an underlying 10-year CVD risk of 35 percent. The use of the multidrug regimen for prevention in patients with a lower underlying CVD risk improves health benefits, but costs increase more than proportionately.

Acute Management of CVD. The cost of treating acute myocardial infarction using aspirin and beta-blockers is less than US\$25 per DALY averted in all regions. Relatively more expensive interventions that offer marginally greater effectiveness include the use of thrombolytics such as streptokinase (US\$630 to US\$730 per DALY averted) and tissue plasminogen activator (US\$16,000 per DALY averted).

The combination of aspirin and the beta-blocker atenolol has been shown to be highly cost-effective in preventing the recurrence of a vascular event. The incremental cost-effectiveness ratio of sequentially adding an ACE inhibitor such as enalapril (US\$660 to US\$866 per DALY averted), a statin such as lovastatin (US\$1,700 to US\$2,000 per DALY averted), and coronary artery bypass graft (more than US\$24,000 per DALY averted) to the baseline therapy is greater when hospital facilities are available. In regions with poor access to hospitals,

the combination of aspirin and a beta-blocker is highly cost-effective (US\$386 to US\$545 per DALY averted). In all regions, treating congestive heart failure using enalapril and the beta-blocker metoprolol is also highly cost-effective (approximately US\$200 per DALY averted).

Acute Management and Secondary Prevention of Stroke.

The cost of treating acute ischemic stroke using aspirin is US\$150 per DALY averted. Relatively cost-ineffective interventions involve the use of a tissue plasminogen activator (US\$1,300 per DALY averted) and anticoagulants such as heparin or warfarin (US\$2,700 per DALY averted). Aspirin is the lowest-cost option for secondary prevention of stroke (US\$3.80 per single percentage point decrease in the risk of a second stroke within two years or US\$70 per DALY averted). The combination of the antiplatelet medication dipyridamole and aspirin is equally cost-effective (US\$93 per DALY averted). In contrast, carotid endarterectomy is expensive for secondary prevention (US\$1,500 per DALY averted).

Strategies for Injury Prevention

Increasing economic development and use of motor vehicles has resulted in increases in traffic-related deaths and injuries; these events account for roughly a third of the burden from all unintentional injuries in LMICs.

Speed bumps appear to be the most cost-effective and cost less than US\$5 per DALY averted in all regions if installed at the most dangerous junctions that account for 10 percent of junction deaths. Increased speeding penalties, media coverage, and enforcement of traffic laws are only slightly less cost-effective. Motorcycle helmet legislation (US\$467 per DALY averted in Thailand), bicycle helmet legislation (US\$107 per DALY averted in China), and improved enforcement of traffic codes through a combination of enforcement and information campaigns (US\$5 to US\$169 per DALY averted) are relatively more expensive but deserve greater attention, given the growing health burden associated with rising levels of vehicle ownership. Research has demonstrated that seat belts and child restraints are effective in the developed world, and lowering their costs and encouraging their routine use may improve their cost-effectiveness in LMICs.

Key interventions to reduce intentional violence, both self-inflicted (suicides) and interpersonal (homicides and war-related deaths), include changing cultural norms, reducing access to guns, and improving criminal justice and social welfare systems, but these interventions are difficult to evaluate using a cost-effectiveness framework, and a cost-benefit analysis is more appropriate. Studies of interventions targeting interpersonal violence in developed countries show that behavioral, legal, and regulatory interventions cost less than the money they save, in some cases by an order of magnitude. Providing shelters for victims of domestic violence in the United States

has a benefit-cost ratio of 6.8 to 18.4. Implementing a gun registration law in Canada involved a one-time cost of US\$70 million, compared with annual health-related costs of US\$50 million for firearm-related injuries in that country. Interventions for troubled youths to reduce criminal activity include mentoring (with net benefits ranging from US\$231 to US\$4,651 per participant), family therapy (US\$14,545 to US\$60,721), and aggression replacement therapy (US\$8,519 to US\$34,071).

Policy Interventions to Lower Alcohol and Tobacco Use

The growing prevalence of smoking, especially among women in LMICs, is a serious threat to health. Interventions to reduce tobacco use are noteworthy not just because they are highly cost-effective but also because the burden of deaths and disability that they can avert is large. Tobacco control through tax increases often has dual benefits of increasing tax revenues as well as discouraging smoking initiation and encouraging smokers to quit. The cost-effectiveness of a policy to increase cigarette prices by 33 percent ranges from US\$13 to US\$195 per DALY averted globally, with a better cost-effectiveness ratio (US\$3 to US\$42 per DALY averted) in low-income countries. In comparison, nicotine replacement therapy (US\$55 to US\$751 per DALY averted) and nonprice interventions, including banning advertising, providing health education information, and forbidding smoking in public places, are relatively less cost-effective (US\$54 to US\$674 per DALY averted) in low-income countries but are still important components of any tobacco control program.

In regions with a relatively high prevalence of high-risk alcohol use—that is, Europe and Central Asia, Latin America and the Caribbean, and Sub-Saharan Africa—tax increases to lower alcohol use are extremely cost-effective (US\$105 to US\$225 per DALY averted). However, in regions with a lower prevalence of high-risk use—namely, East Asia and the Pacific and South Asia—tax-based policies can be among the least cost-effective interventions (more than US\$2,500 per DALY averted). Advertising bans are among the most cost-effective (but least studied) of all interventions to reduce high-risk drinking in all regions (US\$134 to US\$280 per DALY averted). In East Asia and the Pacific, a comprehensive ban on advertising and reduced access to retail outlets are highly cost-effective interventions (US\$123 to US\$146 per DALY averted). Random breath testing is one of the least cost-effective interventions to reduce the alcohol-related disease burden (US\$973 to US\$1,856 per DALY averted). In Sub-Saharan Africa, however, averting the burden of disease associated with drunk driving is an important priority and is addressed effectively through such policies as random breath testing and stricter enforcement of drunk-driving laws (US\$531 per DALY averted). Providing high-risk drinkers with brief advice from a physician in primary care settings is of intermediate cost-effectiveness

(US\$480 to US\$819 per DALY averted) in all regions, but combining this intervention with a tax on alcohol increases cost-effectiveness (US\$260 to US\$533 per DALY averted) in all regions except Sub-Saharan Africa.

Packaging of Interventions and Services

This section examines the overall cost-effectiveness of a service level, including all conditions addressed as part of a package of services, rather than evaluating individual interventions separately.

Emergency and Hospital Care. The cost per death averted of training lay first responders and volunteer paramedics is between US\$130 and US\$283 (or US\$5 to US\$11 per DALY averted) depending on the region. Ambulances outfitted with trained paramedics can avert deaths at a cost of US\$1,148 to US\$3,479 (US\$46 to US\$137 per DALY averted) in urban settings and US\$3,457 to US\$10,449 (US\$140 to US\$410 per DALY averted) in rural settings. Although the evidence for the cost-effectiveness of district and referral hospitals is very limited, it does indicate that basic hospital care at the district level could be highly cost-effective (US\$13 to US\$104 per DALY averted).

Surgery. Some types of surgery are highly cost-effective as part of a country's health strategy. These include providing surgical care to injury victims, including those suffering from head trauma and burns; handling obstetric complications, such as obstructed labor or hemorrhage; and undertaking elective surgery to address conditions such as cataracts and otitis media that have a significant impact on the quality of life. In areas of high prevalence, cataract surgery can be extremely cost-effective at roughly US\$100 per DALY averted.

Many of these surgical interventions—including improved resuscitation and airway management using relatively simple procedures such as chest tubes and tracheostomy, improved fracture management, and improved management of burns covering less than 30 percent of the body—require only the basic facilities offered by district hospitals. The quality of surgery and the risk of complications vary widely, and adequate health system capacity is an important consideration. For the typical surgical facility located in a district hospital in an LMIC, the average cost per DALY averted for a representative set of surgical procedures is between US\$70 and US\$230. General surgery at the district hospital is cost-effective relative to other interventions in South Asia and Sub-Saharan Africa because of the relatively low input costs related to infrastructure and the high level of the avertable disease burden. Examples of surgical interventions with poor cost-effectiveness include first-line treatment of epilepsy with surgery, which is useful only to patients who do not respond to drug treatment, and

percutaneous transluminal coronary angioplasty for cardiovascular events.

Integrated Management of Childhood Illnesses. An intervention package consisting of exclusive breast feeding; vitamin A and zinc supplementation; screening for immunization; and case management of pneumonia, malaria, and diarrhea, including oral rehydration therapy, costs approximately US\$4.10 per child in Sub-Saharan Africa and is a cost-effective approach (US\$38 per DALY averted) to improving the health of children under five when program coverage is 50 percent.

Value of Doing Things Better

Intervention quality is an important determinant of cost-effectiveness, and improving quality can be an efficient way to use resources. Community health status tends to be correlated with the quality of health service facilities, which can be enhanced even in resource-constrained settings. Indeed, resource-poor settings have the greatest potential for improving quality at low cost. In the case of acute respiratory infections, for example, the cost-effectiveness of improving the quality of care by implementing an educational activity for providers ranges from US\$132 to US\$800 per life saved (US\$4 to US\$28 per DALY averted) when initial intervention quality is poor and infections are widespread. Quality improvements can cost between US\$2,000 and US\$5,000 per life saved (US\$70 to US\$176 per DALY averted) with improved baseline quality, low disease prevalence, or both. Educational interventions to improve the quality of diarrhea treatment can be extremely cost-effective (less than US\$18 per DALY averted) depending on these two factors.

Regional Analyses for South Asia and Sub-Saharan Africa

Given the significant health burden borne by countries in South Asia and Sub-Saharan Africa, cost-effectiveness information for interventions related to high-burden health conditions is presented for these two regions. In South Asia (figure 2.4), CVD-related interventions, including tobacco taxes, treatment of acute myocardial infarction with aspirin and beta-blockers, and increasing coverage of the EPI program, rank among the most cost-effective interventions. Treatment of latent TB, coronary artery bypass graft for ischemic heart disease, treatment of depression, and cholera immunization to prevent diarrheal disease rank among the least cost-effective. Vitamin A deficiency, leprosy, and epilepsy are important conditions that impose a relatively lower burden of DALYs on this region, but a number of highly cost-effective interventions to deal with each of these conditions could be scaled up.

In Sub-Saharan Africa (figure 2.5), HIV/AIDS and malaria rank among the highest-burden conditions. Of the 16 most

cost-effective interventions addressing high-burden diseases, 8 are associated with these two sources of ill health alone. Other interventions that are both cost-effective and address high-burden diseases include nutritional support (including breastfeeding advice for mothers) for children under the age of four, and increasing coverage of the EPI. Oral rehydration therapy for diarrheal disease can be cost-effective if the cost of the package is relatively low (that is, less than US\$1 per child per treatment).

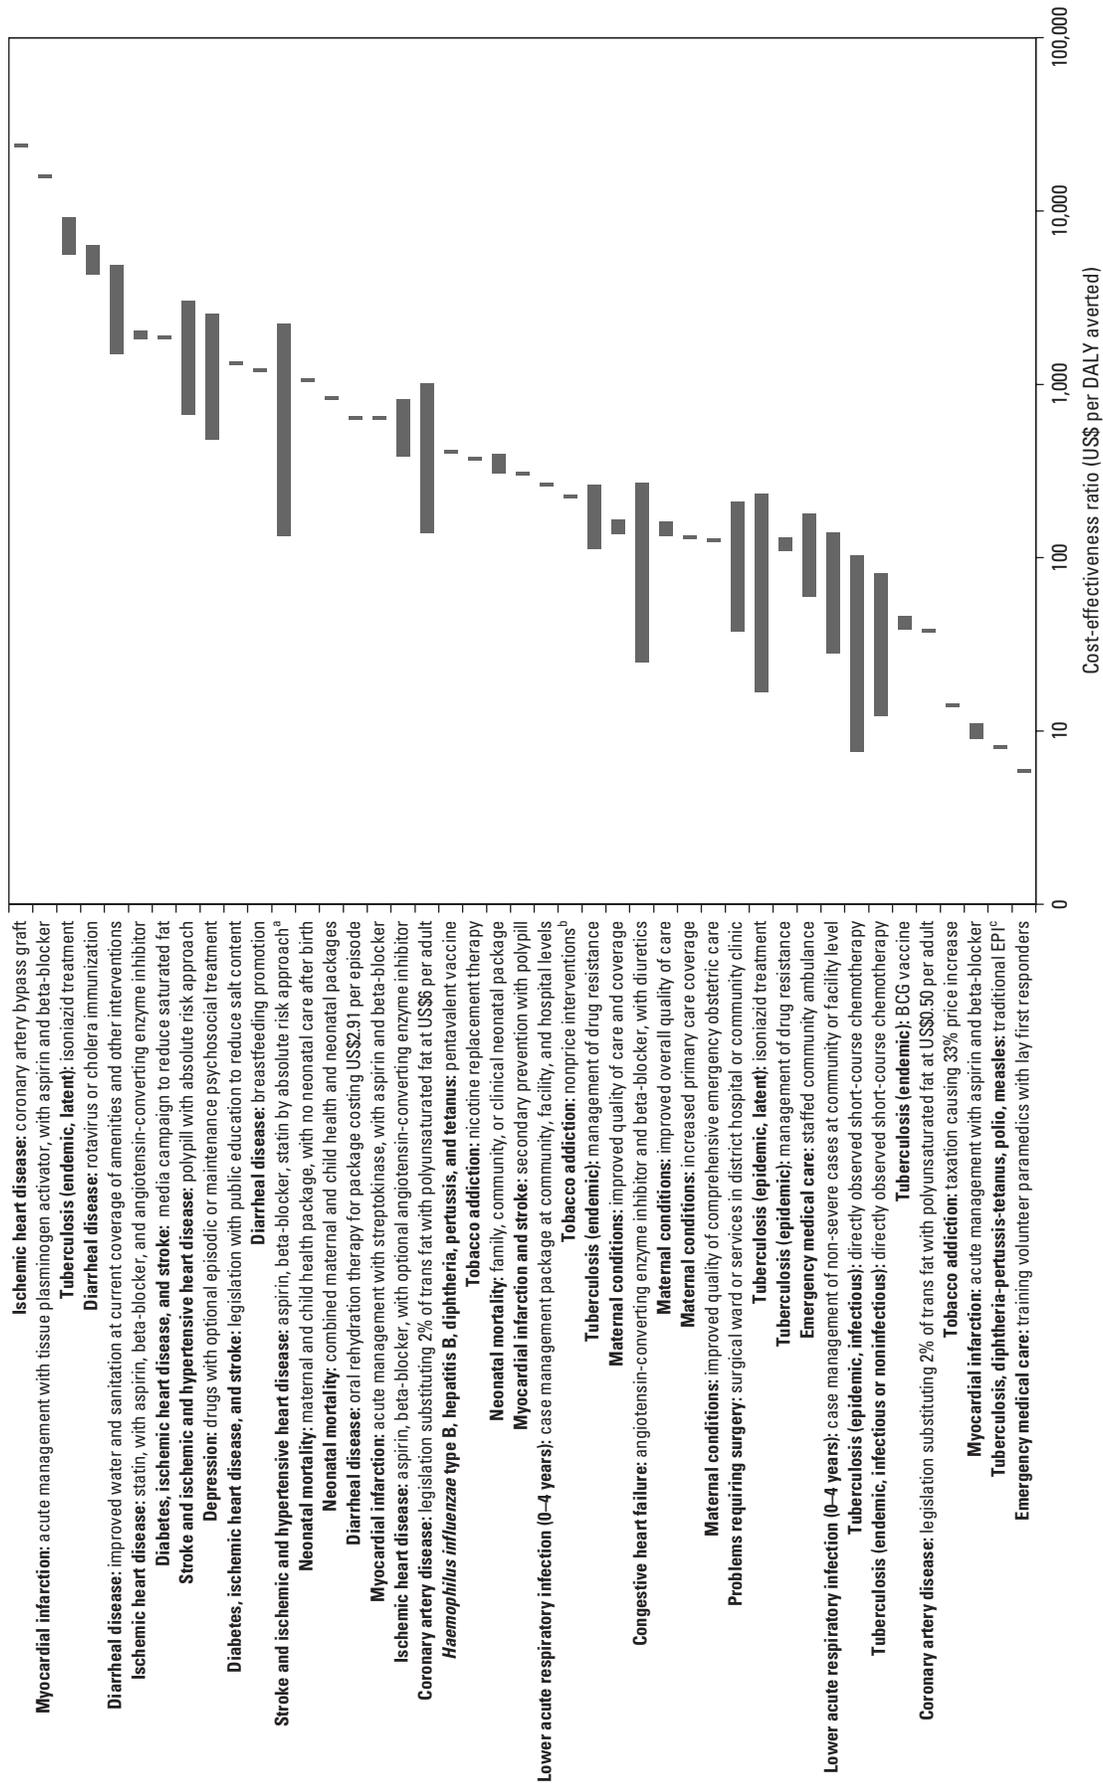

Table 2.2 identifies interventions relevant to South Asia and Sub-Saharan Africa that have been evaluated in this volume and have the greatest potential to reduce the burden of disease in those regions at an affordable price.⁶ The table also highlights interventions that address conditions that account for a moderate to high burden of disease but at a relatively high cost.

Personal versus Population-based Interventions

Figure 2.6 displays a histogram of intervention clusters categorized as either population based or personal (see annex 2.A for definitions). A greater number of personal intervention clusters than population-based intervention clusters are categorized as being highly cost-effective. Although this result may be partly an artifact of the way in which we have grouped interventions into clusters, it lends some support to the observation first made in the first edition of *Disease Control Priorities in Developing Countries* (Jamison and others 1993) that personal interventions are not necessarily less cost-effective than population-based interventions. Population-based interventions are cost-effective when effectively targeted to populations in which disease prevalence (or the potential prevalence and subsequent mortality if the interventions are not implemented) is high. For example, primary prevention of acute myocardial infarction using aspirin is not nearly as cost-effective as secondary prevention in patients who have already suffered a stroke or myocardial infarction, because this latter category has, by virtue of the first event, identified itself as being at higher risk than the general population. Similarly, malaria prevention programs will be highly cost-effective in areas where malaria is a serious problem but less so in countries where the burden of this disease is less and people are better served by treatment with an effective antimalarial.

DISCUSSION

Since the publication of the previous edition of this book, the epidemiological and demographic profiles of many LMICs and the range of available health interventions have changed significantly. This edition has the benefit of hindsight in looking back at the variety and affordability of interventions that were evaluated in the previous edition, both to see how the optimal mix of strategies may have changed in the intervening period and to ascertain trends.

Note: Diseases were considered high burden for South Asia if their total avertable burden was greater than 10 million DALYs. Bars represent the range in point estimates of cost-effectiveness ratios for specific interventions included in each intervention cluster and do not represent variation across regions or statistical confidence intervals. Point estimates for LMICs were obtained directly from the relevant chapters, calculated as the midpoint of range estimates reported in the chapters, or calculated from a population-weighted average of the region-specific estimates reported in the chapters. For details of these intervention clusters, including the specific interventions covered in each, see annex tables 2.B.1 and 2.B.2. Only interventions with cost-effectiveness reported in terms of DALYs are included in this figure. For interventions with cost-effectiveness reported in other units, see annex tables 2.C.1 and 2.C.2.

a. Cost-effectiveness range of aspirin, beta-blockers, and statin to prevent stroke and ischemic and hypertensive heart disease is incremental to salt reduction legislation and health education.

b. Nonprice interventions for tobacco addiction include advertising bans, smoking restrictions, supply reduction, and information dissemination.

c. EPI = Expanded Program on Immunization.

Figure 2.6 Distribution of Interventions in LMICs by Cost-Effectiveness Ratio

Lessons

Three lessons are broadly applicable. They relate to communicable diseases, noncommunicable diseases, and technological progress.

Communicable Diseases. Interventions to treat communicable diseases have been highly cost-effective in the past and remain so despite new challenges, such as drug-resistant pathogens and vectors. Although much progress has been made in lowering the burden of disease associated with vaccine-preventable illnesses, diarrhea, and to a lesser extent with acute respiratory infections, progress made on other diseases, such as malaria and TB, has been rolled back by such challenges as parasite resistance in the case of malaria and the HIV epidemic in the case of TB. An important exception may be diseases for which vaccines have been available, where significant gains in health have been achieved. In general, discerning a link between the availability of effective, affordable interventions in 1993 and a significant effect on the disease burden since that time is difficult because of the problem in defining the appropriate counterfactual of what would have happened in the absence of interventions that were implemented.

Noncommunicable Diseases. Compared with 13 years ago, many more cost-effective interventions have been evaluated and are being used for noncommunicable diseases, which continue to grow in importance as populations undergo the epidemiological transition. Many of these interventions have been available for more than a decade; however, their costs have

dropped as key drugs have gone off patent. Acute management of stroke and myocardial infarction using aspirin, beta-blockers, and nitroglycerin costs as little as US\$15 to US\$30 per DALY averted and ranks among the most cost-effective interventions available in LMICs. Even though many of the interventions were first developed in the industrial world, their benefits are now largely available in the developing world. Thus, the challenge lies in the ability of health care systems in LMICs to adopt these interventions on a large scale.

Technological Progress. Much progress has been made in scientific understanding and in the availability of affordable, population-based and personal interventions for preventing and treating HIV/AIDS; however, adequate scaling up of these interventions remains a challenge, with a few notable exceptions. The international health system has shown remarkable technological agility in responding to this epidemic, demonstrating that the world's scientific-industrial machinery is capable of rising to the challenge of emerging diseases when there is sufficient economic motivation for doing so. For instance, combination antiretroviral treatments are currently available for as little as US\$150 for a year's supply in some countries. In contrast, monotherapy with zidovudine, or AZT, which was the standard of care 10 years ago, was less effective, more expensive, and much more prone to drug resistance. As before, the challenge does not appear to be in the availability of interventions either to prevent infection in adults or to effectively ensure against transmission from infected mothers to newborns. Rather, the challenge lies in the willingness and ability to fund and deploy the interventions effectively. Clearly, much more remains to be done to develop affordable treatments. However, without a vaccine, the only feasible solution appears to be to aggressively prevent further transmission while treating patients under well-implemented programs that can achieve the high rates of treatment adherence required to maintain the continued effectiveness of drug therapy.⁷ More generally, the challenge of motivating technological advances for diseases that do not threaten the developed world remains to be addressed.

Importance of Health Systems

In describing efficient means of producing health, this chapter has said little about how such efficiency may be translated into practice. The overall cost-effectiveness of a service level or package of interventions, rather than the cost-effectiveness of individual interventions, is the appropriate indicator to determine which interventions should be used. From a planning point of view, taking the infrastructure as fixed, at least in the immediate future, and then asking how it can best be used to deliver the most cost-effective interventions might be sensible. Where infrastructure is limited, expanding access will have to take priority. Other factors related to health system

Table 2.2 Neglected Low-Cost Opportunities and High-Cost Interventions in South Asia and Sub-Saharan Africa

Neglected low-cost opportunities in South Asia	Cost per DALY averted^a (US\$)	Thousands of DALYs averted^{a,b} per 20% increase in coverage	Burden of target diseases^a (millions of DALYs)
CHILDHOOD IMMUNIZATION			
Additional coverage of traditional Expanded Program on Immunization (tuberculosis, diphtheria-pertussis-tetanus, polio, measles)	8	n.e.	28.4
HIV AND AIDS			
Voluntary counseling and testing			
Peer-based programs targeting at-risk groups (e.g., commercial sex workers) to disseminate information and teach specific skills	9–126	n.e.	7.4
School-based interventions that disseminate information to students			
Prevention of mother-to-child-transmission with antiretroviral therapy			
SURGICAL SERVICES AND EMERGENCY CARE			
Surgical ward in a district hospital, primarily for obstetrics, trauma and injury	6–212	at least 1.8	48.0–146.3
Staffed community ambulance			
Training of lay first responders and volunteer paramedics			
TUBERCULOSIS			
Childhood vaccination against endemic TB			
Directly observed short-course chemotherapy	8–263	n.e.	13.9
Isoniazid treatment of epidemic TB			
Management of drug resistance			
LOWER ACUTE RESPIRATORY ILLNESSES OF CHILDREN UNDER FIVE			
Community- or facility-based case management of non-severe cases			
Case management package including community- and facility-based care for non-severe cases and hospital-based care for severe cases	28–264	0.7–1.8	9.7–26.4
CARDIOVASCULAR DISEASE			
Management of acute myocardial infarction with aspirin and beta-blocker			
Primary prevention of coronary artery disease with legislation substituting 2% of trans fat with polyunsaturated fat, at \$0.50 per adult			
Secondary prevention of congestive heart failure with angiotensin-converting enzyme inhibitors and beta-blockers incremental to diuretics	9–304	at least 0.1	25.9–39.1
Secondary prevention of myocardial infarction and stroke with polypill containing aspirin, beta-blocker, thiazide diuretic, angiotensin-converting enzyme inhibitor, and statin			
TOBACCO USE AND ADDICTION			
Tax policy to increase price of cigarettes by 33 percent			
Non-price interventions such as advertising bans, health information dissemination, tobacco supply reductions, and smoking restrictions	14–374	at least 2.5	15.7
Nicotine replacement therapy			
MATERNAL AND NEONATAL CARE			
Increased primary care coverage			
Improved quality of comprehensive emergency obstetric care	127–394	at least 1.3	37.7–47.8
Improved overall quality and coverage of care			
Neonatal packages targeted to families, communities, and clinics			

Table 2.2 (Continued)

Neglected low-cost opportunities in Sub-Saharan Africa	Cost per DALY averted^a (US\$)	Thousands of DALYs averted^{a,b} per 20% increase in coverage	Burden of target diseases^a (millions of DALYs)
CHILDHOOD IMMUNIZATION			
Second opportunity measles vaccination ^c Additional coverage of traditional Expanded Program on Immunization (tuberculosis, diphtheria-pertussis-tetanus, polio, measles)	1–5	n.e.	13.5–31.3
TRAFFIC ACCIDENTS			
Increased speeding penalties, media, and law enforcement Speed bumps at the most dangerous traffic intersections	2–12	n.e.	6.4
MALARIA			
Insecticide-treated bed nets ^c Residual household spraying ^c Intermittent preventive treatment during pregnancy ^c	2–24	20.8–37.6	35.4
SURGICAL SERVICES AND EMERGENCY CARE			
Surgical ward in a district hospital, primarily for obstetrics, trauma and injury Staffed community ambulance Training of lay first responders and volunteer paramedics	7–215	1.6–21.2	25–134.2
CHILDHOOD ILLNESSES			
Integrated management of childhood illnesses ^c Case management of non-severe lower acute respiratory illnesses at the community or facility level Case management package including community- or facility-based care for non-severe cases and hospital-based care for severe lower acute respiratory illnesses Breastfeeding support to prevent underweight children ^c	9–218	at least 1.2	9.6–45.1
CARDIOVASCULAR DISEASE			
Management of acute myocardial infarction with aspirin and beta-blocker Primary prevention of coronary artery disease with legislation substituting 2% of trans fat with polyunsaturated fat, at \$0.50 per adult Secondary prevention of congestive heart failure with angiotensin-converting enzyme inhibitors and beta-blockers incremental to diuretics Secondary prevention of myocardial infarction and stroke with polypill containing aspirin, beta-blocker, thiazide diuretic, angiotensin-converting enzyme inhibitor, and statin	9–273	at least 0.04	4.6
HIV AND AIDS			
Peer-based programs targeting at-risk groups (e.g., commercial sex workers) to disseminate information and teach specific skills Voluntary counseling and testing Diagnosis and treatment of sexually-transmitted diseases ^c Condom promotion and distribution ^c Prevention and treatment of tuberculosis co-infection ^c Blood and needle safety programs ^c Prevention of mother-to-child transmission with antiretroviral therapy	6–377	n.e.	56.8
MATERNAL AND NEONATAL CARE			
Increased primary care coverage Improved quality of comprehensive emergency obstetric care Improved overall quality and coverage of care Neonatal packages targeted to families, communities, and clinics	82–409	at least 2.8	29.8–37.7

(Continues on the following page.)

Table 2.2 (Continued)

High-cost interventions in South Asia	Cost per DALY averted ^a (US\$)	Thousands of DALYs averted ^{a,b} per 20% increase in coverage	Burden of target diseases ^a (millions of DALYs)
DEPRESSION			
Episodic treatment with newer antidepressant drug (selective serotonin reuptake inhibitors)	1,003–1,449	0.4–0.8	14.6
Episodic or maintenance psychosocial treatment plus treatment with newer antidepressant drug (selective serotonin reuptake inhibitors)			
HIGH BLOOD PRESSURE AND CHOLESTEROL			
Primary prevention of stroke and ischemic and hypertensive heart disease with aspirin, beta-blocker, and statin, incremental to policy-induced behavior change, at 15 percent risk of CVD event over 10 years	1,120–1,932	at least 6.7	48.6
Primary prevention of stroke and ischemic and hypertensive heart disease with a polypill, containing aspirin, beta-blocker, thiazide diuretic, angiotensin-converting enzyme inhibitor, and statin, at 15 percent risk of CVD event over 10 years			
LIFESTYLE DISEASES			
Primary prevention of diabetes, ischemic heart disease, and stroke through policy that replaces saturated fat with monounsaturated fat in manufactured foods, accompanied by a public education campaign	1,325–1,865	1.3–1.8	39.5
Primary prevention of diabetes, ischemic heart disease, and stroke through legislation that reduces salt content plus public education			
STROKE (ISCHEMIC)			
Acute management with recombinant tissue plasminogen activator with 48 hours of onset			
Acute management with heparin within 48 hours of onset	1,630–2,967	0.03–0.4	2.2–9.2
Secondary prevention with carotid endarterectomy			
DIARRHEAL DISEASES			
Oral rehydration therapy if the package cost is greater than US\$2.30 per child per episode	500–6,390	0.02–2.5	22.3
Rotavirus or cholera immunization			
TUBERCULOSIS			
Isoniazid treatment for latent endemic TB in patients uninfected with HIV	5,588–9,189	n.e.	13.9
SCHIZOPHRENIA AND BIOPOLAR DISORDER			
Antipsychotic medication and psychosocial treatment for schizophrenia	1,743–17,702	0.02–0.12	2.2–2.9
Valproate and psychosocial treatment for bipolar disorder			
CARDIOVASCULAR DISEASE			
Management of acute myocardial infarction with streptokinase or tissue plasminogen activator, incremental to aspirin and beta-blocker			
Secondary prevention of ischemic heart disease with statin, incremental to aspirin, beta-blocker, and angiotensin-converting enzyme inhibitor	638–24,040	0.04–0.3	25.9
Secondary prevention of ischemic heart disease with coronary artery bypass graft			

Table 2.2 (Continued)

High-cost interventions in Sub-Saharan Africa	Cost per DALY averted ^a (US\$)	Thousands of DALYs averted ^{a,b} per 20% increase in coverage	Burden of target diseases ^a (millions of DALYs)
DIARRHEAL DISEASES			
Oral rehydration therapy if the cost per episode is greater than US\$2.80 per child	500–1,658	0.1–4.6	22
Rotavirus or cholera immunization			
HIV AND AIDS			
Home care treatment ^c	673–1,494	n.e.	56.8
Antiretroviral therapy in populations with low adherence ^c			
TRAFFIC ACCIDENTS			
Random driver breath tests			
Enforcement of seatbelt laws	973–2,146	at least 0.05	6.2–6.4
Child restraint promotion			
HIGH BLOOD PRESSURE AND CHOLESTEROL			
Primary prevention of stroke and ischemic and hypertensive heart disease with aspirin, beta-blocker, and statin, incremental to policy-induced behavior change, at 15 percent risk of CVD event over 10 years	1,920	n.e.	10.6
LIFESTYLE DISEASES			
Primary prevention of diabetes, ischemic heart disease, and stroke through policy that replaces saturated fat with monounsaturated fat in manufactured foods, accompanied by a public education campaign	1,766–2,356	1.4–1.8	9.6
Primary prevention of diabetes, ischemic heart disease, and stroke through legislation that reduces salt content plus public education			
STROKE (ISCHEMIC)			
Acute management with recombinant tissue plasminogen activator within 48 hours of onset	1,284–2,940	0.02–0.3	0.9–3.6
Acute management with heparin within 48 hours of onset			
Secondary prevention with carotid endarterectomy			
TUBERCULOSIS			
Isoniazid treatment for latent endemic TB in patients uninfected with HIV	4,129–5,506	n.e.	8.1
CARDIOVASCULAR DISEASE			
Management of acute myocardial infarction with streptokinase or tissue plasminogen activator, incremental to aspirin and beta-blocker			
Secondary prevention of ischemic heart disease with statin, incremental to aspirin, beta-blocker, and angiotensin-converting enzyme inhibitor	634–26,813	0.03–0.2	4.6
Secondary prevention of ischemic heart disease with coronary artery bypass graft

n.e. = not evaluated.

a. Ranges represent variation in point estimates of cost-effectiveness, DALYs averted, or burden of disease among the different interventions listed in each group. Point estimates of cost-effectiveness and DALYs averted were obtained directly from the relevant chapters or calculated as the midpoint of range estimates reported in the chapters. Burden of disease were obtained from the relevant chapters and from Mathers and others 2006.

b. Avertable DALYs per 20% increase in treatment coverage in a hypothetical sample population of one million people.

c. Only evaluated for Sub-Saharan Africa.

capacity and infrastructure may play a key role in determining the adoption of interventions. The current evidence on the cost-effectiveness of service levels such as district or referral hospitals is weak. Even though part of the problem lies with the difficulty of valuing the health benefits these facilities produce, more could be done. Chapter 3 presents a more detailed discussion of issues pertaining to health systems, but the broader questions of why some cost-effective interventions are used while others are not is a subject for future inquiry.

Even though much of the technology to significantly reduce the burden of disease already exists, few cost-effective interventions are available for some diseases. Shaping research priorities in a manner that is responsive to the treatment needs of the millions of HIV/AIDS patients and of people suffering from mental disorders across the range of LMICs is a challenge.

Setting intervention priorities efficiently can make a dollar go farther in improving health and can substantively increase available resources. Moreover, without demonstrably improved efficiency in health spending, aid agencies and development partners are unlikely to be persuaded to dig deeper into their pockets to pay for further expansions of health programs. Improving efficiency should not, however, detract from the importance of increasing resources that are available for implementing these interventions and of meeting broader

internationally agreed-upon development goals such as the Millennium Development Goals. These objectives are complementary.

The lack of reliable data on costs and effectiveness is an important obstacle to efficient priority setting. Despite the relatively good data on the efficacy of interventions in clinical trial settings, reliable effectiveness data are generally lacking. Furthermore, not enough is known about the costs, extent of coverage, and institutional capacity requirements of interventions in developing countries. The messages presented in this chapter represent the best available information about the relative costs of purchasing health through a wide range of interventions. The challenge that lies ahead is for these messages to move beyond the academic realm: ultimately, it is the extent to which policy makers make the commitment to act on them that will save lives.

ACKNOWLEDGMENTS

We are grateful to the many authors and the nine editors of this volume, whose work, guidance, and feedback were essential inputs to this chapter. Pamela Maslen provided valuable assistance in compiling annex tables. Any remaining errors are ours alone.

ANNEX 2.A: INTERVENTION CATEGORIES AND PERTINENT POLICY INSTRUMENTS

The term *intervention* is used to denote actions taken by or for individuals to reduce the risk, duration, or severity of an adverse health condition. Policy instruments encourage, discourage, or undertake interventions. Stopping smoking, for example, is an intervention that an individual can take to reduce his or her risk of a range of diseases, and taxing tobacco products is a potential instrument of government policy to encourage this intervention. Interventions are divided into those that are *population based* and those that are *personal* as follows:

- Population-based primary prevention is directed toward entire populations or population subgroups. These interventions fall into three broad categories: personal behavior change, control of environmental hazards, and population-oriented medical interventions (for example, immunization, mass chemoprophylaxis, and screening and referral).
- Personal interventions are directed toward individuals and can be provided at home; at clinics (community, private, work-based, or school-based); at district hospitals; or at referral hospitals.

Primary prevention aims at reducing the level of one or more identified risk factors to reduce the probability of the initial occurrence of a disease (for instance, providing medication for established hypertension to prevent stroke or myocardial infarction).

Cure of a condition aims at removing the cause and restoring function to what it was before.

Acute management consists of time-limited interventions that decrease the severity of acute events or the level of established risk factors to minimize their long-term effect (for instance, providing thrombolytics for acute myocardial infarction or angioplasty to reduce stenosis in coronary arteries).

Secondary prevention (or *chronic care*) consists of ongoing interventions aimed at decreasing the severity and frequency of recurrent events of chronic or episodic diseases (for instance, providing selective serotonin reuptake inhibitors for severe unipolar depression).

Rehabilitation aims at restoring or partially restoring physical, psychological, or social function resulting from a previous condition.

Palliation aims at reducing pain and suffering from a condition for which no cure or means of rehabilitation is currently available. It may range from the use of aspirin for headaches to the use of opiates to control terminal cancer pain.

Policy instruments are activities that governments or other entities that wish to encourage or discourage interventions or to expand the potential interventions could undertake. The following are five major instruments of policy:

- Information, education, and communication seek to improve the knowledge of individuals and service providers about the consequences of their choices.
- Taxes and subsidies on commodities, services, and pollutants seek to effect appropriate behavioral responses.
- Regulation and legislation seek to limit the availability of certain commodities, to curtail certain practices, and to define the rules governing the financing and provision of health services.
- Direct expenditures seek to provide or to finance the provision of selected interventions (such as immunizations); to provide infrastructure (for instance, medical schools) that facilitates the provision of a range of interventions; or to alter infrastructure so as to influence behavior (for example, by installing speed bumps).
- Research and development, either undertaken directly or encouraged through subsidies, are central to the goal of expanding the range of interventions available and reducing their costs.

ANNEX 2.B: SUMMARY OF INTERVENTIONS

Table 2.B.1 summarizes personal interventions. A summary of population-based interventions is shown in table 2.B.2.

ANNEX 2.C: SUMMARY OF OTHER INTERVENTIONS

Table 2.C.1 summarizes personal interventions for which cost-effectiveness is evaluated using a measure other than US\$/DALY averted. A summary of population-based interventions evaluated using measures other than DALYs is shown in table 2.C.2.

Table 2.B.1 Summary of Personal Interventions

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
African trypanosomiasis	Case finding and treatment	Identification and treatment of <i>Trypanosoma brucei gambiense</i> using the card agglutination trypanosomiasis test with parasitological confirmation, allowing for rapid diagnosis and treatment	Clinic	Primary prevention, cure	All ages	15 (Sub-Saharan Africa)	—	—	2 (Sub-Saharan Africa)
African trypanosomiasis	Melarsoprol	Used in the second stage of the disease	Clinic	Secondary prevention	All ages	10 (Sub-Saharan Africa)	—	—	2 (Sub-Saharan Africa)
African trypanosomiasis	Eflornithine	Used in the second stage of the disease	Clinic	Secondary prevention	All ages	20 (Sub-Saharan Africa)	—	—	2 (Sub-Saharan Africa)
Alcohol abuse	Brief advice to heavy drinkers by primary health care providers	During primary health care visits, provision of advice by physicians through education sessions and psychosocial counseling	Clinic	Primary prevention	Adolescents and adults	642	1.75	—	5
Bipolar disorder	Lithium, valproate, with optional psychosocial treatment, hospital-based	Episodic treatment in a hospital setting with lithium or valproate with or without maintenance or episodic psychosocial treatment	District or referral hospital	Secondary prevention	Adults over 15	4,417	3,590–5,244	1.00	5
Bipolar disorder	Lithium, valproate, with optional psychosocial treatment, community-based	Episodic treatment of bipolar disorder in a community setting using lithium or valproate with or without maintenance or episodic psychosocial treatment	District or referral hospital	Secondary prevention	Adults over 15	3,113	2,498–3,728	1.35	5
Cataract	Extracapsular surgery	Extracapsular cataract extraction with implantation of a posterior chamber intraocular lens; removal of the lens and the front portion of the capsule, which are then replaced with an artificial lens	District or referral hospital	Cure	Adults over 40	183	—	—	3
Congestive heart failure	ACE inhibitor and beta-blocker, with diuretics	Use of ACE inhibitor and an optional beta-blocker (metoprolol), incremental to diuretics	District hospital	Secondary prevention	Adults	150	27–274	11.59	5

Dengue	Improved case management	No specific treatment: early recognition of symptoms such as intense continuous abdominal pain, persistent vomiting, restlessness or lethargy; supportive treatment includes fluid replacement and electrolytic therapy	Clinic or district hospital	Acute management	All ages	587	—	—	2
Depression	Drugs with optional episodic or maintenance psychosocial treatment	Antidepressant drugs (tricyclic antidepressant or selective serotonin reuptake inhibitor) used alone or in combination with psychosocial treatment for episodic depression or maintenance treatment	District or referral hospital	Secondary prevention	Adults over 15	1,699	657–2,741	3.96	5
Diarrheal disease	Oral rehydration therapy for package costing US\$5.50 per episode	Case management of acute diarrheal infection with oral rehydration salt solutions, for package costing US\$5.50 per child per episode	Clinic	Acute management	Children	1,062	—	16.57	5
Epilepsy	First-line treatment with phenobarbital	First line treatment with phenobarbital to treat epilepsy patients	District hospital	Secondary prevention	All ages	89	—	2.99	5
Epilepsy (refractory)	Second-line treatment with phenobarbital and lamotrigine or surgery	Antiepileptic drugs, phenobarbital and lamotrigine, or a combination of phenobarbital and surgery to treat epilepsy patients unresponsive to phenobarbital	Referral hospital	Secondary prevention	All ages	3,027	2,994–3,060	0.29	5
HIV/AIDS	Mother-to-child transmission prevention	All pregnant women offered screening to prevent mother-to-child transmission; administration of a short-course of AZT, lamivudine, or nevirapine to mothers prepartum and intrapartum and to newborns postpartum to reduce the risk of mother-to-child transmission; also includes breastfeeding advice	Clinic	Primary prevention	Mothers and infants	192	7–377	—	2
HIV/AIDS	Sexually transmitted infection diagnosis and treatment	Sexually transmitted infection screening and treatment promotion to prevent future infection and to identify and treat high-risk populations	Clinic	Primary prevention, cure	Adolescents and adults	57 (Sub-Saharan Africa)	9–105 (Sub-Saharan Africa)	—	2 (Sub-Saharan Africa)

(Continues on the following page.)

Table 2.B.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
HIV/AIDS	Treatment of Kaposi's sarcoma	Treatment before or after antiretroviral treatment, including failed antiretroviral treatment; local or systemic treatment of lesions to provide largely cosmetic benefit	Clinic or district hospital	Primary prevention, palliation	All ages 52,449	34,968–69,930	—	—	3
HIV/AIDS	Treatment of opportunistic infections	Opportunistic infection prophylaxis; necessary for patients without access to antiretroviral treatment, for immunosuppressed patients waiting for antiretroviral treatment to take effect, for patients who refuse or cannot take antiretroviral treatment, for patients for whom antiretroviral treatment fails, and for groups of patients who are unable to recover sufficient CD4 cells despite good inhibition of viral replication	Clinic or district hospital	Primary prevention, cure	All ages 156	3–310	—	—	3
HIV/AIDS	Tuberculosis coinfection prevention and treatment	Preventive therapy, short-course chemotherapy, or co-trimoxazole prophylaxis	Clinic	Primary prevention, cure	All ages 121 (Sub-Saharan Africa)	6–235 (Sub-Saharan Africa)	—	—	2 (Sub-Saharan Africa)
HIV/AIDS	Home care	Home visits providing basic care to sick AIDS patients or comprehensive schemes that provide palliative care, nutrition, psychosocial support and counseling, and links to primary and secondary health care	Household	Secondary prevention, palliation	All ages 673 (Sub-Saharan Africa)	—	—	—	2 (Sub-Saharan Africa)
HIV/AIDS	Antiretroviral therapy	Combination therapy with multiple antiretroviral drugs associated with prolonged survival in treated patients	Clinic	Primary prevention	All ages 922 (Sub-Saharan Africa)	350–1,494 (Sub-Saharan Africa)	—	—	3 (Sub-Saharan Africa)

Integrated management of childhood illness	Integrated management of childhood illness	Integration of effective interventions to improve child health and nutrition into a coordinated strategy by improving health worker performance, child health service delivery, and family and community practices	Clinic	Primary prevention, secondary prevention, cure	Children	39 (Sub-Saharan Africa)	3 (Sub-Saharan Africa)
Ischemic heart disease	Aspirin, beta-blocker, and optional ACE inhibitor	Aspirin plus beta-blocker (atenolol) with optional ACE inhibitor (enalapril), with or without hospital availability	District or referral hospital	Secondary prevention	Adults	688	5
Ischemic heart disease	Statin, with aspirin, beta-blocker and ACE inhibitor	Statin (lovastatin), incremental to aspirin, beta-blocker (atenolol), and ACE inhibitor (enalapril), with or without hospital availability	District or referral hospital	Secondary prevention	Adults	2,028	5
Ischemic heart disease	Coronary artery bypass graft	Placement of grafts (usually saphenous vein or internal mammary artery) to bypass stenosed coronary arteries, while maintaining cerebral and peripheral circulation by cardiopulmonary bypass	Referral hospital	Secondary prevention	Adults	36,793	5
Leishmaniasis	Case finding and treatment	Combination of identification and treatment, vector control where feasible, and (in zoonotic foci) control of animal reservoirs	Clinic or district hospital	Primary prevention	All ages	9	2
Lower acute respiratory infections (nonsevere)	Case management at community or facility level	Nonsevere infection diagnosed by breath rate and treated by a community health worker or at a health facility, with amoxicillin, acetaminophen, and possibly salbutamol	Clinic, community	Cure	Children under 5	129	5
Lower acute respiratory infections (severe and very severe)	Case management at hospital level	Severe or very severe infection diagnosed by breath rate and with x-ray tests and treated at a hospital with antibiotics and possibly salbutamol, oxygen, and prednisolone	District hospital	Cure	Children under 5	4,530	5

(Continues on the following page.)

Table 2.B.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Lower acute respiratory infections	Case-management package at community, facility, and hospital levels	Comprehensive case-management strategy covering non-severe infection being treated by a community health worker or at a health facility, severe infection treated at a hospital, and very severe infection treated at a hospital	Clinic or district hospital	Cure	Children under 5	—	11.26	37.86	5
Malaria	Intermittent preventive treatment in pregnancy with sulfadoxine-pyrimethamine	Intermittent preventive treatment in areas with high and stable transmission of <i>Plasmodium falciparum</i> malaria; two curative doses of sulfadoxine-pyrimethamine given during the second and third trimesters of pregnancy during prenatal care visits	Clinic	Primary prevention	Pregnant women	13–24 (Sub-Saharan Africa)	208.00 (Sub-Saharan Africa)	827.80 (Sub-Saharan Africa)	5 (Sub-Saharan Africa)
Malaria	Intermittent preventive treatment in pregnancy with drug other than sulfadoxine-pyrimethamine	Intermittent preventive treatment in areas with high and stable transmission of <i>Plasmodium falciparum</i> malaria; two curative doses of antimalarial treatment given with a possible change in first-line therapies from chloroquine to sulfadoxine-pyrimethamine, chloroquine to artemisinin combination therapy, or sulfadoxine-pyrimethamine to artemisinin combination therapy	Clinic	Primary prevention	Pregnant women	2–11 (Sub-Saharan Africa)	—	77,500.00 (Sub-Saharan Africa)	5 (Sub-Saharan Africa)
Maternal mortality	Increased primary care coverage	Increased percentage of women accessing routine prenatal, intranatal, and postnatal care	Clinic or district hospital	Primary prevention	Pregnant women	—	13.09 (South Asia), 27.88 (Sub-Saharan Africa)	32.00 (South Asia), 77.00 (Sub-Saharan Africa)	5 (South Asia), 5 (Sub-Saharan Africa)
Maternal mortality	Improved quality of comprehensive emergency obstetric care	Increased percentage of women with severe complications receiving comprehensive emergency obstetric care	Clinic or district hospital	Acute management	Pregnant women	—	13.28 (South Asia), 28.28 (Sub-Saharan Africa)	32.00 (South Asia), 78.00 (Sub-Saharan Africa)	5 (South Asia), 5 (Sub-Saharan Africa)

Maternal mortality	Improved overall quality of care	Improvements to quality of prenatal and delivery care; enhanced package including availability of doctor and full range of basic and comprehensive emergency obstetric care (all six essential obstetric functions: administering antibiotics intravenously or intramuscularly, administering oxytocics intravenously or intramuscularly, manually removing the placenta, administering anticonvulsants intravenously or intramuscularly, carrying out instrumental delivery, and removing retained products of conception; optional nutritional supplementation	Clinic	Primary prevention, acute management	Pregnant women	147 (South Asia), 83 (Sub-Saharan Africa)	133–160 (South Asia), 82–85 (Sub-Saharan Africa)	21.90 (South Asia), 53.05 (Sub-Saharan Africa)	56.20 (South Asia), 153.20 (Sub-Saharan Africa)	5 (South Asia), 5 (Sub-Saharan Africa)
Maternal mortality	Improved quality of care and coverage	Improvements to quality of prenatal and delivery care and increase in the proportion of women receiving needed care; enhanced package including availability of doctor and full range of basic and comprehensive emergency obstetric care (all six essential obstetric functions noted above); optional nutritional supplementation	Clinic	Primary prevention, acute management	Pregnant women	152 (South Asia), 86 (Sub-Saharan Africa)	138–167 (South Asia), 85–86 (Sub-Saharan Africa)	23.51 (South Asia), 56.93 (Sub-Saharan Africa)	60.29 (South Asia), 164.14 (Sub-Saharan Africa)	5 (South Asia), 5 (Sub-Saharan Africa)
Myocardial infarction	Aspirin and beta-blocker	Aspirin with or without beta-blocker (atenolol)	District or referral hospital	Acute management	Adults	14	13–15	1.04	—	5
Myocardial infarction	Streptokinase, with aspirin and beta-blocker	Incremental use of streptokinase, in addition to aspirin and beta-blocker (atenolol)	District or referral hospital	Acute management	Adults	671	—	1.04	—	5
Myocardial infarction	Tissue plasminogen activator, with aspirin and beta-blocker	Incremental use of tissue plasminogen activator in addition to aspirin and beta-blocker (atenolol)	District hospital	Acute management	Adults	15,889	—	0.42	—	5
Myocardial infarction and stroke	Polypill	Combination treatment with aspirin, beta-blocker, thiazide diuretic, ACE inhibitor and statin, based on 10-year risk of cardiovascular disease	District hospital	Secondary prevention	Adults	409	—	—	—	5

(Continues on the following page.)

Table 2.B.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Neonatal mortality	Maternal and child health package with no neonatal care after birth	Mother and child health package that includes family planning, prenatal care, and comprehensive obstetric care	Clinic or district hospital	Primary prevention	Mothers and infants	1,060 (South Asia), 924 (Sub-Saharan Africa)	—	—	4 (South Asia), 5 (Sub-Saharan Africa)
Neonatal mortality	Family, community, or clinical neonatal package	Healthy home care practices, including exclusive breastfeeding, clean cord care, care seeking for emergencies; if birth outside a facility, then clean delivery kit	Clinic, community or household	Primary prevention	Mothers and infants	349 (South Asia), 345 (Sub-Saharan Africa)	305–394 (South Asia), 338–351 (Sub-Saharan Africa)	—	4 (South Asia), 5 (Sub-Saharan Africa)
Neonatal mortality	Combined maternal and child health with neonatal packages	Family planning, prenatal care, and comprehensive obstetric care packages, as well as healthy home care practices, including exclusive breastfeeding, clean cord care, care seeking for emergencies; if birth outside a facility, then clean delivery kit	Clinic, community or household	Primary prevention	Mothers and infants	839 (South Asia), 789 (Sub-Saharan Africa)	—	—	4 (South Asia), 5 (Sub-Saharan Africa)
Panic disorder	Drugs with optional psychosocial treatment	Anxiolytic drugs (benzodiazepine), tricyclic antidepressants or selective serotonin reuptake inhibitor used with or without psychosocial treatment	District or referral hospital	Secondary prevention	Adults over 15	734	384–1,084	0.83	5
Parkinson's disease	Ayurvedic treatment and levodopa or carbidopa	Levodopa (L-dopa), carbidopa, or ayurvedic therapy for partial relief of symptoms	District hospital or referral hospital	Secondary prevention	Adults over 45	1,132	752–1,512	0.13	5
Parkinson's disease	Levodopa or carbidopa and deep brain stimulation	Levodopa or carbidopa and deep brain stimulation	District hospital or referral hospital	Secondary prevention	Adults over 45	31,114	—	0.15	5

Schizophrenia	Antipsychotic drugs with optional psychosocial treatment, hospital-based	Maintenance treatment in a hospital setting with antipsychotic drugs, neuroleptic antipsychotic drug, or an atypical antipsychotic drug, with or without psychosocial treatment	District hospital or referral hospital	Secondary prevention	Adults over 15	11,920	4,105–19,736	0.60	—	5
Schizophrenia	Antipsychotic drugs with optional psychosocial treatment, community-based	Maintenance treatment in a community-based setting with antipsychotic drugs, neuroleptic antipsychotic drug, or an atypical antipsychotic drug, with or without psychosocial treatment	Community	Secondary prevention	Adults over 15	9,834	2,472–17,197	0.70	—	5
Stroke (ischemic)	Aspirin	Aspirin dose within 48 hours of onset of acute stroke	Clinic or district hospital	Acute management	Adults over 15	149	—	1.62	0.12	5
Stroke (ischemic)	Heparin and recombinant tissue plasminogen activator	Heparin within 48 hours of onset of stroke or thrombolytic therapy using recombinant tissue plasminogen activator within 3 hours of onset	District hospital	Acute management	Adults over 15	1,977	1,278–2,675	1.22	1.70	5
Stroke (recurrent)	Aspirin and dipyridamole	Daily aspirin dose or combination of aspirin and extended release dipyridamole	Clinic or district hospital	Secondary prevention	Adults over 15	81	70–93	1.77	14.29	5
Stroke (recurrent)	Carotid endarterectomy	Carotid endarterectomy surgery to remove harmful plaque from the carotid arteries	Referral hospital	Secondary prevention	Adults over 15	1,458	—	4.93	39.82	5
Stroke and ischemic and hypertensive heart disease	Polypill by absolute risk approach	Combination treatment with aspirin, beta-blocker, thiazide diuretic, ACE inhibitor, and statin based on 10-year risk of cardiovascular disease	District or referral hospital	Primary prevention	Adults	2,128	773–3,483	61.65	—	5
Tobacco addiction	Nicotine replacement therapy	Smoking cessation treatments in the form of nicotine replacement therapy	Clinic	Primary prevention	Adults	396	—	37.14	452.05	5
Trachoma	Trichiasis surgery	Trichiasis surgery (eyelid correction) to prevent blindness and reduce likelihood of other conditions	District hospital or referral hospital	Secondary prevention	Adults over 40	39	—	—	—	3

(Continues on the following page.)

Table 2.B.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Trachoma	Tetracycline or azithromycin	Tetracycline or azithromycin to treat the initial trachoma infection through either mass treatment of all children younger than 10 or through targeted treatment of infected children and household members	Clinic	Primary prevention	Children and adults	6,269	—	—	3
Tuberculosis (endemic)	Management of drug resistance	Introduction of resistance testing, second-line drugs, longer treatment regimen (12–18 months), and rigorous bacteriological and clinical monitoring; standardized or individualized regimen	District hospital	Secondary prevention, cure	Adults over 15	318	208–429	—	5
Tuberculosis (endemic, infectious or non-infectious)	Directly observed short-course chemotherapy	Short-course chemotherapy of infectious or noninfectious tuberculosis (with or without transmission, non-HIV-positive), diagnosed via directly observed treatment strategy	Clinic	Primary prevention, cure	Adults over 15	301	84–551	—	5
Tuberculosis (endemic, latent)	Isoniazid treatment	Isoniazid treatment of latent infection (with or without x-ray exclusion of active cases; non-HIV-infected population)	District hospital	Secondary prevention	Adults over 15	13,158	9,450–16,867	—	5
Tuberculosis (epidemic)	Management of drug resistance	Management of drug resistance (standard regimen) for epidemic TB conducted via introduction of resistance testing, second-line drugs, longer treatment regimen (12–18 months), and rigorous bacteriological and clinical monitoring	District hospital	Secondary prevention, cure	Adults over 15	207	201–212	—	5
Tuberculosis (epidemic, infectious)	Directly observed short-course chemotherapy	Short-course chemotherapy of infectious TB (allowing for transmission, non-HIV positive) carried out for epidemic TB	Clinic	Primary prevention, cure	Adults over 15	102	15–189	—	5

Tuberculosis (epi- demic, latent)	Isoniazid treatment	Isoniazid treatment of latent infection (x-ray exclusion of active cases; non-HIV-positive population) is conducted for epidemic tuberculosis	District hospital	Secondary prevention	Adults over 15	197	45-348	—	5
Unwanted pregnancy	Family-planning programs	Intrauterine devices, voluntary sterilization, condoms and other barrier methods, implants, and oral contraceptives	Clinic	Primary prevention	Women of childbear- ing age	117	—	—	3
Zinc deficiency	Supplements with oral rehy- dration salts	Provision of zinc as an adjunct to oral rehydration salts in treating diarrhea in young children	Clinic or district hospital	Primary prevention	Children under 5	73	—	—	3

Source: Authors.

ACE = angiotensin — converting enzyme

Note: — = not available.

a. Refers to the age group to whom the intervention is targeted and not necessarily the one that is benefiting.

b. Ranges in cost-effectiveness reflect the variation in point estimates for specific interventions included in each intervention cluster and do not represent either variation across regions or statistical confidence intervals. Point estimates were obtained directly from the relevant chapters, calculated as the midpoint of range estimates reported in the chapters, or calculated from a population-weighted average of the region-specific estimates reported in the chapters. DALYs and deaths potentially avertable are for a 20 percentage point increase in intervention coverage in a hypothetical sample population of 1 million.

c. See table 2.1.

Table 2.B.2 Summary of Population-Based Interventions

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a	Cost-effectiveness (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Adolescent health and nutrition	School health and nutrition programs	Inclusion of deworming of intestinal worms and schistosomiasis; prompt recognition and treatment of malaria; insecticide-treated bednets; micronutrient supplements; breakfast, snacks, other meals; first-aid kits; referral to youth-friendly clinics; and counseling and psychosocial support	Community, school	Population-oriented medical intervention	School-age children	37	—	—	—	3
Alcohol abuse	Excise tax	25 to 50 percent increase in the current excise tax rate on alcoholic beverages	Policy level	Instrument of policy	Adolescents and adults	1,377	1,249–1,504	0.62	—	5
Alcohol abuse	Advertising ban and reduced access to beverage retail	Reduced access to alcoholic beverage retail outlets by reducing the hours of sale or advertising bans on television, radio, and billboards	Policy level	Instrument of policy	Adolescents and adults	404	367–441	0.44	—	5
Alcohol abuse	Excise tax, advertising ban, with brief advice	50 percent increase in the current excise tax rate on alcoholic beverages, combined with advice, education sessions, and psychosocial counseling; possible inclusion of random driver breath testing and advertising bans	Policy level	Instrument of policy	Adolescents and adults	631	601–661	2.85	—	5
Chagas disease	Vector control	Vector control activities including spraying combined with housing improvement, community involvement in surveillance, and strong programs of health education	Community	Control of environmental hazard	All ages	284 (Latin America and the Caribbean)	—	—	—	1 (Latin America and the Caribbean)

Coronary artery disease	Legislation substituting 2% of trans fat with polyunsaturated fat at US\$0.50 per adult	Legislation replacing 2% of dietary trans fat from partial hydrogenation in manufactured foods with polyunsaturated fat, at a cost of US\$0.50 per adult, and assuming a 7% reduction in coronary artery disease	Policy level	Instrument of policy	Adults	48	—	—	5
Coronary artery disease	Legislation substituting 2% of trans fat with polyunsaturated fat at US\$6 per adult	Legislation replacing 2% of dietary trans fat from partial hydrogenation in manufactured foods with polyunsaturated fat, at a cost of US\$6 per adult, and assuming a 7–40% reduction in coronary artery disease	Policy level	Instrument of policy	Adults	838	199–1,478	—	5
Dengue	Vector control	Chemical vector control using larvicides and insecticide space sprays (including emephos, permethrin, methoprene, pyriproxifen, and <i>Bacillus thuringiensis israelensis</i>) to protect drinking water, or environmental vector control, such as removal of standing water	Community or district hospital	Control of environmental hazard	All ages	2,566	1,992–3,139	—	2
Dengue	Immunization	Dengue immunization (a vaccine is currently undergoing clinical trials in Southeast Asia)	Community clinic or district hospital	Population-oriented medical intervention	Children	1,440	—	—	2
Diabetes, ischemic heart disease, and stroke	Legislation with public education to reduce salt content	Legislated reduction in salt content of manufactured foods and an accompanying public education campaign	Policy level	Instrument of policy	All ages	1,937	—	18.73	5
Diabetes, ischemic heart disease, and stroke	Media campaign to reduce saturated fat	Media campaign to reduce saturated fat content in manufactured foods and replace part of the saturated fat with polyunsaturated fat	2,617	Instrument of policy	All ages	2,617	—	13.86	5
Diarrheal disease	Breastfeeding promotion	Promotion of exclusive breastfeeding (recommended for six months) to new mothers, in which no other food or drink, including water, is permitted, except for supplements of vitamins and minerals and necessary medicines	Community, clinic, or district hospital	Personal behavior change	Adult women	930	—	0.43	5

(Continues on the following page.)

Table 2.B.2 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a	Cost-effectiveness (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Diarrheal disease	Cholera or rotavirus immunization	Immunization for endemic cholera with live oral vaccine or rotavirus immunization with rhesus-human rotavirus reassortant-tetravalent vaccine (currently under development) in populations at risk of an outbreak	Clinic	Population-oriented medical intervention	Children	2,712	2,478–2,945	0.62	1.98	5
Diarrheal disease	Improved water and sanitation at current coverage of amenities and other interventions	Improved water supply and excreta disposal where established infrastructure currently exists, in urban or rural settings for at least five years	Community	Control of environmental hazards	All ages	4,185	1,974–6,396	3.52	315.30	5
Diarrheal disease	Hand pump, standpost, or house connection where clean water supply is limited	Installation of hand water pump, standpost, or house connection where clean water supply is limited and associated infrastructure currently do not exist	Community	Control of environmental hazards	All ages	159	—	—	—	1
Diarrheal disease	Water sector regulation with advocacy where clean water supply is limited	Surveillance of drinking water quality and quality of service by the water supply utility in terms of coverage, quantity, continuity, control of sanitary hazards, and cost, as well as advocacy of lower connection charges	Policy level, community	Instrument of policy, control of environmental hazards	All ages	47	—	—	—	1
Diarrheal disease	Construction and promotion of basic sanitation where facilities are limited	Construction of low-cost excreta disposal facilities such as household pit latrines, ventilation-improved latrines, or pour-flush toilets, combined with public promotion of sanitation and hygiene	Policy level, community	Instrument of policy, control of environmental hazards	All ages	141	11–270	—	—	1

Down syndrome	Prenatal screening with option of pregnancy termination	Prenatal genetic screening program, incorporating maternal serum triple screening of all pregnant women, for trisomy of chromosome 21, to allow parents to determine whether to continue with an affected pregnancy	Clinic, district hospital	Population-oriented medical intervention	Pregnant women	15	—	—	5
Emergency medical care	Training volunteer paramedics with lay first responders	Identification and training of community member first responders and paramedics to act in health emergencies, recognize life- or limb-threatening situations, transport patients, and provide basic first aid	Policy level	Instrument of policy	All ages	6	18.42	74.00	5
Emergency medical care	Staffed community ambulance	Introduction or promotion of training programs for emergency responders and ambulance drivers in urban or rural settings for countries that lack ambulances and training programs	Policy level	Instrument of policy	All ages	120	34.84	140.00	5
<i>Haemophilus influenzae</i> type B (Hib)	Vaccine containing Hib	Hib vaccination (three or four doses), given concurrently with diphtheria-pertussis-tetanus	Clinic	Population-oriented medical intervention	Infants and children	733 ^b	29.25	113.83	5
Hib, and hepatitis B, diphtheria, pertussis, and tetanus	Pentavalent vaccine	Hib vaccination (three or four doses) and hepatitis B (three or four doses) given concurrently with diphtheria-pertussis-tetanus vaccine	Clinic	Population-oriented medical intervention	Infants and children	296 ^d	—	—	5
Hepatitis B	Hepatitis B vaccination	Hepatitis B (three or four doses) given through intramuscular injection	Clinic	Population-oriented medical intervention	Infants and children	23,520 ^d	—	—	5

(Continues on the following page.)

Table 2.B.2 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a	Cost-effectiveness (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
HIV/AIDS	Condom promotion and distribution	Targeted distribution and placement of condoms in locations such as bars or brothels; distribution linked to voluntary counseling and testing and sexually transmitted infection care to ensure universal access; information, education, and communication, including education through literature, classroom, and clinical settings and radio, newspapers, and television	Community or Community clinic	Personal behavior change	Adolescents and adults	82 (Sub-Saharan Africa)	52–112 (Sub-Saharan Africa)	—	—	1 (Sub-Saharan Africa)
HIV/AIDS	Blood and needle safety	Screening of all blood for transfusions; sterilization for all injections; harm reduction for injecting drug users, including needle exchange and drug substitution programs	All levels, including community clinics to referral hospitals	Population-oriented medical intervention	All ages	84 (Sub-Saharan Africa)	7–161 (Sub-Saharan Africa)	—	—	2 (Sub-Saharan Africa)
HIV/AIDS	Voluntary counseling and testing	Routine and voluntary confidential HIV counseling and testing	Clinic	Population-oriented medical intervention	Adults	47	10–85	—	—	2
HIV/AIDS	Peer and education programs for high-risk groups	Targeting community members (for example, students or commercial sex workers) to disseminate information and teach specific skills	Community	Personal behavior change	Adolescents and adults	37	6–68	—	—	2
Lymphatic filariasis	Annual mass drug administration	Two annual, single-dose, two-drug regimens are recommended: ivermectin plus albendazole in African countries that are endemic for onchocerciasis, and diethylcarbamazine plus albendazole for all other endemic countries	Clinic, community	Population-oriented medical intervention	All ages	15 (South Asia)	4–27 (South Asia)	—	—	4 (South Asia)

Lymphatic filariasis	Diethyl carbamazine salt	Fortification of salt with diethyl carbamazine	Policy level	Instrument of policy	All ages	22 (South Asia)	1–43 (South Asia)	—	4 (South Asia)
Lymphatic filariasis	Vector control	Integrated vector control to reduce overall prevalence of microfilaria parasites, such as polystyrene beads in vector (mosquito) breeding habitats	Policy level	Instrument of policy	All ages	160 (South Asia)	43–277 (South Asia)	—	4 (South Asia)
Malaria	Insecticide-treated bednets	Impregnation of bednets with deltamethrin, one treatment of permethrin, or two treatments of permethrin, with the bednets either purchased or subsidized	Household	Control of environmental hazards	All ages	11 (Sub-Saharan Africa)	5–17 (Sub-Saharan Africa)	376.00 (Sub-Saharan Africa)	5 (Sub-Saharan Africa)
Malaria	Residual household spraying	One or two doses of malathion, DDT, deltamethrin, or lambda-cyhalothrin applied to household surfaces	Household	Control of environmental hazards	All ages	17 (Sub-Saharan Africa)	9–24 (Sub-Saharan Africa)	376.00 (Sub-Saharan Africa)	5 (Sub-Saharan Africa)
Measles	Second opportunity vaccination in a fixed facility	Second opportunity to receive a dose of measles vaccine (either through routine or supplemental immunization activities) at a fixed facility	Clinic	Population-oriented medical intervention	Infants and children	4	—	—	5
Meningitis	<i>Neisseria meningitidis</i> vaccine	<i>Neisseria meningitidis</i> vaccine for serogroups A, C, Y, W135 only; unconjugated polysaccharides given subcutaneously; one dose with repeat three to five years later for those at high risk	Clinic	Population-oriented medical intervention	Children	12,632 (Sub-Saharan Africa)	—	—	5 (Sub-Saharan Africa)
Problems requiring surgery	Surgical ward or services in district hospital or community clinic	Surgical ward in a district hospital or community clinic to provide care for a wide range of conditions, such as trauma, childbirth, and abdominal conditions	District hospital, clinic	Instrument of policy	All ages	136	54–217	—	5
Onchocerciasis	Ivermectin	Annual dose of ivermectin	Clinic, community	Population-oriented medical intervention	Adults over 40	37	—	—	3
Soil-transmitted helminthic infections	Albendazole	Annual albendazole anti-helminthic drug treatment to reduce morbidity through the deworming of <i>Ascaris</i> , <i>Trichuris</i> , and hookworm in school-age children	Community, school	Population-oriented medical intervention	School-age children	3	—	127.76	1.98
									5

(Continues on the following page.)

Table 2.B2 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population ^a	Cost-effectiveness (US\$/DALY)	Cost-effectiveness range ^b (US\$/DALY)	Number of DALYs averted ^b (hundreds)	Number of deaths averted ^b	Quality of cost-effectiveness analysis evidence ^c
Tetanus	Tetanus toxoid vaccination, mix of strategies	Tetanus toxoid vaccination via a mix of strategies depending on local needs, including fixed facilities, immunization campaigns, mobile delivery, and community outreach	Clinic, community	Population-oriented medical intervention	Infants and children	1,411	—	—	—	5
Tobacco addiction	Taxation causing 33% price increase	A 33 percent price increase due to tobacco taxes to discourage tobacco use, prevent initiation (and subsequent addiction) among youths, increase the likelihood of cessation among current users, reduce relapse among former users, and reduce consumption among continuing users	Policy level	Instrument of policy	Adolescents and adults	22	—	37.27	1,905.99	5
Tobacco addiction	Nonprice interventions	Advertising bans on television, radio, and billboards; health information and advertising in the form of health warning labels on tobacco products; interventions to reduce tobacco supply, such as smuggling control; restrictions on smoking	Policy level	Instrument of policy	Adolescents and adults	353	—	—	—	5
Traffic accidents	Increased speeding penalties, enforcement, media campaigns, and speed bumps	Minimizing exposure to high-risk scenarios by installation of speed bumps at hazardous junctions, increased penalties for speeding, and other effective road-safety regulations combined with media coverage and better enforcement of legislation	Policy level	Instrument of policy	Adults	21	3–38	0.67	197.16	5
Traffic accidents	Enforcement of seatbelt laws, promotion of child restraints and random driver breath testing	Mandatory seat belt and child-restraint laws, enforcement of drunk-driving laws, and random breath testing of drivers	Policy level	Instrument of policy	Adults	2,449	999–3,899	0.32	93.87	5

Tuberculosis (endemic)	BCG vaccine	Live attenuated vaccine, BCG; recommended at birth or at first contact with health services in areas of high incidence	Clinic or district hospital	Primary prevention oriented medical intervention	Children	68	55–82	—	5
Tuberculosis, diphtheria, pertussis, tetanus, polio, measles	Traditional Expanded Program on Immunization (EPI)	Scaling up of EPI, a fixed increment of coverage added for each year 2002–11 to reach 90 percent; coverage increases assumed to result from switching to more effective and intensive implementation strategies rather than additional infrastructure investments	Community	Population-oriented medical intervention	Infants and children	7	—	—	5
Undernutrition and malnutrition	Sustained child health and nutrition program	Possible inclusion of prenatal care, women's health and nutrition, breastfeeding promotion and counseling, complementary feeding, growth monitoring and promotion, micronutrient supplementation, micronutrient fortification, supplementary feeding using local supplies, oral rehydration, and immunization and deworming; actual mix depends on local capabilities and conditions	Community, clinic	Population-oriented medical intervention	Children under five	225	—	—	3
Underweight children	Child survival program with nutrition component	Community-based nutrition programs to prevent growth faltering, control morbidity, and improve survival by promoting breastfeeding, providing education and counseling on optimal child feeding, preventing diarrheal disease, and monitoring growth	Community	Population-oriented medical intervention	Children under five	42	—	—	2

Source: Authors.

BCG = bacillus Calmette – Guérin; DDT = dichlorodiphenyl trichloroethane; EPI = Expanded Program on Immunizations

Note: — = not available.

a. Refers to the age group to whom the intervention is targeted and not necessarily the one that is benefiting.

b. Ranges in cost-effectiveness reflect the variation in point estimates for specific interventions included in each intervention cluster and do not represent either variation across regions or statistical confidence intervals. Point estimates were obtained directly from the relevant chapters, calculated as the midpoint of range estimates reported in the chapters, or calculated from a population-weighted average of the region-specific estimates reported in the chapters. DALYs and deaths potentially avertable are for a 20 percentage point increase in intervention coverage in a hypothetical sample population of 1 million.

c. See table Z.1.

d. Cost-effectiveness ratio calculated from deaths averted only.

Table 2.C.1 Cost Effectiveness of Other Personal Interventions

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population	Cost-effectiveness estimate (US\$) ^a	Quality of CEA evidence ^b
Breast cancer	Clinical breast exam	Examination of the breast performed by doctors or other trained health care professionals; annually, biennially, or every five years; for women ages 40–60	Clinic	Secondary prevention	Women ages 40–60	7,125–9,907 per death prevented (India); 522–722 per YLS (India)	4
Breast cancer	Screening mammography	Examination of the breasts performed by compressing the breast firmly between a plastic plate and an X-ray cassette that contains special X-ray film; one lifetime or biennially	Clinic	Secondary prevention	Women ages 40–70	12,262–24,493 per death prevented (India); 902–1846 per YLS (India); 2,450–14,790a per YLS (Europe); 28,600–47,900 (USA)	2 (USA, Europe); 4 (India)
Breast cancer	Chemotherapy and/or tamoxifen	Tamoxifen and/or chemotherapy for 45-year-old premenopausal women with early-stage breast cancer; for node-positive, node-negative, estrogen-receptor-positive, and estrogen-receptor-negative patients	District hospital	Secondary prevention	Women age 45	12,820–171,700 (USA)	3
Breast cancer	Radiation therapy	Radiation therapy following mastectomy and chemotherapy for node-positive breast cancer in premenopausal women	District hospital	Secondary prevention	Premenopausal women	23,300–44,000 per QALY (USA)	2
Cervical cancer	Nationwide Pap screening program based on five-year intervals	Nationwide Pap screening program based on five-year intervals	District hospital	Secondary prevention	Adult women	769 per YLS (Vietnam)	2
Cervical cancer	Conventional or liquid-based cytology testing	Conventional cytology using the Papanicolaou (Pap) smear and HPV testing every 1 to 10 years; or Liquid-based cytology using the Papanicolaou (Pap) smear and HPV testing every 1 to 5 years	District hospital	Secondary prevention	Adult women	126,500 (USA); 162,400 (Thailand)	2
Cervical cancer	Two-visit HPV testing	HPV DNA testing during the first visit followed by treatment of screen-positive women during the second visit	District hospital	Secondary prevention	Adult women	122 per YLS (Brazil); 167 per YLS (Madagascar); 41 per YLS (South Africa); 117 per YLS (Zimbabwe)	1
Cervical cancer	One-visit VIA	Cervix is viewed after the application of an acetic acid solution; screening and treatment conducted during the same visit	District hospital	Secondary prevention	Women age 35–42	56 per YLS (Brazil); 54 per YLS (Madagascar); 43 per YLS (Zimbabwe)	1
Cervical cancer	Three-visit cytology	Cytology sample obtained during the first visit, colposcopy for screen-positive women conducted during the second visit, and treatment provided during the third visit	District hospital	Secondary prevention	Women age 35–48	589 per YLS (Brazil); 379 per YLS (Madagascar); 331 per YLS (Zimbabwe)	1

Cervical cancer	Chemoradiation therapy	Cisplatin-based chemoradiation regimens on the basis of published and estimated survival	District hospital	Secondary prevention	Adult women	337–31,400 per YLS (USA)	1
Chronic obstructive pulmonary disease	Inhaled medication	Inhaled ipratropium bromide or corticosteroid such as fluticasone propionate	Clinic/district hospital	Palliation	Adults	7,800–13,400 per OALY (High-income countries)	1
Chronic obstructive pulmonary disease	A-1 antitrypsin augmentation therapy	Intravenous treatment of chronic obstructive pulmonary disease related to severe deficiency; ranges with age and efficacy	Clinic/district hospital	Palliation	Adults	14,400–215,000 per OALY (High-income countries)	1
Chronic obstructive pulmonary disease, asthma, and cardiovascular disease	Mechanical ventilation or oxygen therapy	Mechanical ventilation with inspiratory support, invasive respiration in intensive care unit, or long-term home oxygen therapy	Clinic/district hospital	Palliation	Adults	15,000–19,000 per YLS (High-income countries); 32,350–47,850 per OALY (High-income countries)	1
Colorectal cancer	Flexible sigmoidoscopy every 5 years with or without fecal occult blood test	Flexible sigmoidoscopy enables the physician to look at the inside of the large intestine from the rectum through the last part of the colon, called the sigmoid or descending colon; fecal occult blood test checks stool samples for traces of blood.	District hospital	Secondary prevention	Adults	18,700–25,954 (USA)	2
Colorectal cancer	Double-contrast barium enema every 5 years	A series of x-rays of the colon and rectum taken after the patient is given an enema, followed by an injection of air. The barium outlines the intestines on the x-rays, allowing many abnormal growths to be visible. This is conducted every 5 years.	District hospital	Secondary prevention	Adults	11,503–26,393 per YLS (USA)	2
Colorectal cancer	Colonoscopy every 10 years	Colonoscopy allows the physician to look inside the entire large intestine, from the lowest part, the rectum, all the way up through the colon to the lower end of the small intestine. The procedure is used to look for early signs of cancer in the colon and rectum.	District hospital	Secondary prevention	Adults	9,309–22,672 per YLS (USA)	2
Colorectal cancer	Chemotherapy	Adjuvant chemotherapy for stage three colon cancer	District hospital	Secondary prevention	Adults	3,000–7,000 per YLS (High-income countries)	1
Colorectal cancer	Radiation therapy	Preoperative radiation therapy for rectal cancer patients; with varying rates of recurrence and survival advantage with and without radiation treatment	District hospital	Secondary prevention	Adults	908–15,228 per YLS (Sweden)	1

(Continues on the following page.)

Table 2.C.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population	Cost-effectiveness estimate (US\$)	Quality of CEA evidence
Diabetes	Smoking cessation	Counseling and medication such as the nicotine patch	Clinic	Primary prevention	Adolescents and adults	870 per QALY (EAP); 1,170 per QALY (ECA); 1,450 per QALY (LAC); 1,230 per QALY (MNA); 730 per QALY (SAR); 660 per QALY (SSA)	5
Diabetes	Annual eye examination	Dilated eye examination to detect proliferative diabetic retinopathy and macular edema followed by appropriate photocoagulation therapy to prevent blindness	Clinic	Secondary prevention	Adults	420 per QALY (EAP); 560 per QALY (ECA); 700 per QALY (LAC); 590 per QALY (MNA); 350 per QALY (SAR); 320 per QALY (SSA)	5
Diabetes	ACE inhibitor	ACE inhibitors for blood pressure control	Clinic	Secondary prevention	Adults	620 per QALY (EAP); 830 per QALY (ECA); 1,020 per QALY (LAC); 870 per QALY (MNA); 510 per QALY (SAR); 460 per QALY (SSA)	5
Diabetes	Metformin intervention for preventing type 2 diabetes	Metformin therapy for preventing type 2 diabetes among people at high risk, such as those with prediabetes	Clinic	Primary prevention	Adults	2,180 per QALY (EAP); 2,930 per QALY (ECA); 3,630 per QALY (LAC); 3,080 per QALY (MNA); 1,820 per QALY (SAR); 1,640 per QALY (SSA)	5
Diabetes	Cholesterol control	Cholesterol control for people with total cholesterol higher than 200 milligrams/deciliter	Clinic	Secondary prevention	Adults	4,420 per QALY (EAP); 5,940 per QALY (ECA); 7,350 per QALY (LAC); 6,240 per QALY (MNA); 3,680 per QALY (SAR); 3,330 per QALY (SSA)	5
Diabetes	Intensive glycemic control	Intensive glucose control to lower the level of glucose in the person with diabetes to a level close to that of a person without diabetes, for people with HbA1c higher than 8 percent, in order to prevent or delay long-term diabetes complications	Clinic	Secondary prevention	Adults	2,410 per QALY (EAP); 3,230 per QALY (ECA); 4,000 per QALY (LAC); 3,400 per QALY (MNA); 2,000 per QALY (SAR); 1,810 per QALY (SSA)	5
Kidney disease	Hemodialysis	Most common method used to treat advanced and permanent kidney failure; conducted in a treatment center or home.	Clinic, home	Secondary prevention	Adults	42,700–70,000 per YLS (USA); 61,000–99,400 per QALY (USA)	1

Kidney disease	Kidney transplant	Kidney transplant surgery	District or referral hospital	Cure	Adults	10,000 per LYS (USA); 11,000 per QALY (USA)	2
Kidney disease	ACE inhibitors	ACE inhibitors for all type-1 diabetics with macroproteinuria and all type-2 diabetics	Clinic	Secondary prevention	Adults	1,100–7,700 per QALY (USA)	4
Mild to moderate asthma	Quick-relievers in addition to inhaled corticosteroids	Rapid-acting bronchodilators that act to relieve bronchoconstriction and accompanying acute symptoms of wheeze, chest tightness, and cough, e.g., salbutamol; incremental to inhaled corticosteroid treatment	Clinic or district hospital	Palliation	Adults	10,600–13,900 per QALY (High-income countries)	1
Opioid abuse	Naltrexone induced rapid opioid detoxification under sedation (RODS)	Patient is given naltrexone under general anesthetic.	District hospital	Rehabilitation	Adults	2,498 per week of abstinence (Australia)	1
Opioid abuse	Conventional outpatient detoxification	Conventional outpatient detoxification is supervised withdrawal from a drug of dependence that attempts to minimize withdrawal symptoms.	Clinic	Rehabilitation	Adults	12,764 per abstinent patient (Australia)	1
Opioid abuse	Drug-free treatments	Residential or outpatient drug-free treatments as well as self-help group attendance	Clinic	Rehabilitation	Adults	7,000–13,000 ⁸ (USA)	1
Opioid abuse	Methadone maintenance substitution	Substitution of short-acting heroin with long-acting orally administered opioid Methadone; includes heroin users living in communities with high HIV prevalence	Clinic	Rehabilitation	Adults	6,800 per LYS (High-income countries); 9,000 per QALY (High-income countries, high-HIV prevalence)	1
Opioid abuse	Buprenorphine maintenance substitution	Buprenorphine substitution maintenance treatment for non-methadone patients.	Clinic	Rehabilitation	Adults	49,000 per QALY (High-income countries)	1
Osteoarthritis	Lifestyle change	Exercise (aquatic) and calcium supplements	Clinic	Primary/secondary prevention	Adults age 55–75; postmenopausal women	96,119–498,700 per QALY (High-income countries)	1
Osteoarthritis	Replacement surgery	Synovial fluid replacement (hylan G-F 20) for patients with osteoarthritis of the knee; or complete hip joint or knee replacement with implant	Clinic, district hospital	Secondary prevention; tertiary intervention	Elderly men and women	5,233–6983 per QALY (High income countries)	1
Osteoporosis	Hormone replacement therapy	Estrogen replacement from age 50, 60, or menopause for healthy women; 5-year to lifetime treatment	Clinic	Primary/secondary prevention	Postmenopausal women and women age 50 and up	5,088–23,734 per QALY	1

(Continues on the following page.)

Table 2.C.1 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population	Cost-effectiveness estimate (US\$) ^a	Quality of CEA evidence ^b
Osteoporosis	Calcium supplements with or without vitamin D	Calcium with or without vitamin D supplements, based on evidence that it reduces appendicular fractures; assumes a compliance rate of 70%	Clinic	Primary prevention	Women age 50 to 80	37,633–149,705 per QALY	1
Osteoporosis	Nonestrogen drug treatments	Raloxifene or calcitonin to reduce bone fractures; with or without 5 years of therapy	Clinic	Secondary prevention	Postmenopausal women age 50 to 80	34,166–835,622 per QALY (High income Countries)	1
Osteoporosis	Fluoride	Fluoride appears to decrease the risk of vertebral fracture for women with established osteoporosis; assumes neutral effect on hip fractures	Clinic	Secondary prevention	Postmenopausal women	46,684 per QALY (UK)	1
Pain	Morphine	Providing oral morphine and necessary associated drugs	Clinic	Palliation	All ages	210–408 per year of pain free life added (Chile, Romania, Uganda)	4
Primary care ailments	Limited care	Includes treatment of infection and minor trauma; for more complicated condition, includes diagnosis, advice and pain relief, and treatment as resources permit	Clinic	Cure	All ages	253–380 per DALY (Low income countries); 507–760 per DALY (Middle income countries)	1
Respiratory disease (end stage)	Lung transplant	Surgical replacement with donor lung	District hospital	Cure	Adults	238,200–464,000 per QALY (High-income countries)	1

Table 2.C.2 Cost-Effectiveness of Other Population-Based Interventions

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population	Cost-effectiveness estimate (US\$) ^a	Quality of CEA evidence ^b
Asthma	Education	Education in addition to exercise program	Clinic	Personal behavior change	Adults	71,500/QALY (High-income countries)	1
Colorectal cancer	Fecal occult blood test	Fecal occult blood test to check stool samples for traces of blood; conducted annually or biennially	District hospital	Secondary prevention	Adults	3,200–12,100 per YLS (High-income countries)	2
Diarrhea	Improved quality of care	Educational interventions to improve quality of care and encourage oral rehydration therapy in hospitals; varies with marginal improvement; low to average prevalence	Clinic/district hospital	Instrument of policy	All ages	14–6000 ^a per death averted	4
Diabetes	Lifestyle intervention (type 2 prevention)	Behavioral change for weight reduction by means of a combination of a low-calorie diet and moderate physical activity	Clinic	Personal behavior change	Adults	80 per QALY (EAP); 100 per QALY (ECA); 130 per QALY (LAC); 110 per QALY (MNAI); 60 per QALY (SAR); 60 per QALY (SSA)	5
Diabetes	Influenza and pneumococcal vaccinations	Influenza and pneumococcal vaccinations for elderly individuals with type 2 diabetes	Clinic	Population-oriented medical intervention	Elderly	220 per QALY (EAP); 290 per QALY (ECA); 360 per QALY (LAC); 310 per QALY (MNAI); 180 per QALY (SAR); 160 per QALY (SSA)	5
Diabetes	Screening	Screening of individuals at increased risk for undiagnosed diabetes	Clinic, district hospital	Population-oriented medical intervention	Adults over 25	5,140 per QALY (EAP); 6,910 per QALY (ECA); 8,550 per QALY (LAC); 7,260 per QALY (MNAI); 4,280 per QALY (SAR); 3,870 per QALY (SSA)	5
Diabetes	Annual screening for microalbuminuria	Screening for microalbuminuria and treating those who test positive	Clinic, district hospital	Population-oriented medical intervention	Adults	3,310 per QALY (EAP); 4,450 per QALY (ECA); 5,510 per QALY (LAC); 4,680 per QALY (MNAI); 2,760 per QALY (SAR); 2,500 per QALY (SSA)	5
Indoor air pollution-related illness	Liquefied petroleum gas	Substitution of wood, dung, and crop residues with liquefied petroleum gas for cooking and heating	Policy level	Instrument of policy	All ages	103–1,746 per healthy year (EAP); 1,258–1,361 per healthy year (ECA); 806–1,447 per healthy year (LAC); 779–785 per healthy year (MNAI); 321–558 per healthy year (SA); 534–736 per healthy year (SSA)	5

(Continues on the following page.)

Table 2.C.2 (Continued)

Condition	Intervention	Intervention description	Intervention setting	Objective	Target population	Cost-effectiveness estimate (US\$) ^a	Quality of CEA evidence ^b
Indoor air pollution-related illness	Kerosene	Substitution of wood, dung, and crop residues with kerosene for cooking and heating	Policy level	Instrument of policy	All ages	12–232 per healthy year (EAP); 172–188 per healthy year (ECA); 109–650 per healthy year (LAC); 98 per healthy year (MNA); 37–65 per healthy year (SAR); 62–87 per healthy year (SSA)	5
Indoor air pollution-related illness	Improved stove	Replacement of traditional open stoves with enclosed stoves that are more efficient and/or have flues for ventilation	Policy level	Instrument of policy	All ages	306–605 per healthy year (EAP); 975–1,134 per healthy year (LAC); 379–471 per healthy year (MNA); 13–15 per healthy year (SAR); 21–26 per healthy year (SSA)	5
Indoor air pollution-related illness	Improved stove with kerosene or LPG	Replacement of traditional open stoves with enclosed stoves that use kerosene or liquefied petroleum gas (LPG)	Policy level	Instrument of policy	All ages	26–85 per healthy year (EAP); 522–1,416 per healthy year (ECA); 305–784 per healthy year (LAC); 227–624 per healthy year (MNA); 27–182 per healthy year (SAR); 46–304 per healthy year (SSA)	5
Lung cancer	Early detection screening	Screening of high-risk individuals, such as current and former smokers, for lung cancer using helical computed tomography	District hospital	Population-oriented medical intervention	Adults	20,000–100,000 per YLS (USA)	3
Pneumonia	Improved quality of care	Improved quality of care, including education for health providers and treatment of non-severe and severe pneumonia; varies with marginal improvement; low to average prevalence	Clinic/district hospital	Instrument of policy	Children	132–5,000 ^a per death averted	4
Pollution-related illness	Control of toxins related to energy industry	Interventions include coal-fired power plant emissions controls, gasoline lead reduction, and desulphuring of residual fuel oil	Policy level	Instrument of policy	All ages	less than 0 per LYS (USA)	1
Pollution-related illness	Control of toxins related to agriculture and forestry	Interventions include targeted pesticide bans and emissions standards at processing facilities	Policy level	Instrument of policy	All ages	less than 0 per LYS (USA)	1
Pollution-related illness	Control of toxins related to residential sector	Interventions include radon remediation and sedimentation, filtration, and chlorination of drinking water	Policy level	Instrument of policy	All ages	5320–7730 per LYS (USA)	1

Pollution-related illness	Control of toxins related to industrial sector	Interventions include arsenic emissions standards at copper smelters and asbestos ban for brake linings	Policy level	Instrument of policy	All ages	less than 45,600 per LYS (USA)
Silicosis	Engineering control	Wet method e.g. spraying a surface or wetting a blade to reduce dust; local exhaust ventilation; total plant ventilation	Policy level	Control of environmental hazards	Working adults	105 ^a per DALY (USA and Canada); 109 ^a per DALY (Western Pacific)
Silicosis	Comfort or dust mask	Comfort or dust mask with associated training	Policy level	Instrument of policy	Working adults	111–191 ^a per DALY (USA and Canada); 117–174 ^a (Western Pacific)
Silicosis	Respirator	Half-face or full-face respirator and associated training	Policy level	Instrument of policy	Working adults	300–305 ^a per DALY (USA and Canada); 266–274 ^a per DALY (Western Pacific)

NOTES

1. Few other cost-effectiveness studies have covered a similarly extensive set of health interventions (Dixon and Welch 1991; Jamison and others 1993; Tengs and others 1995), and only one of those studies makes these comparisons on a global scale (Jamison and others 1993). The current World Health Organization project CHOICE (Choosing Interventions That Are Cost-Effective) is a parallel effort to make such global comparisons (Murray and others 2000; <http://www.who.int/evidence/cea>).

2. Of these 319 cost-effectiveness estimates, 257 were in terms of U.S. dollars per DALY and therefore comparable. Interventions with cost-effectiveness in terms of dollars per DALY were grouped into 121 intervention clusters to facilitate analyses and presentation.

3. *Health system capacity* is often used to describe both the level of care (primary, secondary, and tertiary) and the institutional and organizational capacities. We use the term to refer to the latter.

4. Chapter 15 presents a fuller discussion of these methods. Note that not all chapters have used these standardized costs. Furthermore, the analyses have used U.S. dollars rather than purchasing-power parity dollars (which provide a better measure of input resource intensity and are less susceptible to exchange rate fluctuations) in order to provide a monetary estimate that may be more useful to policy makers and donors.

5. Noneconomic reasons for maintaining certain interventions can include retaining key technical skills that may be required in the future and may lead to the development of new methods that may be more cost-effective (see chapter 66 on referral hospitals for a more in-depth discussion).

6. Some interventions with high potential to reduce the burden of disease may have been excluded due to the way their cost-effectiveness ratios were calculated. For example, nutrition-related interventions are excluded from the table because those evaluated in the volume address either vitamin A deficiency or iodine deficiency both of which are associated with low avertable burden. Also, only the burden of children age 0 to 4 was considered, further lowering the avertable burden. Another example is of the integrated management of infant and childhood illness, which is evaluated for Sub-Saharan Africa but not for the South Asia Region.

7. The second and third observations speak more generally to the global public goods nature of health research (see chapter 4 for an in-depth discussion). In relation to both HIV/AIDS and noncommunicable diseases, the responsiveness of the medical research system to threats to populations in developed countries has the potential to bring great benefits to people living in LMICs.

Chapter 3

Strengthening Health Systems

Anne Mills, Fawzia Rasheed, and Stephen Tollman

Interventions are not generally provided as freestanding activities but are delivered in a variety of packages and through different levels of a health system.¹ For this reason, this book—in addition to including the disease- and program-specific chapters—addresses not only the cost-effectiveness of levels of care, packages of care, and services but also the strengthening of the management of health systems as a whole.

Cost-effectiveness data reflect largely what can be achieved in a reasonably well-functioning health system. In that sense, they can be considered to represent potential cost-effectiveness and need to be supplemented with evidence and guidance on how health systems can be strengthened to provide interventions effectively, efficiently, and equitably. This argument is given added weight by evidence on inadequacies in the performance of health institutions in countries at all levels of development (Hensher 2001; Preker and Harding 2003). Hensher (2001) documents the extensive inefficiencies in low- and middle-income countries, including the following:

- failure to minimize the physical inputs used—for example, prescribing excessive quantities of drugs
- failure to use the mix of inputs that costs the least—for instance, allocating a high proportion of expenditure to staff salaries and only a small share to operating costs and maintenance
- failure to operate at the appropriate scale—for example, running extremely large hospitals that suffer from scale inefficiencies
- failure to pay staff enough to encourage good performance.

Hensher estimates that hospital inefficiencies could easily account for up to 10 percent of total health spending.

Such inefficiencies have two main causes. First, they may occur because decision makers lack incentives to behave efficiently; for example, their promotion chances may not depend on how well they perform in managing a hospital. Second, decision makers may be constrained in their ability to make efficient choices; for instance, they may lack knowledge or experience of what to do or political factors may affect whether they can dismiss underperforming staff members or determine which company they must buy drugs from. Evidence on the quality of care (chapter 70) demonstrates that health systems may not merely be inefficient in failing to minimize costs but may also fail to deliver effective care.

The extent of inequities is also a major concern. Recent analyses show that even when interventions are provided, the poorest members of society usually have the least access to them (Gwatkin and others 2000). In many countries, gaps in child mortality between the poor and the better off widened during the 1990s (World Bank 2004). Thus, health systems need to have the capacity not only to deliver interventions efficiently but also to sustain high levels of coverage, especially of the poorest and most vulnerable.

Awareness has grown that international targets, such as the Millennium Development Goals (MDGs) and the provision of antiretroviral treatment for HIV/AIDS patients cannot be achieved without the key elements of a functioning health system. The example of the reduction of maternal mortality in Sri Lanka (chapter 8) demonstrates the improvements in health outcomes that are possible once a basic platform of functioning health services is available on which targeted initiatives can build (Levine 2004).

Thus, the aim of this chapter is to review how health systems can be strengthened in differing country contexts to deliver

interventions effectively, efficiently, and equitably. The chapter is mainly concerned with strengthening health services: issues in managing core public health functions are reviewed elsewhere (Khaleghian and Das Gupta 2004). Although the chapter seeks to draw valuable lessons from all parts of the world, it focuses on countries with the least capacity, especially the poorer countries in Sub-Saharan Africa and Asia.

HISTORY AND CURRENT THEMES

Efforts to improve health in low- and middle-income countries over the past 50 years can be divided into a number of periods, with pendulum swings between focused, disease-specific support and broader health service or health system support. The 1950s, 1960s, and 1970s witnessed a number of successful disease control efforts, often termed *mass campaigns*—notably smallpox eradication, but also, for example, malaria and yaws control (Walt 2001). These mass campaigns built on earlier efforts, including those of the Rockefeller Foundation from the 1920s in controlling hookworm, yellow fever, and malaria. Despite regional differences in the degree of progress—for example, malaria control was not attempted in most of Sub-Saharan Africa—successes in regional and global control of diseases such as Chagas disease and measles in Latin America and the Caribbean and, more recently, polio worldwide have continued since the 1960s.

From early in the history of mass campaigns, the terminology used was of *vertical* and *horizontal* approaches (Gonzalez 1965), referring essentially to two key dimensions in program organization (Mills 2005): the extent to which program management was integrated into general health systems management, especially at lower management levels, as opposed to kept strictly separate, and the extent to which health workers had one function as opposed to many functions. Vertical programs (also known as *categorical programs*) had their own financing, management structures, and staff, even down to the service delivery level, instead of relying on existing systems. In contrast, horizontal programs delivered a number of services through the general health service structure.

In malaria control, for example, the World Health Organization defined a process whereby an initial vertical approach would evolve into a horizontal approach as the incidence of malaria fell. Initially, the effort required to detect and treat cases demanded dedicated and mobile workers. As transmission was reduced, these workers would detect fewer and fewer cases, so on efficiency grounds, detection and treatment activities needed to be handed over to the general health service infrastructure. However, this approach faced the dilemma that such services were often not strong enough to carry the control efforts forward.

The Alma Ata Declaration of 1978 was a turning point. The increasing emphasis on building networks of peripheral health

services in a number of postindependence Sub-Saharan African countries and the health successes of countries such as China and Cuba influenced a new international emphasis on a broadly based definition of primary health care. Quickly, however, the advocates of more focused disease-specific efforts responded with the notion of selective primary health care (Walsh and Warren 1980), focused on a limited number of presumed cost-effective interventions.

Since 1980, this tension in international health policy has persisted, with four main strands, namely:

1. The health care reform movement of the 1990s, which has continued into the new millennium in a somewhat attenuated form, has focused almost exclusively on financing and organizational changes, largely neglecting the question of whether improved health outcomes have been achieved.
2. The definition and development of cost-effective packages of care has progressed, as reviewed in chapter 64, with some attention given to their implications for services and systems.
3. The emphasis on specific disease-focused international programs, as reflected in the Global Fund for AIDS, Tuberculosis, and Malaria, has been increasing, and resources for such programs have been expanding.
4. The effort to encourage investment in integrated health services has continued.

Recent events indicate that these tensions remain unresolved. For example, Molyneux and Nantulya (2004) call for combining community-driven, global health initiatives (including drug distribution for schistosomiasis, filariasis, and onchocerciasis; trachoma control; bednet distribution for malaria control; and immunization), with little mention of how community-based efforts might link with the general health infrastructure. In contrast, Unger, de Paepe, and Green (2003) examine how best to implement disease control programs so as to strengthen existing health systems and propose a code of best practice for such programs.

This debate is being given a new urgency by the introduction of treatment for HIV/AIDS. Immunization can be delivered using either a vertical or a horizontal approach. HIV/AIDS treatment, which requires continuing care, calls for strong health service backup. Nonetheless, such treatment services could be organized so that they isolate themselves from the broader health system—say, through separate clinics with their own workers and separate laboratories—or they could contribute to a greater degree of integration by sharing resources.

The implications of these different approaches for health system change are not purely academic. Table 3.1 compares the responses to health system constraints that derive from a

Table 3.1 Typical Health System Constraints and Possible Disease-Specific and Health System Responses

Constraint	Disease-specific response	Health system response
Financial inaccessibility: inability to pay, informal fees	Allowing exemptions or reducing prices for focal diseases	Developing risk-pooling strategies
Physical inaccessibility: distance to facility	Providing outreach for focal diseases	Reconsidering long-term plans for capital investment and siting of facilities
Inappropriately skilled staff	Organizing in-service training workshops to develop skills in focal diseases	Reviewing basic medical and nursing curricula to ensure that basic training includes appropriate skills
Poorly motivated staff	Offering financial incentives for the delivery of particular priority services	Instituting performance review systems, creating greater clarity about roles and expectations, reviewing salary structures and promotion procedures
Weak planning and management	Providing ongoing education and training workshops to develop planning and management skills	Restructuring ministries of health, recruiting developing a cadre of dedicated managers
Lack of intersectoral action and partnership	Creating disease-focused, cross-sectoral committees and task forces at the national level	Building systems of local government that incorporate representatives from health, education, and agriculture, promoting the accountability of local governance structures to the people
Poor-quality care among private sector providers	Offering training for private sector providers	Developing accreditation and regulation systems

Source: Travis and others 2004.

disease-specific focus as opposed to a health systems focus. A disease-specific focus leads to solutions for the specific program, whereas a health systems focus identifies a somewhat different set of reform priorities that relate to system-level changes and affect disease management across multiple diseases and conditions. The disease-focused responses can generally be implemented relatively quickly, whereas the systems-focused actions take longer. However, numerous, separate disease-specific responses can rapidly overwhelm frontline workers and managers.

HEALTH SYSTEM CONSTRAINTS ON THE DELIVERY OF PUBLIC AND PERSONAL HEALTH SERVICES

The challenge of scaling up services to meet the health-related MDGs and concerns that the multiple international efforts may overwhelm countries' fragile infrastructures have encouraged efforts to think systematically about health system constraints on achieving the MDGs, and the extent to which additional funding can readily and quickly improve services (Ranson, Hanson, and Mills 2003; Travis and others 2004). Weaknesses in service delivery—for example, at the health center level—may stem from problems at that level, such as staff shortages, or may be affected by factors higher up the system, such as a poor drug distribution system. Ranson and others (2003) therefore analyze constraints by five different levels: community and household, health services delivery, health sector policy and strategic management, public policies cutting across sectors, and environmental and contextual characteristics (see table 3.2).

At the community and household level, lack of demand can limit coverage. This lack may stem from cultural factors, such as low acceptability of immunization or prenatal care, but it may also result from financial and physical barriers to access. For example, estimates indicate that, in Niger, children under five average only 0.5 visits to a health provider per year, and in Bangladesh, only 8 percent of ill children were taken to a qualified provider (see chapter 63). Many barriers can be reduced by increasing accessibility, for example, by expanding the service infrastructure closer to communities. In Cameroon, Litvack and Bodart's (1993) study finds that a combination of user fees and improved quality, including a better drug supply and improved geographic access, led to increased use despite the user fees.

Low use may stem less from inaccessibility than from low quality at the level of health care delivery. Low quality can result from human resource shortages, limited incentives for the staff to provide good quality care, training inappropriate to local needs, poor drug supply systems, and lack of simple equipment such as that needed to measure blood pressure (Southern Africa Stroke Prevention Initiative Project Team 2004). In Tanzania, an analysis of the treatment-seeking decisions of those who later died from malaria showed that the great majority had preferred modern medicine, even for cerebral malaria, which according to a substantial body of evidence mothers view as a condition best treated by traditional healers (de Savigny and others 2004). Yet despite high rates of seeking modern medicine, malaria mortality remained high, whether because of delay in seeking treatment, poor quality care, or poor patient adherence. Treatment quality can be improved by increasing resources, although it may also demand change

Table 3.2 Constraints on Improving Access to Essential Health Interventions, by Level

Level of constraint	Types of constraints
Community and household	Lack of demand for effective interventions Barriers to the use of effective interventions (physical, financial, social)
Health services delivery	Shortages and inadequate distribution of appropriately qualified staff Weak technical guidance, program management, and supervision Inadequate drugs and medical supplies Lack of equipment and infrastructure, including poor accessibility of health services
Health sector policy and strategic management	Weak and overly centralized planning and management systems Weak drug policies and drug supply system Inadequate regulation of pharmaceutical and private sectors and improper industry practices Lack of intersectoral action and partnership for health between government and civil society Weak incentives to use inputs efficiently and to respond to users' needs and preferences Reliance on aid agency funding, which reduces flexibility and ownership Aid agency practices that overload country management capacity
Public policies cutting across sectors	Government bureaucracy (civil service rules and remuneration, centralized management system) Poor availability of communications and transportation infrastructure
Environmental and contextual characteristics	Governance and overall policy framework: <ul style="list-style-type: none"> • Corruption, weak government, weak rule of law, weak enforceability of contracts • Political instability and insecurity • Low priority attached to social sectors • Weak structures for public accountability • Lack of a free press Physical environment: <ul style="list-style-type: none"> • Climatic and geographic predisposition to disease • Physical environment unfavorable to service delivery

Source: Hanson and others 2003.

higher up the system; for example, better health worker performance may not be possible without reforming human resource management systems.

Performance at the third level, health sector policy and strategic management, can have a pervasive influence on performance at lower levels and is less easy to address through additional funding alone. Some improvements, such as orienting management more toward good performance and reduced corruption, may require a change in organizational culture or a change in structures—for instance, decentralizing authority or creating autonomous agencies. Such changes can be difficult and may take time to implement (Preker and Harding 2003). Other improvements require action outside the country—for example, a change in aid agency practices so that weak country management structures are not overloaded by multiple demands and reporting structures.

Finally, at the highest levels, broad multisectoral public policies and environmental and contextual characteristics set limits on what the health sector can change without help. For exam-

ple, wage policies for the public sector health staff are usually set centrally and linked to overall levels of pay for the public sector. Even if funds are available, increasing the wages of only health staff members may not be possible.

At this highest level, constraints also reflect much broader institutional influences, as was demonstrated by recent analyses of the results of efforts to build state capacity in Africa. Levy's (2004) review points out that the results are mixed at best. For example, of all World Bank civil service reform projects completed by 1997, only 29 percent were rated as satisfactory by the operations evaluation department. Levy argues that a key reason for the limited success was an implicit presumption that the weakness of public administration was managerial and could be remedied through organizational change and financial support for technical advice, hardware, and training. However, public administrations are part of political institutions and of social, economic, and political interests more broadly, and they do not change readily or quickly. Nevertheless, windows of opportunity may open that drastically

affect the chances of change within a few years. Consider the cases of Mozambique, Rwanda, and Uganda, all countries that experienced many years of conflict and economic collapse but that have since made significant progress in reforming government institutions and performance. Apart from those exceptional cases, Levy argues that the way forward for administrative reform is likely to be an incremental one.

In general, straightforward shortages of buildings, equipment, and drugs and a lack of specific skills on the part of health workers and managers can be addressed fairly rapidly with additional funding. Remedying staff shortages takes somewhat longer, especially if the education system is producing insufficient numbers of people with the qualifications needed to enter health training programs. The constraints most impervious to additional funding are likely to relate to broader systems and institutional deficiencies, such as a bureaucratic culture that does not reward good performance and political systems that ignore the voices of the poor. Long-term and carefully phased capacity building in the broadest sense, including political development and strengthened governance structures, is likely to be required to relax these constraints (Mills and others 2001).

ASSESSMENT OF APPROACHES TO STRENGTHEN HEALTH SYSTEM CAPACITY

Strengthening health system capacity to improve performance is a wide-ranging subject, likely to require action—often simultaneously or appropriately sequenced—on many fronts. In particular, it requires attention to the various functions of the health system, especially to the various dimensions of management, as well as to the relationships between the health system, its patients (clients), and their communities. Evidence on which approaches work best is limited. The coverage of this section is therefore selective, drawing on chapters in part III and focusing on stewardship and regulation, organizational structures and their financing, and general management functions—namely, human resources and quality assurance.

When possible, we identify general lessons and note instances of relevant country experiences. In interpreting them, readers will need to keep in mind the strengths and weaknesses of their own country's health system. For example, in South Africa, where basic hospital supplies are good, improved training of health staff members reduced case-fatality rates for severe malnutrition, whereas in settings that experience shortages of antibiotics, potassium, and milk powder and that lack a doctor, training alone is highly unlikely to reduce high case-fatality rates (Ashworth and others 2004).

Stewardship and Regulation

Saltman and Ferroussier-Davis (2000, 735) explain stewardship as a “function of governments responsible for the welfare of populations and concerned about the trust and legitimacy with

which its activities are viewed by the general public.” The importance of the stewardship role is indicated by analyses that suggest that, in countries with good governance, a relationship is apparent between increased health spending and reduced child mortality (chapter 9), but that such a relationship is not apparent in countries that scored less well on indicators of good governance.

Strengthening structures of accountability to communities and introducing mechanisms to ensure that users have a voice in the local health system and can influence priorities are likely to be important in encouraging good performance. Methods to increase the transparency of resource allocation to peripheral services are also needed. In Burkina Faso, participation by community representatives in public primary health care clinics has increased the coverage of immunization, the availability of essential drugs, and the percentage of women who get two or more prenatal visits. In Ceara, Brazil, strengthened community accountability mechanisms helped improve service delivery (chapter 9). Factors identified as important to the success of community-based health and nutrition programs in chapter 56 include the existence of an effective, respected, and socially inclusive organization at the community level that builds on established community procedures.

Because of the substantial role that private sources of care play in almost all low- and middle-income countries, regulating and developing creative ways to work with the private sector are important. This effort needs to be seen as part of the stewardship role. Even though most countries have a network of regulations controlling private providers and products such as drugs, the regulations are often outdated and poorly enforced and can even be counterproductive (box 3.1).

Evidence is growing that using a mix of measures to influence both consumers and providers can improve the quality of care obtained through private providers. Chapter 70 provides several examples, including introducing total quality management practices and training with peer review feedback. Providers in the informal sector are some of the hardest to reach because of their wide distribution, small scale, and minimal education; however, some evidence indicates that their dispensing practices can be improved (box 3.2).

Regulation can be used as an intervention in its own right, as well as a way to improve health service delivery. The list of interventions identified as success stories (chapter 8) includes these in which a change in regulation was at the root of success:

- regulations requiring all sex workers in brothels to use condoms in Thailand
- tobacco control legislation in Poland and South Africa
- provision of a legal and regulatory framework for adding fluoride to salt in Jamaica
- legislation banning the sale of noniodized salt in China.

Box 3.1

Bringing de Jure and de Facto Regulations in Line

In Tanzania, local drug shops are important sources of drugs. They are required to obtain a permit each year and to meet certain conditions related to premises, qualifications of the seller, and products (nonprescription medicines only). A study in three districts found that, despite regular inspections of drug shops, infringement of the regulations was widespread—including the sale of prohibited or inappropriately packaged drugs, which inspectors must have known about. Illegal drug sales may have contributed to poor-quality treatment and encouraged the development of drug resistance, but they had important benefits in terms of accessibility, because drug supplies in drug shops

Source: Goodman 2004.

were more reliable than those in government facilities. Revising the regulations to permit drug shops to stock a small set of oral antibiotics, for example, would allow more constructive engagement between sales staff members and regulators, including the provision of information on essential drugs, registered brands, appropriate dosing, and consumer advice. The Strategies for Enhancing Access to Medicines Project is experimenting with allowing a wider range of drugs to be provided in one region using accredited outlets for dispensing drugs (drug shops that meet specified quality criteria and whose staff members have been trained by the project).

Box 3.2

Improving the Quality of Drug Dispensing by Private Sector Shops

In Kilifi district, Kenya, an education program piloted by the Kenya Medical Research Institute–Wellcome Trust Collaborative Research Programme worked with district health managers to train and inform rural drug retailers and communities. Its effect was evaluated by means of annual household surveys of drug use and shop surveys in an early and a late implementation area. The program showed major improvements in drug-selling practices.

Source: Marsh and others 2004.

Between 1998 and 1999, the proportion of antimalarial drug users obtaining an adequate dose rose from 8 to 33 percent, and by 2001, with a national change to sulfadoxine pyrimethamine, to 64 percent. The proportion of those with malarial fevers who received an adequate dose of a recommended antimalarial drug within 24 hours rose from 1 to 28 percent by 2001.

Given that enforcement is the Achilles heel of regulation, a noteworthy point is that these countries are all middle-income countries with a reasonable level of enforcement capacity. In other countries, approaches such as that outlined in box 3.2, where the authorities work with the private sector rather than seeking to control it, may have a better chance of succeeding.

Organizational Structures and Financing

The appropriate configuration of health system structures can ensure a clear delineation of responsibilities and accountabilities inside organizations, linking performance with rewards. Governance and organizational structures can also help ensure organizations' accountability to the public.

In recent years, the approach known as *new public management*, explained further in chapter 73, has encouraged a rejection of traditional, hierarchical forms of public sector management, whereby a single organization both finances and provides health services. For example, the U.K. health service has introduced a clear separation between the entities purchasing services (deciding what services are required for a given population and allocating funds for them) and those providing services. One aim of such arrangements is to ensure that providers' interests—as opposed to users' interests—do not dominate decisions on what services are funded. In addition, separating purchasers and providers allows competition to be introduced in service provision. Although introducing competition is widely considered desirable to encourage efficiency, debate continues on the magnitude of potential adverse effects.

Examples of new organizational structures include removing national health services from civil service control, introducing executive agencies to manage health services, and using contracts to govern relationships, both within the public sector (between public purchasers and public providers) and between the public and private sectors (Preker and Harding 2003). Colombian reforms introducing competition in both insurance and provider markets are among the most comprehensive. Another reform example is Ghana's creation of the Ghana Health Service, which is separate from the Ministry of Health.

The high transaction costs involved in creating and managing these types of arrangements and the lack of evidence that competition improves the quality of care have moderated initial enthusiasm for new forms of public management. In addition, critics argue that such arrangements are more demanding on management capacity than is direct service provision (Mills and others 2001). Moreover, implementation has proved challenging. For example, in Trinidad and Tobago and in Zambia, reforms to create new health service agencies have

run into major opposition from public sector workers, who oppose changes in their terms and conditions of service.

Some of the more successful elements of new public management reforms are those that involve contracting out services, especially to nongovernmental organizations (NGOs). Early evaluation of contracting experiences indicated that, even though contracting had been perceived as a way to avoid the inefficiencies inherent in public sector provision, it nonetheless required public sector capacity to manage the contracting process (Mills 1998). This situation was particularly a problem if the contractor was a commercial firm or individual provider with incentives to maximize profits (box 3.3). Contracting with individuals and firms that are strongly influenced by a profit motive requires a certain level of state capacity to ensure that the arrangements work in the interests of the state and the general public. In some countries, therefore, NGOs may be more appropriate service providers (Palmer and Mills 2003). A number of quite positive results from contracting with NGOs are now available (World Bank

Box 3.3

The Importance of Government Capacity: Contracting Out Health Services in South Africa

Successive studies have evaluated experiences in contracting out hospital care and primary care services in South Africa. The hospital study compared three district hospitals whose management had been contracted out to the same private company with three nearby, comparable, publicly managed district hospitals. Overall, the contractor hospitals were able to provide care of more or less equivalent quality at significantly lower cost to themselves—in major part because their productivity was more than double that of the public hospitals as a result of their effective human resource policies. However, the contractor captured all the efficiency gains as profit, leading to a situation where contracting out was actually more costly for the government than direct provision. The contractor's capacity to profit from the arrangement was due mainly to its ability to secure highly favorable contract terms and prices and to ensure a high total number of days of care. Interview data confirmed a substantial imbalance between the government and the contractor in relation to the skills, capacities, and information required to negotiate contracts. In addition, government officials underestimated the extent of potential competition for contracts and therefore overestimated their dependence on the one contractor.

A similar study evaluated the performance of contracts with general practitioners for primary care in two provinces and compared their performance with that of public clinics. General practitioners' costs were similar to those of small public clinics, but the service was generally of poorer quality. Exploration of the relationship between purchasers and providers found that the contract was incomplete and open to interpretation and that monitoring was constrained both by a lack of capacity and resources and by the difficulty of monitoring a complex service delivered in remote locations. Sanctions were vaguely specified and rarely used because of a sense of mutual dependence between parties to the contract that lessened their willingness to enter into disputes. In addition, the two provinces varied in terms of their capacity to monitor performance. The province with lesser capacity had little information about general practitioners' performance and little contact with them, which seemed to increase suspicions of what general practitioners were doing. In contrast, the province with greater capacity had a better information system and a decentralized management system that led to greater contacts between managers and general practitioners and an apparently greater degree of understanding between the parties.

2004), and the example of Cambodia is one of the most frequently quoted (chapter 13). Nevertheless, most evidence comes from programs with substantial external financial and technical resources, and long-term experience of sustainability is lacking.

Management decentralization has been another continuing theme in recent years. One variant is its application to hospital management, which involves giving hospitals autonomous or corporate status along with much greater responsibilities for raising income and managing their own affairs. A second variant is the creation of autonomous government agencies, and a third is decentralization to general management structures at lower levels, such as a health authority or local government.

Some pushing down of the locus of control over decision making is a prerequisite for effective management at the local and facility levels. However, without the necessary resources and management expertise at these levels and the right incentives, adverse consequences may arise for both efficiency and equity. For example, experience with hospital autonomy in low-capacity settings suggests that making the hospital partially dependent on fees for its income will restrict access by the poor to the hospital and also worsen the care they receive when admitted (Castaño, Bitrán, and Giedion 2004). However, for nonpatient care services, whose functions are easier to specify and monitor, autonomous agencies may have some advantages. For example, the Tamil Nadu Medical Supply Corporation has greatly improved the efficiency and effectiveness of drug purchasing and distribution (Mills and others 2001).

For decentralization of general health service management to succeed, attention must be paid to the entire management system, including management skills, information, analytical tools, and accountability mechanisms both to the community and to higher levels of management. Because decentralization is a complex process, takes a variety of forms, and is affected by the local context, research on its merits and demerits has been inconclusive (Alliance for Health Policy and Systems Research 2004). Some evidence indicates that decentralization to local governments can lead to neglect of broader public health functions and disease control, because these types of care are less visible to the public than curative care, as Khaleghian and Das Gupta (2004) indicate occurred in the Philippines.

Reviews of the merits of integrating services and of the effect of vertical programs on health systems have also been inconclusive. Some positive examples are available, such as the strengthening of health infrastructure and surveillance systems by the polio elimination campaign in Latin America and the Caribbean (Levine 2004). Nonetheless Briggs, Capdegelle, and Garner's (2001) review of the effects of strategies for integrating primary health care services on performance, costs, and patient outcomes finds too few studies of good enough quality to draw firm conclusions.

Human Resources

Achieving health policy goals depends on being able to train, recruit, and retain a staff with the necessary bundles of skills. In planning for human resource needs, countries must relate the numbers and levels of each category of staff members to health policy goals and the priorities that are set, given the overall availability of resources and local labor market constraints.

In recent years, concerns about the international brain drain have increased greatly, with evidence indicating that migration by doctors and nurses is severely affecting health services in some Sub-Saharan African countries (Physicians for Human Rights 2004). Actions by developing countries to improve recruitment and retention should either raise the rewards, both financial and nonfinancial, of local employment or reduce the attractiveness of alternative employment—for example, by making qualifications less portable across countries (chapter 71). Raising the remuneration of health workers may be difficult because it is likely to lead to demands for increased pay from other public sector employees. There is a long history of making use of local cadres, which can also allow training that is more specific to the needs of the local health system and its priorities.

Examples include nurses with extended training and roles and people working at subnurse levels with training of a few weeks to three years. For example, Bangladesh employs family welfare visitors, health assistants, and medical assistants; Uganda provides three years of training to clinical officers, who function as subdoctors, and three months of training to nursing aides; and Malawi trains clinical officers, who carry out surgical procedures and administer anesthetics in addition to providing medical care. Despite widespread use of such workers, evidence on how they perform relative to more qualified staff members is limited, though a study of clinical officers in Malawi suggests that well-trained clinical officers can safely substitute for doctors in performing cesarean deliveries (Fenton, Whitty, and Reynolds 2003).

The salaries necessary to recruit and retain staff members will depend on the opportunities they have for other employment both within the country and in other countries. Salary levels will also depend on health workers' preferences between financial and nonfinancial incentives. Evidence suggests that influences on motivation, though reflecting universal principles, will vary considerably from place to place (Brown 2002). Therefore, compensation and incentive structures need to be adapted to countries' circumstances; however, evidence is scanty on how countries have attempted to adapt such structures and whether they have been successful in improving recruitment and retention.

One approach to improving health workers' performance is to link performance and remuneration. The Chinese national tuberculosis (TB) program, identified as a success story (chapter 8), provided village doctors with incentives to treat TB

patients. However, performance-related pay requires a good regulatory framework, skilled managerial resources, and careful monitoring to counter adverse effects—all features that are unlikely to be available in countries with limited capacity. Even in China, other experiences are much less positive because managers were not required to take likely adverse health consequences into account (box 3.4). Similar comments apply to the widespread practice of allowing doctors to work in both the public and the private sectors to increase their incomes. Doctors may exploit their private practice rights by encouraging patients to attend privately if they want better quality care—or even by diverting government resources, such as drugs, to private patients. Thus, the effects of private practice on incentives in public practice tend to be negative unless carefully monitored and controlled.

Nonmonetary rewards to encourage staff retention can be useful in such settings, as well as easier to manage. They include

the availability of facilities and materials; of opportunities for learning and career progression; of subsidized housing and education for dependents; and of a culture that values the contribution of health workers to the achievement of organizational and system goals. In addition, the methods and levels of funding, the extent of organizational autonomy, the nature of support and supervisory systems, the role of the organization and of providers in the health system, and the regulation and accountability structures all influence how organizations and individuals function. Thailand provides an example in which the provision of both monetary and nonmonetary rewards has improved the recruitment, retention, and status of rural doctors (box 3.5).

The introduction of well-funded disease control programs runs the risk of attracting the most able staff members away from other positions. Past programs have successfully used combinations of financial and other incentives to encourage

Box 3.4

Incentive Payments in China

China has made wide use of incentive payments in hospitals—and even in public health programs. Research suggests that such payments have deleterious effects when their ability to skew behavior is not controlled. In Shandong province, studies found that a change in the bonus system for hospital doctors from one that was tied to the quantity of services provided to one that was tied to revenue generated was associated with a significant increase in hospital revenue. About 20 percent of hospital revenue was generated by the provision of unnecessary care. Although data did not permit linking bonus type to

quality of care, the bonus system was clearly designed to achieve financial goals rather than quality goals. Furthermore, during the 1980s and 1990s, the government provided a decreasing share of the income of public health institutions, and the share of service charges greatly increased. As a result, public health institutions became heavily dependent on generating their own income. Negative effects included duplicate inspections of factory premises by different public health units, excessively frequent inspections, and neglect of less profitable factories that were less able to pay inspection charges.

Box 3.5

The Role of Financial and Nonfinancial Incentives in Thailand

Thailand has experienced periods of severe medical brain drain from the public to the private sector and has had great difficulties in staffing hospitals in rural areas. Since the late 1970s, policies have been directed at making service in rural areas more attractive. Measures include substantial salary increases, good working conditions in district hospitals, and provision of housing. Professional

self-esteem has been increased by providing career opportunities up to the post of deputy director general, an annual award for rural doctors, and membership in the rural doctor society. Substantial experience as a rural doctor is explicitly valued by leading public health specialists, who themselves have spent substantial periods working as rural doctors.

Box 3.6

Improving Staff Performance in Cambodia

An NGO contracted to manage a district in Cambodia introduced contracts between the NGO's managers and facility staff members involving a monthly incentive payment, a punctuality incentive, and a performance bonus. The contracts were initially introduced in three facilities, which subsequently experienced significantly higher use levels than those that did not have the incentive payments. Because individual contracts were too demanding to manage and excluded health center and hospital directors from staff management, the system was changed to one of subcontracting with facility managers. Output improved even

Source: Soeters and Griffiths 2003.

more. Subcontracts were made competitive: if a health center's management or output was poor, other health workers or managers were asked to apply to take over the contract. During 2001, four contracts were replaced. Monitoring activities, especially spot checks at the household level to verify that recorded visits had taken place, were considered vital to ensuring quality and transparency. Soeters and Griffiths (2003) argue that outsiders—in this case the NGO—are better able to introduce new management procedures than a ministry of health, which tends to be risk averse.

good worker productivity and program performance (chapter 71). Incentives have included better salaries; field and transportation allowances; and nonfinancial incentives such as streamlined management, specialized training, availability of facilities and material resources, and results-oriented management that provides effective administrative and technical support. Governments need to find ways of benefiting and learning from these experiences. For example, governments might allow periods of secondment to externally funded programs, after which staff members return to the government with enhanced skills. The success of such an approach will depend on remuneration not differing too greatly and on government bureaucracies providing the scope for staff members to use their new skills.

However, the history of civil service reform is not encouraging (Nunberg 1999). Reforms have sought to reduce the size of the civil service and to improve productivity using incentive schemes such as performance-based pay and promotion structures. Such reforms have been largely unsuccessful because of the political difficulties of reducing the size of the civil service. Structural and organizational changes are typically unpopular with labor unions, especially if they perceive such changes as threatening workers' well-being. Experience demonstrates the difficulties of aligning system and organizational objectives with individual workers' objectives (Martineau and Buchan 2000) and suggests that solutions need to be sought that do not involve radical reform of employment patterns unless the country setting is particularly propitious.

Where contracting with NGOs or other private providers is an option, doing so may permit changed employment patterns and improved performance without the widespread disruption that can result from attempting to change government workers' terms and conditions of service. In Cambodia, a project contracted to an NGO (HealthNet) obtained some improvements

in staff performance by establishing clear agreements with staff members concerning issues such as the working hours that would be expected and the informal charges that staff members were not to demand from patients. In return, staff members received substantial incentive payments (box 3.6).

Quality Assessment and Assurance

The quality of health services has a number of important implications. It affects the outcomes that a health system can achieve—both directly, through patient treatment, and indirectly, by encouraging or discouraging use of the services. It also affects staff morale, because working in an environment where employees know the treatment quality is poor is not motivating.

Substantial evidence, reviewed in chapter 70, indicates that the quality of care is often suboptimal and varies widely within countries. In part this suboptimal quality is attributable to resource constraints, but providing good-quality care is possible even in resource-poor settings.

Evidence on how providers' practices can be improved can be grouped into two categories: policies that indirectly affect providers' practices by changing structural conditions, including the practice environment, and policies that directly affect individual and group practices.

In the first category, legal mandates and administrative regulations can be used to bar unqualified workers from practicing; professional oversight and clinical guidelines can encourage good practices; contracts can specify and monitor quality standards, such as immunization coverage targets; and accreditation can stimulate quality improvements. Among policies that directly affect providers' behavior, training with peer review feedback has been shown to improve quality, as have total quality management approaches; remuneration can be

made dependent on performance subject to the caveats raised earlier. Measures that improve quality can increase use, strengthen the public sector's capabilities, and be highly cost-effective—even cost saving.

TARGETING RESOURCES

An important dimension of health system capacity that has not been considered explicitly so far, is the ability to ensure that resources are used in ways that meet health system objectives. As noted earlier, many health systems fail to perform as well as they might on effectiveness, efficiency, and equity criteria. This section addresses what policy instruments might be available to ensure that additional resources are used to the greatest effect, first at the systems level and then at the level of service delivery.

Systems-Level Mechanisms

At the systems level, tools available to decision makers include regulation and legislation, resource allocation formulas, and financial incentives.

Decision makers can use regulation and legislation to set minimum standards of care that insurance packages must cover, for instance. They can influence the availability of drugs by, for example, liberalizing prescribing and introducing accompanying measures to educate providers and users so as to increase the use of certain drugs that are safe to distribute on a large scale. One approach that has worked in Uganda is a social-marketing program making subsidized and clearly packaged drugs for sexually transmitted diseases available through the retail sector (Mills and others 2002).

In some settings, explicit rationing of the provision of care in the public and private sectors can be used to prioritize the most cost-effective interventions and limit the provision of less cost-effective ones. However, regulatory controls are unlikely to be effective in low-capacity settings and will simply encourage illicit activities. Moreover, explicit rationing requires a high degree of public acceptance and public involvement in the pri-

oritization process. A more acceptable strategy in most settings is to constrain the overall public sector resource envelope in terms of staff, buildings, equipment, and drugs and to leave rationing decisions within the envelope to clinical discretion (Segall 2003). However, clinicians may implicitly ration services in inequitable ways—for example, on the basis of age or social status—and supplementary measures are likely to be needed to ensure that health workers do not discriminate against poorer and marginalized members of society.

Resource allocation formulas have an important role to play in the public sector in directing resources to underserved geographic areas and population groups and to underfunded programs (Musgrove 2004). Given the typical shortages of health workers in more remote areas, such formulas should include remote area allowances or allow for the higher costs of delivering services in such areas. A formula in Zambia, for example, used distance from the railway line as a proxy for remoteness.

A similar approach to ensuring that resources go where they are most needed is the “marginal budgeting for bottlenecks” approach of the World Bank (see chapter 9). This country-based planning and budgeting approach assesses health sector impediments to faster progress toward the MDGs, identifies ways to remove them, and estimates both the costs and the likely effects of their removal on MDG outcomes.

In targeting resources to specific programs, expansion of one area of health provision should not occur at the expense of another priority area. For example, where staff capacity and facilities are limited, targeting additional funding to TB case detection and treatment may simply take staff time away from child health. This problem of the systemwide effects of disease-specific programs was discussed earlier. Addressing this problem requires empowering a central body, such as a ministry of health or a regional or district health authority, to take an overall view of priorities so that resource conflicts can be resolved.

Even though financial incentives need to be used cautiously, they can be powerful tools for influencing providers' behavior, as indicated earlier. They can also be an important influence on users' behavior. Experience in South Africa and Uganda (box 3.7)

Box 3.7

Removal of Fees at the Primary Care Level in Uganda

In February 2001, the government of Uganda abolished cost sharing in public facilities at the community level. This move was followed by a marked increase in the use of health services by all population groups. For villages near public health centers, the increase was greatest among the poorest groups. The frequency with which centers ran out

of drugs worsened during the first year of implementation but gradually improved during the second year. A study concluded that before the policy change user fees were probably a major deterrent to the use of public health services and that their removal was especially beneficial to the poor.

Source: Nabyonga and others 2005.

suggests that, in some settings, removing or reducing user fees at the primary care level may be an important element in encouraging greater take-up of primary care. Further studies of the effects of fee removal are needed.

Service-Level Mechanisms

At the service level, evidence suggests the value of providing a framework of resources and guidance within which managers and health workers can prioritize their efforts. The experience of the Tanzania Essential Health Interventions Program (chapter 54) highlights the health gains that a decentralized management structure can achieve when district managers are provided with the information, tools, and training to enable them to match services and additional resources with the local burden of disease. Berwick (2004) draws similar lessons from the experience of several highly successful projects in resource-poor settings: set clear aims and targets, use a team approach, build an infrastructure of human resources and data systems, engage with the policy environment, and develop simple approaches to rapid scaling up.

Patient education on major causes of ill health is also important to ensure that people know when to seek care (for example, in the case of childhood illness); understand their rights to various services and the official level of charges; and can make appropriate decisions about drug purchases. Patient charters may play a role in making explicit what patients have the right to expect from their health services and what level of service providers should achieve. Local policies on service provision need to relate to community preferences: if they do not, clients' confidence in the public health system will be undermined. One simple example is the pervasive view in some South African communities that public clinics water down medicines, thereby rendering them ineffective (Schneider and Palmer 2002). Indeed, generic medicines used by the public sector are often perceived as less effective than name brand drugs. Accurate public information is needed to counter that perception.

SOLUTIONS IN LOW-CAPACITY ENVIRONMENTS

Developing countries possess a range of capacities to improve the functioning of their health systems, but one group of countries faces the greatest constraints to doing so. Analyses undertaken for the Commission on Macroeconomics and Health used the framework presented in table 3.2 to understand the dimensions of the constraints problem in 79 low-income countries. Using proxies for the various types and levels of constraints—gross domestic product per capita, female literacy rate, number of nurses per population ratio, diphtheria-pertussis-tetanus immunization coverage, access to health services, control of corruption, and government effectiveness—countries can be classified as more or less constrained. Table 3.3

shows key indicators for the most constrained and other countries.

The most constrained group has significantly worse health indicators and much worse access to health resources. For example, countries in this group have almost twice the infant mortality rate and more than twice the maternal mortality rate of other countries but only one-sixth as many nurses. In absolute terms, the most constrained group represents a relatively small share of the total population of countries analyzed and consists, for the most part, of small countries (more than half have populations of less than 10 million) in Sub-Saharan Africa.

The key question in relation to improving health outcomes is what financing and delivery strategy might work best in these settings. Should it take the form of a limited number of programs, each addressing one or a few diseases? Or should efforts be devoted to building up the basic health service infrastructure on which targeted efforts to address specific health problems can then be built? Given the lack of evidence, providing guidance is difficult, and the chapters in this book present different views. Chapter 63 firmly dismisses the option of bypassing organized health services altogether in the poorest countries and promoting the delivery of child health interventions directly to households through, for example, community-based projects dispensing antimalarials or antibiotics. It argues that, though this approach may be a short-term solution, successes using it largely occur in small-scale pilots with strong managerial backup. Chapter 56 suggests that in the poorest societies basic preventive services should be introduced first—especially immunization, access to basic drugs, and management of the most severe threats to health such as emergency care for traffic injuries. At slightly higher levels of development, the introduction of community-based activities may be cost-effective if coverage by the formal health service is poor. Both chapters imply that the issue is not which approach to use but how to phase approaches and use a mix that depends on the intervention and the local context. Accomplishing this requires not only service delivery capacity but also management capacity to plan and evaluate the mix of approaches and make adjustments over time.

Molyneux (2004) suggests that disease control programs can be used to build capacity for the long term and that, with time, such programs can become more advisory and less managerial. For example, in Pakistan, primary health care was built on the experience of TB and leprosy clinics. In China, the vertical programs for disease control purchased time from health service operational staff members, thereby ensuring that funds flowed into the health service infrastructure (Dean Jamison, personal communication, 2004). In seven countries in southern Africa, a successful combined strategy for measles immunization started with a single, nationwide catch-up campaign in which mobile teams vaccinated all children in a particular age group (Levine 2004), an action that can sharply

Table 3.3 Health Indicators by Country Level of Constraint

Indicator	Unit	Most constrained countries ^a	Other countries
Total population (in 2000)	Millions	401	3,525
Population living on less than US\$1/day	Millions	123 (9 countries)	886 (29 countries)
Population living on less than US\$1/day	Percent ^b	30	25
Population living on less than US\$2/day	Millions	192 (9 countries)	2,128 (30 countries)
Population living on less than US\$2/day	Percent ^b	48	60
Physicians	Per 100,000 population	8.9	101.7
Nurses	Per 100,000 population	39.6	208.7
Hospital beds	Per 1,000 population	0.78	3.00

n.a. = not applicable.

Note: Calculations were performed for a constraints index with up to three missing variables. Values for missing variables were imputed using a method described in the source.

a. These are the bottom quartile of countries, according to the constraints indicators, compiled into an index. The constraints index was calculated by normalizing each of the variables (subtracting the mean and dividing by the standard deviation) and then summing the normalized values. This calculation gives each variable equal weight in the index.

b. These averages are population weighted, whereas all other means in the table are unweighted.

reduce the spread of the virus. Routine services were used to continue measles immunization but with a follow-up campaign three to four years later to prevent the number of susceptible cases from rising to the level required for transmission. Over five years, measles virtually disappeared from southern Africa. However, maintaining this achievement requires that routine services be able to reach more than 80 percent coverage, a level many countries find hard to sustain. Moreover, in low-capacity environments, campaigns can divert attention and resources from routine primary health care services. Schreuder and Kostermans (2001) indicate that this problem occurred in southern Africa, particularly with respect to diverting scarce management capacity, implying that reducing deaths from one cause may risk worsening services for other diseases and conditions.

Victora and others (2004) suggest that the most appropriate mix of vertical and horizontal approaches depends on the human and financial resources available, the urgency with which results need to be achieved, the existing organization of health services, and the natural development of programs over time. Within a horizontal approach, the weaker the health

system setting is, the more important the provision of good technical and management backup will be to service delivery. The authors ascribe some of the difficulties that integrated management of infant and childhood illness (IMCI) faced in several countries to the absence of full-time IMCI coordinators, operational plans, and specific budget lines. They suggest that, when health systems are extremely weak, vertical programs may be required; however, as health systems strengthen, financing and delivery strategies can become less vertical and more horizontal and less selective and more integrated.

RESEARCH PRIORITIES

A notable paucity of evidence is apparent in relation to most key areas discussed in this chapter. This lack of evidence is illustrated by a recent review of the evidence on the equity of utilization and financing strategies (box 3.8). This and other reviews of the available evidence have led the *Lancet* to call for a new health systems research specialty (“Mexico 2004: Global Health Needs a New Research Agenda” 2004).

Box 3.8

Gaps in the Evidence on Equity of Health Financing and Utilization in Low-Income Settings

A recent review evaluated evidence on the effect of various financing strategies on use of health care. It found that most research was small scale and had findings of limited applicability. Well-designed, large-scale evaluations of the effect of alternative financing interventions were lacking, and a multitude of case studies described specific experiences but with little methodological rigor. The review recommended larger-scale, more systematic studies in a

range of settings, including nonrandomized designs when randomization is impossible or inappropriate and multi-center case studies that examine why arrangements do or do not work in different settings. The study proposed developing and applying quality criteria for quantitative and case study research along the lines of guidelines recently developed for randomized group trials.

Source: Palmer and others 2004.

Areas where evidence is especially limited that are identified in this chapter—where research is a high priority—include the following:

- Evidence on most health system reforms—for example, hospital autonomy reforms and decentralization—is inadequate to draw conclusions about the circumstances under which reforms are likely to improve the efficiency and equity of service delivery.
- Few studies relate a reform to health outcomes, and even evidence on intermediate outcome measures, such as costs and quality of service provision, is often lacking.
- Virtually no information is available about the costs of strengthening capacity or the effectiveness of different approaches to capacity strengthening, even though the lack of system capacity is widely noted.
- Evidence is largely lacking on the characteristics of delivery strategies capable of achieving and maintaining high coverage for specific interventions in various epidemiological, health system, and cultural contexts.
- Evidence is lacking on what types of governance and institutional arrangements will support the achievement of widespread health improvements, especially for the poorest members of society.

Addressing the deficiencies in the evidence base requires developing better study designs and analytical methods and building expertise in and understanding of health systems research. Capacity for research and analysis in health policy and health systems is currently limited. A recent survey (Alliance for Health Policy and Systems Research 2004) estimated that project funding for health systems research accounted for less than 0.02 percent of the total annual health expenditure of developing countries. More than half of research projects had budgets of less than US\$25,000. Of institutions identified as engaged in health systems research, a third had no staff qualified at the

doctoral level, and researchers with doctoral degrees made up only a quarter of the research workforce. An analysis of studies cited in Medline showed that only 5 percent of the health systems research literature concerned developing countries.

Given the importance of influencing policy and practice, the approach to research needs to encompass solving operational problems in real-life settings. Ethical issues arise in using limited supplies of talent to study problems unrelated to the local context when the human resources and systems required to improve operational programs are lacking. Moreover, the quality and effect of investigations are much improved when they are based on dialogue with the primary users and set in real-life contexts. The concept of the cycle from research to policy and practice needs to be emphasized more strongly. It encompasses not only generating knowledge but also managing the research agenda, including setting priorities, and promoting the use of evidence through means such as advocacy channels and specific mechanisms designed to link producers and users of research (Alliance for Health Policy and Systems Research 2004). Given the importance of context in translating research evidence into service and system practice, operational research and program evaluation capacity must be built among country-based scientists and practitioners.

CONCLUSIONS

This chapter has sought to address the question of how health systems can be strengthened to deliver cost-effective and equitable interventions and services. Recent cross-country analysis on the association between health expenditure by government and health outcomes has suggested that the effectiveness of increased health expenditure depends heavily on governments adopting the right policies (World Bank 2004). What are the right policies, and what are effective implementation processes? The review in this chapter suggests that in many areas not enough is known to recommend particular approaches and

also that recommendations need to be adapted to local contexts. Nonetheless, six key points can be identified in relation to improving health systems:

- Health systems face numerous constraints in low-income countries, but they are the basis for the long-term future of sustained health improvements. The health of the system must, therefore, be carefully considered whenever major new programs are put in place.
- If capacity constraints are such that a focused disease- or program-specific effort is desirable to address an urgent problem, the effort should be designed to contribute to the long-term system strengthening, rather than detracting from it. Countries must avoid having multiple vertical programs competing for limited human resources and managerial capacity. Over time, as horizontally organized services strengthen, the need for more vertical financing and delivery strategies will lessen.
- Reforms affecting organizational structures and human resource management are likely to play an important role in improved performance. However, emerging evidence suggests in most settings that changes are most likely to be successfully implemented if they are incremental and gradual rather than “big bang” reforms. Stability of policies and consistent implementation are also required.
- Linking financial incentives to performance, whether through contracts with health care providers or through performance-related pay, may bring rewards if careful monitoring is possible; however, evidence on the sustainability of such arrangements is lacking, and effective monitoring may require long-term external involvement. Evidence is needed on alternative approaches to improving performance.
- Organizational reforms must keep the goal of improved health outcomes, equity, and responsiveness in sight. Doing so requires paying special attention to users’ demands, to primary care and first-level hospitals, to quality of care, and to technical backup for disease control programs.
- Capacity-strengthening efforts in most settings must encompass action at all levels, from increasing leadership of the ministry of health at the national level through strengthening support for peripheral levels.

The current body of knowledge represents a largely ad hoc and disjointed collection of facts, figures, and points of view. Making confident recommendations relevant to strengthening health system capacity is thus difficult. Although international financing is vital, countries need flexibility to develop solutions based on local assessments and experience and to progress at a pace commensurate with their situations. Sustained investment in analytical and operational research capacity is needed as part of program and systems support, to serve national priority setting and policy formulation.

ACKNOWLEDGMENTS

Discussions at a workshop sponsored by the Disease Control Priorities Project in South Africa during June 30–July 3, 2004, contributed considerably to the development of ideas for this chapter.

NOTE

1. The health system is understood to encompass all activities whose prime intent is to improve health.

Chapter 4

Priorities for Global Research and Development of Interventions

Barry R. Bloom, Catherine M. Michaud, John R. La Montagne,
and Lone Simonsen

It is a profound and necessary truth that the deep things in science are not found because they are useful; they are found because it was possible to find them.

—J. Robert Oppenheimer

In R. Rhodes, *The Making of the Atomic Bomb*

NEEDS, CONTEXT, OPPORTUNITIES, AND MAJOR CHALLENGES

Half of the entire increase in human life expectancy—a crude but easily defined measure of the health of populations—realized over recorded history occurred in the 20th century. From 1900 to 2000, life expectancy at birth increased from 48.0 to 77.1 years in the United States and from 48.0 to 77.7 years in the United Kingdom, gains of almost 30 years. However, improvements in life expectancy were not limited to the industrial nations. For example, between 1900 and 1990, life expectancy in India increased from 27 to 59 years, a gain of 32 years (Fogel 2004). These increases are largely attributable to a better understanding of biology, medicine, and public health—that is, to the benefits of research.

Research is traditionally defined as the generation of new knowledge and the development of new and enabling technologies to identify or respond to major gaps in current knowledge. Research includes the development of new tools, methodologies, and strategies. The World Health Organization (WHO) and its Advisory Committee on Health Research have suggested two other defining aspects of health research—namely, the verification of knowledge in different contexts and the creation and dissemination of products of knowledge. The Institute of Medicine (1997, page 1) in

the United States has defined the realm of global health research as “problems, issues, and concerns that transcend national boundaries and may best be addressed by sharing knowledge and cooperative action.”

An important corollary of this definition is that global health research is derived from individuals and institutions rather than from nation states. Thus, global health knowledge should be available to everyone, not just to the country in which it is done or that sponsored it. As a result, knowledge derived from health research is a true public good, which by definition possesses the following two special properties (Commission on Macroeconomics and Health 2001):

- *Nonexclusivity.* Thus, when supplied it does not require payment to benefit individuals or groups (for example, the benefit to the world community of eliminating smallpox).
- *Nonrivalry.* Hence, the use of the benefits by an individual, group, or country will not diminish others’ ability to benefit from the same good or service.¹

Investments in research have produced remarkable improvements in global health, especially over the past 20 years. Immunization programs have led to unprecedented progress in the fight against common childhood diseases (such as measles,

pertussis, poliomyelitis, and tetanus) and in the eradication of smallpox. At the same time, vaccination programs have catalyzed the construction of a global infrastructure for epidemiological monitoring and research, especially in the Americas and in Asia. Moreover, researchers are rapidly developing many preventive, diagnostic, and therapeutic tools, and the growing power of genomics and proteomics will accelerate the pace.

The 21st century will see a continuation of the inexorable trend toward the globalization of travel, trade, and communications. At one level, economic globalization has increased disparities between countries in terms of gross domestic product per capita. On a population basis, however, economic gains by China, India, and other developing countries have made vast numbers of people substantially wealthier than ever before (Fischer 2003). Cell phones and radios are ubiquitous, even in the most remote parts of Africa and Asia, and the Internet has permitted the transmission of data across long distances rapidly,

accurately, reliably, and cheaply. With these technologies, global research relationships that once would have been impossible are now commonplace. For example, in a matter of weeks, researchers in China could sequence the gene for the surface protein of the coronavirus associated with severe acute respiratory syndrome (SARS) and then produce the surface protein as diagnostic antigen. Such speedy reaction would have been inconceivable just a decade ago.

Daunting challenges remain, however, that health research alone is unlikely to solve. The context for health is very complex and varies in different countries of the world (box 4.1). The predictable outcome of current trends is an increase in the health and technology gaps between the rich and poor countries. Tip O'Neill, the colorful speaker of the U.S. House of Representatives for 10 years, often said that "all politics is local." A provocative thesis we present here is that (a) all health care is national, and (b) all health research is global.

Box 4.1

Context of Global Health

Advances include the following:

- the globalization of knowledge and the increased mobility of the world's population
- the expansion of knowledge about disease problems in most of the developing world
- the remarkable progress achieved in the control of infectious diseases in most parts of the world
- the worldwide penetration of new forms of communication
- the promise of new technologies in biomedical research (for example, in the fields of genomics, transgenic organisms, informatics, robotics, and nanotechnology)
- the increasing flow of private resources devoted to understanding health problems related to development.

The following concerns are pertinent:

- The world's population continues to grow, numbering 6.3 billion people in 2004, with 200,000 added each day. In at least 68 countries, more than 40 percent of the population is younger than 15, whereas in wealthy countries, the proportion of elderly people in the population is expanding quickly.
- Despite falling global poverty rates, progress is uneven: 1.2 billion people still live on less than US\$1 a day, and 2.8 billion live on less than US\$2 a day. One in six children is chronically hungry.

- Disparities have increased. The richest 20 percent of the world's population now accounts for 150 times the income of the poorest 20 percent. The ratio of the income of the top 20 percent to that of the poorest 20 percent rose from 30 to 1 in 1960 to 61 to 1 in 1991 and to 78 to 1 in 1994. Evidence of global environmental degradation is apparent, especially in the developing world. For example, 45 percent of tropical rain forest has already been lost, at least 20 percent of current species will be extinct by 2030 and 50 percent by the end of the century, and half of China's and many other countries' cities already face water shortages.
- With global warming, temperatures will likely rise 1.0°C to 4.5°C this century, threatening coastal areas and changing patterns of vectorborne and epidemic disease.
- The pace of migration from rural to urban environments is speeding up, giving rise to more megacities.
- The period 1955–98 witnessed 31 civil and foreign wars, 35 million displaced people and refugees, and 127 instances of state failures—ethnic wars, revolutionary wars, and disruptive regime changes—in 96 states.
- Terrorism has become a global threat.
- Gender discrimination persists.

Global Burden of Disease

Tables 4.1 and 4.2 summarize some of the key findings that are most relevant to a discussion of global health research priorities. The magnitude and distribution of the burden of disease across different regions in 2001 reveals a great deal about unmet research needs (Mathers and others 2003), in particular:

- Communicable diseases and maternal, perinatal, and nutritional conditions remain the major contributors to the burden of disease in Sub-Saharan Africa and in parts of East Asia and the Pacific. These regions differ significantly from all the other low- and middle-income regions and call for a unique set of priorities in relation to global health research.
- Noncommunicable diseases are already the leading contributors to the disease burden in all other low- and middle-income regions, which are undergoing rapid demographic, economic, and epidemiological transitions. Not only does the world face an epidemic of cardiovascular

disease and major unipolar depressive disorders, for example, but also these two chronic conditions already account for an increasing burden of disease and death in developing countries. Demographic changes in many low- and middle-income countries are driving the observed transition toward patterns of disease previously seen only in the industrial countries. The incidence of both ischemic heart disease and cerebrovascular disease increases rapidly with age; thus, countries in which the proportion of elderly people in the population increases will also experience increases in the relative importance of noncommunicable illness. Unlike communicable illnesses among younger people, chronic illness associated with aging cannot be entirely prevented, only delayed. These factors must be considered when setting priorities for global health research.

Children under five still account for an unnecessarily large share of the disease burden in many low- and middle-income

Table 4.1 Broad Patterns of the Disease Burden, by World Bank Region, 2001

Category	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa	High-income countries	World
Population (<i>millions</i>)	1,851	477	526	310	1,388	668	929	6,150
Communicable, maternal, perinatal, and nutritional conditions (<i>prevalence, percent</i>)	22.2	9.4	21.8	27.1	44.3	70.4	5.7	36.7
Noncommunicable diseases (<i>prevalence, percent</i>)	65.8	76.4	65.0	59.3	44.4	21.2	86.7	52.6
Injuries (<i>prevalence, percent</i>)	12.0	14.3	13.2	13.7	11.4	8.4	7.5	10.7

Table 4.2 Leading Causes of the Disease Burden, by World Bank Region, 2001

Rank	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa	High-income countries
1	Cerebrovascular diseases	Ischemic heart disease	Perinatal conditions ^a	Ischemic heart disease	Perinatal conditions ^a	HIV/AIDS	Ischemic heart disease
2	Perinatal conditions ^a	Cerebrovascular diseases	Unipolar depressive disorders	Perinatal conditions ^a	Lower respiratory infections	Malaria	Cerebrovascular diseases
3	Chronic obstructive pulmonary disease	Unipolar depressive disorders	Homicide and violence	Traffic accidents	Ischemic heart disease	Lower respiratory infections	Unipolar depressive disorders
4	Ischemic heart disease	Self-inflicted injuries	Ischemic heart disease	Lower respiratory infections	Diarrheal diseases	Diarrheal diseases	Alzheimer's disease and other dementias
5	Unipolar depressive disorders	Chronic obstructive pulmonary disease	Cerebrovascular diseases	Diarrheal diseases	Unipolar depressive disorders	Perinatal conditions ^a	Tracheal and lung cancer

Source: Mathers and others 2003.

a. Perinatal conditions include low birthweight, birth asphyxia, and birth trauma.

regions where lower respiratory infections, diarrheal diseases, and perinatal conditions persist. Because these diseases can largely be prevented through relatively low-cost interventions, research into how best to implement these interventions and reduce the infectious disease burden in lower-income countries remains a priority.

The 10:90 Issue

Efforts over the past two decades by the Commission on Health Research in Development, the WHO human reproduction and tropical disease research programs, the WHO Ad Hoc Committee on Research Relating to Future Intervention Options, and—more recently—the Global Forum for Health Research have been largely responsible for the increasing focus on the role of health research in economic and social development. At a time when few health research resources were being devoted to the specific health problems of developing countries, these entities played a critical role in making the case that more should be done. The Global Forum for Health Research took the most effective advocacy position, arguing that 90 percent of the US\$70 billion per year devoted to health research and development (R&D) was spent on diseases of the rich countries and only 10 percent was spent on the diseases uniquely afflicting poor countries. This advocacy has been effective and has galvanized global recognition that more research funding should be devoted to improving the health of the 85 percent of the world's population who live in developing or transition countries.

An absolute divergence in gross domestic product persists between industrial and developing countries and, thus, what they can reasonably devote to research. Infectious diseases continue to exact their highest tolls in the poorest countries, and new tools to prevent and treat HIV/AIDS, tuberculosis (TB), malaria, respiratory and diarrheal disease, SARS, influenza, and more exotic infections such as Ebola are urgently needed.

A longer-term view of global health problems recognizes the increasing convergence of health problems, particularly chronic diseases and injuries. It is no longer true that research on cardiovascular disease, diabetes, or depression, for example, is not relevant to developing countries. Vast knowledge is available on how to prevent a major portion of heart disease, lung cancer, type 2 diabetes, sexually transmitted infections, and injuries in the elderly, yet most countries do not implement that knowledge effectively. Thus, more research is needed to successfully transfer that knowledge from industrial to developing countries. For example, if monitored carefully, cost-effective, community-based antihypertensive, antiretroviral, and antidepressive treatments could have an enormous effect in most developing countries.

Increased surveillance and diagnostic capacity for emerging infectious diseases in developing countries will prevent

enormous new disease burdens in those countries, while at the same time providing early warning to industrial countries to stimulate new research on vaccines and drugs. Even though industry in developing countries may currently be devoting more effort to creating look-alike drugs, which are unlikely to add a great deal to the duration or quality of life, than to creating drugs for major global killers, and even though market incentives for interventions in resource-poor countries are lacking for most diseases, the solution is not to balkanize research and science, but to stimulate scientific capacity in all countries. Local researchers and industries in developing countries might be able to create interventions that can find a niche in markets in developing countries or that public sector or public-private partnerships are prepared to support.

Global Health Agendas

Some major global health problems cannot be addressed with the available knowledge and existing tools. Major challenges for R&D remain to reduce the unfinished burden of infectious diseases; address the rapidly increasing burden of chronic diseases in aging populations; and reduce the unnecessary burden caused by injuries, casualties of war, and humanitarian emergencies.

The Unfinished Agenda of Infectious Diseases. In 1969, the U.S. surgeon general issued a now famous, if less than prescient, pronouncement: “The time has come to close the book on infectious diseases” (WHO 2000). In 2001, infectious diseases still accounted for 32 percent of the global burden of mortality and 37 percent of the global burden of disease. In Sub-Saharan Africa, they are responsible for 68 percent of deaths. The HIV/AIDS epidemic continues to spread, affecting large proportions of populations in Sub-Saharan Africa, but it is at only an early stage in Asia, when effective prevention efforts could make a difference, as they did in Thailand. AIDS is responsible for the decline in life expectancy to less than 40 years of age in five Sub-Saharan African countries. Yet recent promising results of public health efforts in Brazil, Senegal, Thailand, and Uganda demonstrate that HIV/AIDS can be prevented and controlled on a nationwide scale.

Even though the public in industrial countries often seems surprised by each new outbreak of infectious disease, the pattern of emerging infectious diseases worldwide is continuing and, at the same time, is constantly changing. Since 1970, people have been afflicted by 32 new diseases that had never previously been reported in humans, such as hepatitis C, Legionnaire's disease, Ebola, *Vibrio cholerae* 0139 epidemic, Nipah virus encephalitis, SARS, and the highly pathogenic avian influenza. The 1918 influenza epidemic killed 20 million to 40 million people worldwide. Precisely when human-to-human transmission of the avian influenza viruses will occur is impossible to predict, but it is likely to happen eventually. This

eventuality underscores the importance of encouraging systematic collaboration on emerging and reemerging infections and strengthening global surveillance and laboratory capability. A syndromic approach to diagnosis and surveillance, as for the identification of flaccid paralysis, which accelerated the elimination of poliomyelitis in the Western hemisphere, may be crucial when laboratory diagnosis is not readily available.

Finally, the deliberate dissemination of anthrax spores in September and October 2001 in the United States has raised the specter of biological terrorism, either with pathogens natural to the environment that took years to eradicate, like smallpox, or genetically engineered pathogens of unknown capability.

Thus, the global infectious disease agenda remains unfinished. Given the continuing emergence of new infectious diseases and the increasing resistance of microbial pathogens to existing drugs and of insect vectors to pesticides, as well as low compliance with treatments, it is likely to remain so.

The Coming Epidemic: Chronic Diseases and Aging Populations. In 1998, for the first time, chronic diseases contributed more to the global burden of disease than infectious diseases, indicating the emergence of a convergence between the principal diseases of the developing countries and the industrial countries. Worldwide, cardiovascular disease is the major cause of mortality and morbidity (13.6 percent of total disability-adjusted life years) followed by cancer (6.6 percent of total disability-adjusted life years). Diabetes type 2 is increasing in most countries of the world at an alarming rate. An unanticipated finding from the global burden of disease analysis was that psychiatric illness, particularly depression, is a major cause of disability everywhere (Murray and Lopez 1996a, 1996b). Depression is now the most important disability among women in the United States, and globally it is projected to be the second largest contributor to the burden of disease by 2020.

The success of public health and childhood immunization in reducing the number of childhood deaths from infectious disease is partially responsible for the increasing burden of chronic diseases. However, part of the increase is caused by poor eating habits, lack of exercise, smoking, and other unhealthy lifestyle choices that tend to increase with a nation's income. Even though noncommunicable diseases associated with aging are increasingly contributing to the global burden of disease, the emergence of a highly virulent infectious disease pandemic could allow communicable illnesses to reassert their primacy.

The Unnecessary Epidemic: Injuries, Casualties of War, and Humanitarian Emergencies. Before the analysis of the global burden of disease, the contribution of injuries to the burden of disease and disability was unclear. The most rapidly rising category of injuries is that resulting from motor vehicle crashes. If present trends continue, by 2020 motor vehicle crashes will be

the third largest contributor to the global burden of disease. Clearly public health sectors have a great deal to contribute in terms of reducing injuries from motor vehicle crashes, falls, and workplace injuries. Less amenable to intervention by public health systems will be wars and humanitarian emergencies. Obtaining accurate figures is difficult, but as Murray and others (2002) note, available statistics have greatly underestimated the burden of war and civil strife on health systems.

The Crisis in Health Systems

Unprecedented advances in the development of health care technologies, drugs, vaccines, and new diagnostics, which hold the promise of healthier and longer lives for many, have profound influences on health systems worldwide; in rich and poor countries alike, they raise expectations and demand for health services along with difficult issues relating to access to information, costs, quality of care, equity, organization, and accountability. All systems are challenged by the need for quality improvement and self-learning.

The overall cost of health care has increased so much that fewer individuals can afford to pay for the best available care; thus, the financing of health systems has become central to national policy debates worldwide. Access and equity considerations pose particularly daunting challenges in poor countries, where access to treatment may be a matter of life and death for entire populations. This situation now prevails in the Sub-Saharan African countries, where the continuing spread of the HIV/AIDS epidemic has resulted in a sharp drop in life expectancy.

Comparative analysis of health systems worldwide seeks to understand the determinants of their performance—for instance, financing, human resources, health information, and quality of care—and to find ways to correct failures. Strengthening such research is one obvious way to tackle the current crisis in health systems. Another less obvious but important implication of the current situation is the need to pursue the best possible science to develop new and better tools and the concomitant need to ensure the availability and affordability of drugs and technologies where they are needed to address major health problems.

New Frontiers for R&D

The extraordinary advances in science provide unprecedented opportunities for both industrial and developing regions. The following sections highlight promises as well as potential pitfalls of frontier research.

Genomics, Molecular Epidemiology, and Preventive Medicine. Probably the most exciting area of biomedical research for at least the next decade derives from the Human

Genome Project and other efforts to sequence entire genomes of mammals, birds, insects, and microbial pathogens. Examination of these genome sequences will allow investigators to define and understand intrinsic risks for disease as well as interactions between genes and environmental threats. The sequencing of the major microbial pathogens has given rise to molecular targets for new drugs against specific pathogens that are distinct from their host counterparts and unique antigenic fragments that may become effective components of new vaccines. Researchers have sequenced the genomes of virtually all major viral, bacterial, and parasitic infectious disease agents and placed the results in databases available to everyone, a true public good (see The Institute of Genomic Research at <http://www.tigr.org>).

The availability of these genome sequences has catalyzed ambitious research efforts. For example, a project is under way to genetically engineer the *Anopheles* mosquito to render it unable to transmit malaria. Even if this effort fails, knowledge of the mosquito's genome has given new life to medical entomology and will likely help reduce vectorborne diseases in other ways. In a second example, the growing number of available influenza virus sequences will greatly aid understanding of the epidemiology and evolution of pandemic and inter-pandemic influenza viruses and will be a powerful tool for guiding vaccine strain selection.

The genome project has already changed the understanding of health and disease (box 4.2). Until now, epidemiology has dealt largely with external and environmental risks for disease. What the Human Genome Project offers is knowledge of the other side of the health equation—that is, the intrinsic risks for disease. Previously undreamed of molecular and cellular tools to explore gene expression and function are becoming available

to provide such knowledge on a scale that was inconceivable even five years ago.

The hope is that genomics and related biomedical research on stem cells will give rise to new therapies for repairing and remodeling tissue damaged by chronic disease, from heart disease to diabetes and chronic neurological diseases. The possibility of preventive treatment has now also arisen—that is, the identification of risks for chronic disease early in life and the implementation of preventive strategies—behavioral, nutritional, or medical—to avert or overcome intrinsic risks and thereby prevent disease.

Despite the optimism and enthusiasm, a darker side of the Human Genome Project is emerging. Because individuals face different risks, the focus on “boutique medicine” will increase—that is, the focus on risks for individuals and the development of niche interventions targeting those risks, rather than the focus on populations. Identification of those intrinsic risks at birth, for example, will for some time be a luxury available to better-off children in rich countries but not to babies in poor countries or to poor populations of rich countries. Ultimately the Human Genome Project and the rapid advances in biomedical research in the industrial world have the unintended potential to increase the gap between rich and poor. If, however, most complex diseases have multigenic susceptibilities, the magic bullet approach of boutique medicine may not fulfill current expectations of rich or poor countries.

New therapies, whether they arise from genomics or from more traditional pharmacology, must be tested carefully to ensure that people in developing countries are not unfairly treated in clinical trials. Contract research organizations now carry out 60 percent of clinical trials. Many of these organizations already test products in developing countries that will

Box 4.2

Uncovering Individual Risks for Specific Diseases

Genomic information makes possible predicting individual risks for certain diseases and to certain components of the environment. One level relates to polymorphisms in individual genes that represent intrinsic risks for certain conditions (for example, breast cancer). A second level relates to differences in the expression patterns of multiple genes on DNA chips that make it possible, for example, to distinguish melanomas from lymphomas from colon cancers or stages within these cancers that no pathologist could duplicate for accuracy. Within patterns for breast cancer or certain types of leukemia, experts can now distinguish those likely to survive five years from those with

Source: Authors.

a poor prognosis and are creating the first generation of drugs effective against mutated genes causing specific cancers.

The promise of the genome is first and foremost a greater knowledge about disease, risks for disease, and mechanisms of pathogenesis. The exploitation of knowledge from the genome is just beginning, and practical ramifications and many effective products have yet to be realized. Despite the hyperbole about its promise, the genome does represent a new frontier, beyond random testing of compounds, for rational and evidence-based design of effective interventions.

have anticipated markets in rich countries but are unlikely, should they be licensed, to be available or affordable to populations in developing countries. This practice is both an ethical and a practical health problem.

Finally, in countries where testing for genetic risks becomes available, the likelihood of risk adjustment—that is, the exclusion of people with some risks from insurance and discrimination in relation to jobs, marriage, and housing—can be anticipated. In this information age, personal genetic information will certainly present an unprecedented challenge to privacy and confidentiality.

A Faint Hope: Population-Based Research. The focus of future research in the rich countries will likely be on individual risks and on interventions tailored to those risks. Yet from the point of view of the world as a whole, the most effective interventions are population-based interventions, such as vaccines, insecticide-impregnated bednets, environmental modifications, antismoking campaigns, clean water, and safe sex. With knowledge derived from biomedical science and the Human Genome Project, it is hoped that some interventions will emerge that do not require knowing any individuals' intrinsic genetic risks and that may apply to entire populations at risk. The hope is that they could be comparable to existing population-based interventions—for example, vaccines recommended for all children to prevent major infectious diseases, treatment of schoolchildren once a year with ivermectin to prevent onchocerciasis, and antismoking campaigns.

In the rich countries, research has shown that aspirin and a combination of inexpensive antihypertensive drugs reduce deaths from heart attacks by 30 percent and from strokes by 50 percent. Even though they are off patent, these interventions are currently not widely used in developing countries. These findings are the products of basic research, but their effective use will depend on operational research.

The Next Frontier: Human Behavior and Social Determinants of Disease. Another revolution in research is emerging: understanding the functioning of the human brain and, ultimately, human behavior. Biomarkers for neuropsychiatric disease and environmental stresses are being sought, and with MRI and positron emission tomography technology, researchers can see areas of the brain that are thinking, remembering, or enjoying music. Within the next 50 years, science will have the technical ability to begin to untangle the processes of thinking in molecular terms, with exciting or frightening possibilities to alter or affect them. Anticipating quantifiable biomarkers for stresses and psychopathology as well as objective tools for measuring the effectiveness of new psychotropic interventions in changing behavior is not unreasonable.

The factors that lead people to engage in unhealthy or destructive behaviors are more complex than simple individual choices.

Many of the lessons of social epidemiology—and the flourishing world of advertising—indicate that most behaviors, including risky or unhealthy behaviors, are socially patterned. Science has unfortunately not done a good job of learning how to change social patterns. For example, merely targeting individuals at high risk for HIV/AIDS without changing the social context that might reinforce stigmatization is not the best way to prevent disease. Indeed, in many developing countries that now provide free counseling, testing, and antiretroviral drugs for people with HIV/AIDS, the biggest barrier remains the social stigma of being HIV positive. Health systems must widen their view beyond individual patients to target entire communities and the media to change unhealthy socially patterned behavior. In the United States, epidemiological estimates indicate that 50 percent of the 2.3 million annual deaths are preventable or postponable. McGinnis and Foege (2004) find that in 2000, 19 percent of deaths were caused by tobacco, about 14 percent were attributable to poor diet and lack of exercise, and about 12 percent to injuries. One of the great challenges is to learn how to communicate what is known about the prevention of such conditions as heart disease, obesity, and diabetes more effectively.

Reliable and comparative analysis of health risks is key for preventing disease and injury. A recently published study (Ezzati and others 2003) reports estimates of the disease burden caused by the joint effect of 20 selected leading risk factors in 14 subepidemiological regions of the world. In regions where high mortality persists, four risk factors—underweight in childhood, micronutrient deficiency, indoor smoke from solid fuels, and tobacco—caused 35 to 42 percent of lower respiratory infections in 2000. In the same regions, the combined risks of high blood pressure, high cholesterol, high body mass index, low fruit and vegetable intake, and physical inactivity caused 82 to 89 percent of the burden of ischemic heart disease. Important gaps in scientific evidence about the effects of multiple risk factors and risk factor interactions persist and require further exploration (Ezzati and others 2003). In this context, investigators should not underestimate social and behavioral determinants of disease, including poverty, environment, culture, and so on.

“Appropriate Science” for the Developing World

Although much discussion about “appropriate technology” for developing countries has taken place in recent decades, curiously little discussion has occurred about appropriate science. Much of the past debate assessed the imbalance of research relevant to developing countries' health problems largely as a function of the projected affordability of the products of the research—drugs, diagnostics, and new technologies developed in the industrial countries—rather than considering the potential contributions that scientists from developing countries could make both to advancing science and to addressing their

countries' health problems. Although some technologies are more or less appropriate to contexts in developing countries for reasons of cost, maintenance, or skill requirements, no limitation exists on what science or knowledge is appropriate in developing countries.

Some might argue that people in developing countries should restrict their research focus to diseases that principally affect their countries. If that were generalized to all countries, rich countries would not carry out research on tropical diseases, and the developing countries would do little research on chronic diseases. This strategy would violate two fundamental principles of science. First, connectivity in science is unpredictable: research on one disease or problem often brings conceptual or technological advances that are vital to progress in others; therefore, to the extent possible, every country should support a relatively broad spectrum of research. Second, creative science requires the freedom to pursue ideas. Progress in science is not fostered by restricting freedom of inquiry. There is every reason to believe that scientists in developing countries will create knowledge of value to diseases that primarily afflict people in industrial countries, both because of the convergence of health problems and because scientific knowledge is a public good.

Epistemology is the formal study of knowledge, and theories of how knowledge is generated abound. One such theory particularly relevant in the context of health research holds that three basic kinds of knowledge exist:²

- *Public knowledge.* This knowledge is generally published in the scientific literature, available in principle to all (with the glaring exception of those who cannot afford the major scientific journals). Because this knowledge is available to the entire global scientific community, it is a true public good. Indeed, publication in such journals is the basis for most judgments of academic and scientific achievement and is a precondition for scientific support and advancement.
- *Contextual knowledge.* This kind of knowledge is absolutely essential to bringing the fruits of public knowledge to a particular country or people. It requires learning and experience and involves cultural, social, and economic knowledge of a place, without which effectively implementing public knowledge or scientific discoveries in that context or evaluating the success of programs within national contexts is often impossible. In this case, research may have to be carried out in relation to how to implement interventions, as WHO's Special Programme for Research and Training in Tropical Diseases programs in leprosy and malaria have done in the absence of full scientific evidence. As essential as it may be, the global scientific and academic communities do not widely recognize or value contextual knowledge.
- *Tacit knowledge.* In contrast to public knowledge and contextual knowledge, tacit or intrinsic knowledge is impossible to write down or teach because it depends on a special kind

of communication between individuals that makes transmission of knowledge possible. One thinks of a few great clinical teachers who simply "know" the diagnosis without laboratory tests, or health care professionals who can put their colleagues in developing countries at ease and bring out the best in everyone being taught rather than being condescending or patronizing. Tacit knowledge is intuitive, breaks down barriers of culture or training, is highly motivating, and is often transformational in people's lives.

A few examples illustrate the importance of contextual knowledge. Many ideas and interventions are available, but knowledge on their effectiveness in different populations and on how to increase their usefulness is limited. The need to define best practices in different circumstances is urgent in relation to health. For example, data from the industrial countries indicate that providing a three-drug package containing aspirin to people with hypertension as preventive treatment might be possible on a population-based model as well as by individual physicians or medical personnel. However, Asians are more predisposed to hemorrhagic strokes than Europeans; therefore, treatment with such a regimen in Asia might have a significantly increased risk of adverse effects.

In another example, antiretroviral drugs are responsible for the 50 percent decline in mortality from HIV/AIDS in the United States, and the Global Fund to Fight AIDS, Tuberculosis, and Malaria; bilateral agencies; and the pharmaceutical industry are engaging in major efforts to make them available to resource-poor endemic countries. Despite encouraging examples in Brazil and Haiti, it is unclear whether—as in DOTS (directly observed treatment short course), a supervised method of administering drugs used for treating TB in resource-poor countries—these drugs can be given safely and effectively by community-based treatment programs, be appropriately monitored, and prevent the emergence of drug resistance or toxicity and thus provide cures for a high percentage of the patients in poor countries. However, if this method can be used, it will strengthen the fight against HIV/AIDS.

Research on community-based programs for treating children with epilepsy or adults with depression provides another example. The provision of ivermectin (Mectizan) to prevent and treat onchocerciasis revealed that even making a drug to be taken only once a year available and providing it free of charge had an almost negligible effect initially, because in some areas of Sub-Saharan Africa an effective health delivery system was simply not available. It is to Merck's credit that the Mectizan program invested considerable resources to create a delivery and monitoring system that has moved onchocerciasis to the category of diseases targeted for elimination as public health problems by WHO.

The flow of knowledge is not unidirectional. Reciprocity between research in different fields and different countries is

vital for the expansion of knowledge, and the unique contributions of developing countries to global health research are often overlooked and not always appreciated. For example, DOTS was initially developed in Tanzania, where researchers found that the best drug combination given with supervision, even though more costly, was both more effective in preventing relapse and emerging drug resistance and more cost-effective than the cheapest combinations. Similarly, artemisinin, the most rapidly acting drug for treating cerebral malaria, derives from an ancient Chinese medicine, qinghaosu, and is now a major tool in the armamentarium of malaria treatments. Research on isolated populations in developing countries can further the understanding of some of the genetic determinants of a variety of diseases, and transnational research on almost any disease has the potential to provide important insights into differences in risk factors in different contexts.

Such reciprocity depends critically on the development of scientific capacity. In terms of resource allocation, research funders often appear to have overlooked the necessary connection between research and training the next generations of researchers. Scientific and health capacity building and training are inseparable from research, yet funders seldom recognize the training aspect, and it is difficult to ensure that funding for training will be recognized as integral to research.

“Appropriate Technology” for the Developing World

The development community has long debated the nature of appropriate technology for resource-poor countries. Innumerable instances exist of high-tech biomedical equipment standing unused in laboratories and hospitals throughout the developing world, serving as status symbols but not as tools to further knowledge or alleviate illness. However, the best tools appropriate for learning from the research should be made available when the primary purpose of research is to acquire knowledge, particularly if human subjects are engaged as volunteers in clinical studies to help develop that new knowledge. For example, researchers studying the effectiveness of antiretroviral drugs in resource-poor countries should have access to technology that can measure CD4 cells, viral loads, and antiviral drug resistance, which are critical for analyzing the drugs' effectiveness. Sophisticated technology may be vital to establish the scientific principle of effectiveness, thereby enabling implementation of the most cost-effective treatment program in settings where the high-tech methodology may no longer be necessary on a large scale but may remain useful for validating the effectiveness of lower-tech surrogate markers.

Strengthening Capacity and Institutions

A 1996 WHO report (Ad Hoc Committee on Health Research Relating to Future Intervention Options 1996) emphasizes

three research needs that had not previously been articulated as essential to development.

- The first is a need for new knowledge through research to develop new tools for addressing continually emerging global health problems. Some of this knowledge will be generalizable, but much will be context specific and perhaps country specific.
- The second is the recognition that in many developing countries research capacity—that is, people with the training to carry out surveillance and laboratory and operational research—is limited, indicating an enormous need for training. Career structures and incentives to retain trained professionals in public health, medical sciences, and health systems in developing countries are also needed. An enormous brain drain is under way for nursing and other health professionals. The inducements to leave developing countries for higher salaries and better working conditions in the industrial world are compelling, even though many in the health field would prefer to help alleviate their own countries' health problems if it were feasible for them to do so.
- The third is that all the key priorities depend on the strengthening of institutions: universities, schools of public health and medicine, centers for disease control, and research institutions for health policy and economics. As the report indicates, remarkably few high-level institutions for research and training in public health have been created in developing countries during the past 25 years. Little progress has been made since the mid 1990s. Thus, their large needs for human capacity as well as laboratory and research infrastructure for public health are not surprising. For this situation to improve in a timely way, a new basis for cooperation in support of people and institutions must be forged between the developing and industrial countries.

Clearly governments should make greater commitments to health training and institutions. Whereas the international community has focused primarily on access to drugs in resource-poor countries, new partnerships in research are clearly needed. It is gratifying that programs that encourage and support cross-national, North-South, and South-South scientific collaborations and institutional links have been increasing, and the tremendous effect of the Bill & Melinda Gates Foundation in supporting research has emphasized the value of public and private commitments and partnerships in research. Regrettably, concomitant commitment has been lacking on the part of governments and many foundations to support training in research; career path opportunities; and institutions such as university science departments, medical schools, and schools of public health, all of which are critical for reducing the research and capacity gap between rich and poor countries.

No simple answer is available regarding the best ways to ensure effective collaboration in relation to global health. Global

Box 4.3

SARS and Influenza: A Paradigm Shift for Global Research Collaboration

Outbreaks of emerging infectious diseases are by their nature unpredictable. They can be contained when they are detected early and the number of cases is small. When they are not contained, they can have enormous human and economic consequences. Economic losses attributed to SARS, which infected 8,000 people and killed 774, have been estimated at US\$30 million per day in Canada and a total of US\$16 billion to US\$30 billion in Asia.

The global response to the SARS epidemic demonstrated the power of international collaboration under leadership of WHO among public health professionals, researchers, and institutions in several countries to halt the progression of a new disease (La Montagne and others 2004). Another example is influenza: an existing international network of influenza research sites, which is critical for defining the strains to be used each year for immunization, was instrumental in developing an

unprecedented rapid response to the potentially devastating bird H5N1 influenza A.

These examples represent an important paradigm shift in global research collaboration in that they required national surveillance at the epidemiological and laboratory levels; unprecedented sharing of information at all levels of the health system; and close cooperation among clinicians, epidemiologists, and bench scientists, as well as those involved in veterinary surveillance, for the rapid development of effective intervention strategies. Integrated global responses raise difficult issues pertaining to information sharing and ownership of specimens and reagents, which have profound implications for future global health R&D. They also underscore that, despite the political temptations of denial and the economic threats of epidemic disease, honest and accurate information is essential for early warning and for making effective health policy.

Source: Authors.

collaborations can be difficult, they are not inexpensive, and their successes are limited in number, but they can potentially have a major effect (box 4.3). Questions arise about how to develop economies of scale in R&D and institutional capabilities; how many research centers are optimal in a developing country; how much should be done by country partners and how much in the developing countries; and what the roles of basic scientific versus epidemiological, clinical, and operational research should be. The experience of working together in true partnerships appears to be generally rewarding for scientists in both industrial and developing countries and seems to be an effective way of increasing research capacity. One set of lessons still to be learned is what the best forms of collaboration are: individual scientist, institutional, transnational, or multinational.

PRIORITY SETTING

Setting priorities for R&D of interventions is both complex and critical in the context of severely constrained resources. A systematic approach that takes into account the disease burden as well as scientific opportunities has been proposed to guide decisions.

Approaches

The challenge is to ensure that available resources are targeted at major health problems.

Inherent Difficulties in Setting Priorities. The first part of this chapter underscored the immense scope of health problems and the potential of global health research to make a difference. Given the complexity of the task and the multiple participants involved in the process, defining priorities for the global health research agenda is daunting.

Scientists tend to argue that more research is urgently needed on the diseases they are studying. Their research may certainly include worthwhile issues, but they may not be priorities in the wider context of global health R&D.

Some hold the view that the choice of priorities should begin with a statement defining topics that should not be priorities—for example, the development of vaccines (such as a leprosy or hookworm vaccine) when cost-effective treatments are available. Others strongly disagree, given the interconnectivity and unpredictability of science.

The failure of the U.S. “war on cancer” offers a useful caution on the limitations of rational planning of science. In the 1960s, a group of distinguished scientists developed a set of future research priorities for the National Cancer Program. Despite the importance of the problem, the requisite scientific knowledge was not then available to develop the modern tools that have recently been successful in treating and preventing cancer. Planning for where the new innovations and discoveries will come from is hard, and planners have to be open to changing their priorities and incorporating new approaches.

A key challenge is the problematic nature of anticipating scientific connections in advance. For example, the sequencing of a mouse leukemia virus genome as part of the National Cancer Program is what enabled scientists years later to classify HIV as a related member of the retrovirus family. Indeed, who would have predicted that research on the once arcane coronavirus would become essential to control the spread of SARS? Or that the esoteric question of whether tumor cells extinguished differentiated functions of normal body cells would lead to the discovery of monoclonal antibodies? Or that the study of sex in bacteria would give rise to the entire genetic revolution of the past half century? The need to recognize the unpredictability of science and the limitations of scientists at any time is best illustrated by Oppenheimer's statement at the beginning of this chapter.

Systematic and Evidence-Based Approach to Priority Setting.

The process of setting priorities for the global health research agenda is complex and includes accurate or perceived assess-

ments of the burden of disease; developed countries' threat assessments, for example, in relation to bioterrorism and epidemic potential; scientific or technical opportunities; advocacy; political commitment; ethical considerations; and funding availability.

Using a systematic and evidence-based approach to priority setting, the WHO Ad Hoc Committee for Health Research Relating to Future Intervention Options (1996) undertook the first broadly based, systematic effort to formulate "best buys" for health R&D (table 4.3). The steps included assessments of the following:

- size of the disease burden
- reasons the disease burden persisted
- adequacy of the current scientific knowledge base
- cost-effectiveness of potential interventions and the probability of successful development of new tools
- adequacy of the current level of ongoing research and funding.

Table 4.3 R&D Best Buys

Category	Key R&D investments
<i>Maternal and child health</i>	
Strategic research	Understand the relative importance, in different environments, of increased nutrient intake and of control of infectious disease as a way to reduce malnutrition
Package development and evaluation	Evaluate and refine the package for the integrated management of the sick child Develop, evaluate, and refine the mother-baby package for pregnancy, delivery, and neonatal care Evaluate the implementation of a range of family planning packages offering a wide choice of methods
New tools to improve package content	Evaluate the efficacy and optimal dosage of candidate rotavirus vaccines in low-income countries Evaluate the efficacy of optimal dosage of candidate conjugate pneumococcal vaccines and the effectiveness of existing vaccine against influenza B in low-income countries Develop and evaluate ways to increase efficiency in the Expanded Program on Immunizations by simplifying delivery and maximizing use of opportunities for immunization Evaluate the promotion of insecticide-impregnated bednets for inclusion in a future healthy household package Develop new contraceptive methods, particularly to widen the choice of long-term but reversible methods, postcoital methods for regular and emergency use, and methods for men
<i>Microbial threats</i>	
Strategic research	Screen drugs on molecular targets predicted by the genome sequence of major pathogens Investigate influences on the spread of antimicrobial resistance and approaches to monitoring resistant strains with the aim of identifying ways of slowing their emergence
Intervention development	Develop an effective prophylaxis for TB—for example, depot (or long-acting), or a vaccine chemoprophylaxis Develop a malaria vaccine Develop an HIV vaccine Develop improved methods for the diagnosis, prevention, and treatment of sexually transmitted diseases, including vaginal microbicides
<i>Noncommunicable diseases and injuries</i>	
	Establish a special program for research and training on noncommunicable diseases and healthy aging Establish a special program or initiative for research, training, and capacity building on injuries
<i>Health policy</i>	Establish a special program for research and training on health systems and policy

Source: Ad Hoc Committee on Health Research Relating to Future Intervention Options 1996.

This five-step approach has been influential. The Global Forum for Health Research and the Special Programme for Research and Training in Tropical Diseases have endorsed it and further developed it. The Global Forum's combined approach matrix links the five steps with four actors or factors determining the health status (Global Forum for Health Research 2002):

- individual, family, and community
- health ministry, health research institutions, and health systems and services
- sectors other than health
- central government macroeconomic policies.

The five steps also provide the basis for the strategic emphases matrix for tropical diseases research (Remme and others 2002).

The individual disease chapters in this volume used a slightly modified version of the framework developed by the WHO Ad Hoc Committee to identify gaps and guide the formulation of research priorities on the basis of the following premise: even though the current mix of available cost-effective interventions averts a proportion of the burden of any particular disease and the remaining burden could be further reduced with improved application of existing technologies to affected populations, a fraction of disease remains that cannot be averted. Two reasons account for this fact. First, the cost for extending the existing technology to the remainder of the population would be prohibitive. Second, the existing interventions may simply not be sufficiently effective. These two categories define the magnitude of the need for new or better tools and, in essence, serve as a rationale and indicate priorities for research.

A clear example is the case of HIV/AIDS. Neither behavioral interventions, such as exhortations for abstinence and fidelity and the provision of condoms, nor antiretroviral therapy has stopped the global spread of HIV, which challenges the scientific community to undertake more research on preventive vaccines. The availability of highly active antiretroviral therapy challenges the research community to find ways of providing effective and life-saving treatment for HIV/AIDS patients in a manner that ensures proper use and compliance, averts the development of drug resistance, and thereby becomes a financially sustainable policy.

Participants and Decision Makers. Two main concerns lie at the core of most discussions of the priority-setting processes: the predominance of the industrial countries and the predominance of the scientific community in formulating research agendas. Two-thirds of respondents in a survey of researchers that was funded by the National Institute of Allergy and

Infectious Diseases of the U.S. National Institutes of Health and was conducted in May 2004 were leading scientists from low- and middle-income developing countries and worked in the same region in which they held their citizenship. The survey highlighted their views about key factors influencing research priority setting as well as major barriers that hampered stronger participation by scientists from developing countries in global health research. According to the survey, the most important factors determining research priorities were the magnitude of disease burdens and the needs of the industrial countries. Major barriers to the success of research collaboration in global health were the lack of sustained funding; the difficulty of linking research, programs, and policy; the weak research leadership; and the absence of a science culture (Harley, Simonsen, and Breman 2004).

A more balanced participation of scientists from industrial and developing countries, a better gender mix, and the inclusion of major stakeholders are essential to the successful development of a truly global health research agenda. The challenge is to develop creative mechanisms for addressing current shortcomings.

The process for selecting the best research projects and programs within each priority area is well established and is grounded in scientific merit, based primarily on trust in peer review and expert judgment. Keeping this process independent from political pressures is extremely important. However, the peer review process has limitations, including a natural conservatism and risk aversion by scientists, given the responsibility for the allocation of public funding, their often narrow base of expertise in one discipline, and their specific cultural perspective. Alternative models of project selection from industry and other scientific, mission-oriented entities might offer interesting alternatives—for example, managerial systems or strategic planning processes, particularly for translating knowledge into successful interventions, an area that research is currently emphasizing.

Ethical considerations and pressures exerted by advocacy groups—such as public-private partnerships for targeted drug or vaccine development, fresh looks at “orphan drug” legislation, patent rules ensuring financial returns to industry as well as the affordability of new products in developing countries, and commitment before their development by the public and private sectors to subsidize their development or ensure markets for the products—are likely to counterbalance to some extent the lack of incentives for the pharmaceutical industry to develop drugs, diagnostics, and vaccines for which markets do not exist or are not profitable. In addition, one might hope that the growing pharmaceutical and vaccine industry in developing countries might place a higher priority on addressing nationally and regionally important health problems than do multinational companies.

The share of total R&D funds allocated to major causes of the disease burden in developing countries remains insufficient. As a result, the availability of funding to support global health R&D is ultimately the defining factor regarding the implementation of selected R&D priorities. Thus, the Bill & Melinda Gates Foundation has become a major driving force in defining priorities for global health R&D through its support of promising public-private partnerships. The new US\$200 million it provided to finance the Grand Challenges in Global Health represents the newest large influx of funds in support of global health research (see Foundation of National Institutes of Health at <http://www.grandchallengesgh.org>).

Findings

Research agendas proposed in the various chapters fall into three broad categories:

- priorities that are already on the global health agenda
- important topics that are not yet on the global agenda, but should be pursued
- promising research topics that are not yet priorities, but should be pursued.

Michaud and others (2005) provide a more exhaustive account of the research priorities summarized here and recommended in the volume.

Priorities Already Part of the Global Health Agenda.

Priorities that are already the most prominent part of the global health agenda relate almost exclusively to the unfinished agenda of infectious diseases and to the continuous threats of emerging infectious diseases, including bioterrorism. The largest investments pertain to the development of new drugs and vaccines that are needed to reduce the burden of HIV/AIDS, malaria, and TB; to the early detection and control of new highly pathogenic viral agents (for example, SARS); and to the prevention and treatment of infectious diseases resulting from microbial terrorism (for instance, anthrax and smallpox).

In 2001, the National Institute of Allergy and Infectious Diseases developed a global research plan for HIV/AIDS, malaria, and TB. The plan outlines a comprehensive approach for fighting infectious diseases that involves building a sustainable research capability domestically and internationally and enhancing global partnerships. It comprises short-, medium-, and long-term goals for research that “will lead to prevention and treatment strategies that are effective, feasible, and realistic for individual countries struggling with the burden of numerous infectious diseases” (National Institute of Allergy and Infectious Diseases 2001).

Since the mid 1970s, the WHO Special Programme for Research and Training in Tropical Diseases and a few other institutions have been key players in strengthening research and research capacity for tropical diseases that are endemic in specific developing regions—African trypanosomiasis, Chagas disease, dengue, leishmaniasis, leprosy, lymphatic filariasis, malaria, onchocerciasis, and schistosomiasis. As a result, effective control measures are now available for Chagas disease, leprosy, lymphatic filariasis, and onchocerciasis—but questions remain regarding effective implementation strategies. The other diseases still lack effective control measures and, thus, require further research to develop better tools and effective control strategies (<http://www.who.int/tdr/grants/strategic-emphases/default.htm>).

The process that led to the formulation of the Grand Challenges in Global Health represents two important departures from earlier approaches to priority setting. First, the announcement of the call for ideas in May 2003 had an unprecedented dissemination worldwide and resulted in over 1,000 submissions from scientists and institutions in 75 countries. Second, the formulation of a grand challenge, described as “a call for specific scientific or technological innovation that would remove a critical barrier to solving an important health problem in the developing world with a high likelihood of global impact and feasibility” (Varmus and others 2003) was broad and had a clear goal.

The research agendas proposed in chapters 16, 18, and 21 are extensive and encompass research on basic epidemiology and risk factors and the development of new or better drugs, vaccines, diagnostics, and intervention methods. The fact that these priorities do not represent a marked departure from previous research priorities for these conditions attests to the complexity of these diseases and their importance in the poorest countries. They will require a broadly based and sustained global research effort to overcome the rapid spread of antibiotic and insecticide resistance, limited human resources, and poorly developed health systems that severely constrain the health community’s ability to reduce the burden of disease.

Important Topics That Are Not Yet on the Global Research Agenda but Should Be Pursued.

Cardiovascular diseases, neuropsychiatric disorders, obesity, diabetes, and cancers are causing a rapidly increasing share of the disease burden in all developing regions, with the exception of Sub-Saharan Africa; however, they do not yet figure prominently on the global health research agenda. The research priorities recommended independently by the authors of various chapters pertaining to major causes of noncommunicable diseases converge. Indeed, diet, lifestyle, obesity, tobacco, and alcohol are common risk factors for cardiovascular diseases, certain cancers, and

diabetes. These diseases and risk factors represent a cluster of conditions that pose similar research challenges.

The first important cross-cutting theme emerging from this cluster of chapters is the issue of portability, or how to bring knowledge and programs from one location and define how they can become best practices elsewhere. Cost-effective preventive strategies and therapeutic approaches to reduce the burden of cardiovascular diseases, cancer, diabetes, and mental disorders have been developed and tested in industrial countries. Much of the extensive knowledge base accumulated in industrial countries to prevent the development of cardiovascular diseases, diabetes, and cancers is likely to be relevant to developing countries, yet few epidemiological studies have quantified the impact of major risk factors for chronic diseases in developing regions, and few trials have been conducted to assess the effectiveness of different intervention strategies. Research to explore the transferability of cost-effective interventions from industrial to developing countries therefore figures prominently in several chapters.

The primary prevention for noncommunicable diseases in industrial countries rests on the reduction of major risk factors—namely, diet, lifestyles, and tobacco and alcohol consumption. Research priorities include the development of epidemiological databases and of intervention studies to identify cost-effective strategies to reduce the prevalence of major risk factors in different contexts in developing countries. The transfer of personal and population-based interventions to reduce the risk of cardiovascular disease, which are based on decades of research in the industrial countries, is particularly promising. Research priorities include evaluating a range of intervention strategies, from simple dietary interventions to reduce the risk of cardiovascular disease (for example, food supplementation with folic acid and linoleic acid and reduction in the salt, saturated fat, and trans fat content of processed foods), to the hypothetical “polypill,” which would combine drugs to lower cholesterol, clotting, and blood pressure. Reducing the risk of cardiovascular disease is particularly important for diabetes, which is itself an important risk factor for cardiovascular disease.

The second theme pertains to lifelong medical management of chronic conditions that cannot be cured but could be improved through the development and testing of public health prevention and treatment algorithms. This issue has been little considered in past discussions of priorities for global health research but now appears to be reasonably cost-effective. Examples include unipolar depression, bipolar disorders, schizophrenia, epilepsy, diabetes, and secondary prevention of ischemic heart disease and stroke.

The third theme pertains to crucial implementation research that combines operations research and health services and systems research. Such research is becoming central to ensuring the success of the rapid scaling-up of cost-effective interventions that is required to meet the health targets of the

Millennium Development Goals, particularly in resource-poor countries with weak health systems. In this context, further research is critical to elucidate neglected areas of health system reforms, including the following (Mills 2004):

- improving public service provision
- enhancing human resources
- ensuring accountability for health outcomes, funds, and medicines
- ensuring a functioning central government
- providing evidence for policy.

Promising Research Topics Not Yet Global Priorities. Other important research topics emerge from the various chapters that are not yet global priorities but that are nevertheless worthwhile pursuing. Major themes pertain to the following:

- epidemiology of injuries and cost-effective interventions to reduce the burden resulting from both intentional and unintentional injuries, particularly motor vehicle crashes and road and vehicle safety
- major risk factors for disease in different contexts (for example, tobacco, obesity, physical activity)
- medical and surgical errors
- occupational and environmental health
- risk analysis and risk communication
- delivery of care at different levels of the health system
- performance of health systems
- management of health research
- reproductive and sexual health
- health effects of global warming.

The importance of strengthening the research agenda in those and other areas and the resultant opportunities to make a real difference have not been sufficiently recognized in the past.

KEY RECOMMENDATIONS

The priority-setting process should focus initially on defining a small number of key priorities that have a reasonable chance of succeeding and yielding cost-effective outcomes in resource-constrained environments and that are, thus, least likely to divert limited resources from being more effectively directed elsewhere. Five broad recommendations emerge from this chapter.

Invest More Wisely in Health R&D

The focus should be on how best to invest limited resources for health R&D. This approach raises hard questions about selecting priorities and the extent to which the burden of disease and scientific opportunity to play a role. A telling example of the

dilemma may be a vaccine against bird flu. Because bird flu, A (H5N1) or other strains, is not yet a major human disease, the setting of priorities by the disease burden criterion would not accord a bird flu vaccine high priority. But knowing that between 20 to 40 million people died in the 1918 influenza epidemic, and that with a transmission time of 1.5 days, there would be few public health measures other than a vaccine that would make a difference in preventing a pandemic, developing and testing multiple candidate vaccines should be an urgent research priority.

Despite the paucity of past analysis of the relationship between the cost of research in an area and its success in improving the level of health, the amount invested is unlikely to have been the most important determinant of success. The What Works Working Group has developed 17 case studies of success stories, all of which were supported by public finance mostly in resource-constrained settings (Levine and What Works Working Group 2004). A review of lessons learned from the 20 biggest research successes in improving health in low- and middle-income countries would be a worthwhile undertaking.

Shift the Paradigm for Priority Setting

The paradigm shift from dividing the world's health problems into those of the industrial countries and those of the developing countries toward creating a better understanding of the commonality of health problems between the industrial and most developing countries lies at the core of priority setting for global health research. Implicit in this shift is the recognition that the health problems of Sub-Saharan Africa are urgent and require special emphasis on the devastating burden of infectious diseases, particularly HIV/AIDS, and on the need to develop effective infrastructure for health. In time, the expectation is that the health needs of most Sub-Saharan African countries will similarly converge with those of other regions of the world and that knowledge developed in these regions will be transferable and helpful to accelerating development there.

As sociologists have long recognized, scientific and medical technology diffuses from the industrial to the developing countries, and it will, in the short term at least, increase the disparities between rich and poor countries—and perhaps to a comparable extent between the rich and the poor within countries—because more affluent and better-educated populations tend to have greater access to new technologies. However, even though disparities in health between affluent urban dwellers and poor rural populations in China and India have increased over the past decade, the overall quality of health of the entire population has increased during the same period. The hope is that information derived from research will be a great leveler over time and will contribute to reducing global inequities.

The shift in thinking in relation to the convergence of health burdens and research opportunities in both industrial and developing countries has far-reaching implications for the formulation of research priorities. In addition to emphasizing the commonality of health problems, it also emphasizes the importance of stronger global research collaboration in tackling major health problems and underscores the need for much stronger public-private partnerships to ensure that affordable drugs and vaccines will be developed and made available in resource-constrained environments.

Maximize the Potential of Information Technology

No advances in science have more potential for improving health globally than the information and communication sciences. At the scientific level, the ability to handle increasingly massive amounts of data, whether from genetics, epidemiology, or clinical trials, offers the opportunity to mine the world of knowledge in ways that could not be contemplated a decade ago. Knowledge can be transferred instantaneously through the Internet; through access to open databases; and through the new public libraries of science and medicine, such as the U.S. National Library of Medicine PubMed Central. With information technology, procedures can be put in place to minimize medical and pharmaceutical errors and to provide greater accounting for medical costs and outcomes. Finally, research with partners in many parts of the world can now be carried out in real or in lag time, as in the case of clinical research on malaria (Royall and others 2004). The tools, hardware, and software for this informatics revolution must be made available as widely as possible to universities and health systems in developing countries.

Increase Global Research Capacity

Research capacity continues to limit the successful implementation of those interventions most needed to improve health in resource-constrained environments. The number of people trained to carry out the surveillance and the laboratory and operational research that are so essential to the successful implementation of cost-effective interventions remains woefully inadequate. Redressing this limitation is a daunting task that will require substantial financial investment and creative approaches to create conditions that will reverse the brain drain and strengthen academic and research institutions in developing countries.

Create a Global Health Architecture

Health is not the sole provenance of the health sector, and yet there is no forum or architecture for coordinating the increasingly important multisectoral interactions to improve health.

Cardiovascular and pulmonary disease in Europe and the United States are increasingly determined by China's energy sector, and global warming is impacted by the policy of the U.S. President. Health is critically affected by education, energy, transport, finance, trade, immigration, communication, and the environment. Major health problems will be most successfully addressed if partnerships can be developed between sectors, governments, NGOs, business and industry, and academe.

Support Freedom of Scientific Inquiry

No country has a monopoly on ideas, and every country has something important to contribute to knowledge about health. The universality of science requires that scientists everywhere strive for the highest level of rigor and quality and that every country have some sustainable level of scientific research and problem-solving capacity. Encouraging and supporting scientists with the ability and passion to contribute to knowledge about health, globally or locally, must become one of the key aims of the global health and development agendas.

ACKNOWLEDGMENT

This chapter is dedicated to the memory of John La Montagne, who was a tireless supporter of health research into problems of developing countries, a good friend, and an inspiration to us all.

NOTES

1. Obviously, nonrivalry does not pertain to knowledge that is proprietary, as in the pharmaceutical industry, although the system of patents was created to make such enabling knowledge available to all by providing a limited monopoly for its exploitation by discoverers or inventors.

2. For this formulation, we are indebted to Suwit Wibulpolprasert, deputy permanent secretary of the Ministry of Health, Thailand.

Chapter 5

Science and Technology for Disease Control: Past, Present, and Future

David Weatherall, Brian Greenwood, Heng Leng Chee,
and Prawase Wasi

As we move into the new millennium it is becoming increasingly clear that the biomedical sciences are entering the most exciting phase of their development. Paradoxically, medical practice is also passing through a phase of increasing uncertainty, in both industrial and developing countries. Industrial countries have not been able to solve the problem of the spiraling costs of health care resulting from technological development, public expectations, and—in particular—the rapidly increasing size of their elderly populations. The people of many developing countries are still living in dire poverty with dysfunctional health care systems and extremely limited access to basic medical care.

Against this complex background, this chapter examines the role of science and technology for disease control in the past and present and assesses the potential of the remarkable developments in the basic biomedical sciences for global health care.

MEDICINE BEFORE THE 20TH CENTURY

From the earliest documentary evidence surviving from the ancient civilizations of Babylonia, China, Egypt, and India, it is clear that longevity, disease, and death are among humanity's oldest preoccupations. From ancient times to the Renaissance, knowledge of the living world changed little, the distinction between animate and inanimate objects was blurred, and speculations about living things were based on prevailing ideas about the nature of matter.

Advances in science and philosophy throughout the 16th and 17th centuries led to equally momentous changes in

medical sciences. The elegant anatomical dissections of Andreas Vesalius swept away centuries of misconceptions about the relationship between structure and function of the human body; the work of Isaac Newton, Robert Boyle, and Robert Hooke disposed of the basic Aristotelian elements of earth, air, fire, and water; and Hooke, through his development of the microscope, showed a hitherto invisible world to explore. In 1628, William Harvey described the circulation of the blood, a discovery that, because it was based on careful experiments and measurement, signaled the beginnings of modern scientific medicine.

After steady progress during the 18th century, the biological and medical sciences began to advance at a remarkable rate during the 19th century, which saw the genuine beginnings of modern scientific medicine. Charles Darwin changed the whole course of biological thinking, and Gregor Mendel laid the ground for the new science of genetics, which was used later to describe how Darwinian evolution came about. Louis Pasteur and Robert Koch founded modern microbiology, and Claude Bernard and his followers enunciated the seminal principle of the constancy of the internal environment of the body, a notion that profoundly influenced the development of physiology and biochemistry. With the birth of cell theory, modern pathology was established. These advances in the biological sciences were accompanied by practical developments at the bedside, including the invention of the stethoscope and an instrument for measuring blood pressure, the first use of x-rays, the development of anesthesia, and early attempts at the classification of psychiatric disease as well as a more humane approach to its management. The early development of the use of statistics for analyzing data obtained in medical practice also

occurred in the 19th century, and the slow evolution of public health and preventive medicine began.

Significant advances in public health occurred on both sides of the Atlantic. After the cholera epidemics of the mid 19th century, public health boards were established in many European and American cities. The Public Health Act, passed in the United Kingdom in 1848, provided for the improvement of streets, construction of drains and sewers, collection of refuse, and procurement of clean domestic water supplies. Equally important, the first attempts were made to record basic health statistics. For example, the first recorded figures for the United States showed that life expectancy at birth for those who lived in Massachusetts in 1870 was 43 years; the number of deaths per 1,000 live births in the same population was 188. At the same time, because it was becoming increasingly clear that communicable diseases were greatly depleting the workforce required to generate the potential rewards of colonization, considerable efforts were channeled into controlling infectious diseases, particularly hookworm and malaria, in many countries under colonial domination.

However, until the 19th century, curative medical technology had little effect on the health of society, and many of the improvements over the centuries resulted from higher standards of living, improved nutrition, better hygiene, and other environmental modifications. The groundwork was laid for a dramatic change during the second half of the 20th century, although considerable controversy remains over how much we owe to the effect of scientific medicine and how much to continued improvements in our environment (Porter 1997).

This balance between the potential of the basic biological sciences and simpler public health measures for affecting the health of our societies in both industrial and developing countries remains controversial and is one of the major issues to be faced by those who plan the development of health care services for the future.

SCIENCE, TECHNOLOGY, AND MEDICINE IN THE 20TH CENTURY

Although rapid gains in life expectancy followed social change and public health measures, progress in the other medical sciences was slow during the first half of the 20th century, possibly because of the debilitating effect of two major world wars. The position changed dramatically after World War II, a time that many still believe was the period of major achievement in the biomedical sciences for improving the health of society. This section outlines some of these developments and the effect they have had on medical practice in both industrial and developing countries. More extensive treatments of this topic are available in several monographs (Cooter and Pickstone 2000; Porter 1997; Weatherall 1995).

Epidemiology and Public Health

Modern epidemiology came into its own after World War II, when increasingly sophisticated statistical methods were first applied to the study of noninfectious disease to analyze the patterns and associations of diseases in large populations. The emergence of clinical epidemiology marked one of the most important successes of the medical sciences in the 20th century.

Up to the 1950s, conditions such as heart attacks, stroke, cancer, and diabetes were bundled together as degenerative disorders, implying that they might be the natural result of wear and tear and the inevitable consequence of aging. However, information about their frequency and distribution, plus, in particular, the speed with which their frequency increased in association with environmental change, provided excellent evidence that many of them have a major environmental component. For example, death certificate rates for cancers of the stomach and lung rose so sharply between 1950 and 1973 that major environmental factors must have been at work generating these diseases in different populations.

The first major success of clinical epidemiology was the demonstration of the relationship between cigarette smoking and lung cancer by Austin Bradford Hill and Richard Doll in the United Kingdom. This work was later replicated in many studies, currently, tobacco is estimated to cause about 8.8 percent of deaths (4.9 million) and 4.1 percent of disability-adjusted life years (59.1 million) (WHO 2002c). Despite this information, the tobacco epidemic continues, with at least 1 million more deaths attributable to tobacco in 2000 than in 1990, mainly in developing countries.

The application of epidemiological approaches to the study of large populations over a long period has provided further invaluable information about environmental factors and disease. One of the most thorough—involving the follow-up of more than 50,000 males in Framingham, Massachusetts—showed unequivocally that a number of factors seem to be linked with the likelihood of developing heart disease (Castelli and Anderson 1986). Such work led to the concept of *risk factors*, among them smoking, diet (especially the intake of animal fats), blood cholesterol levels, obesity, lack of exercise, and elevated blood pressure. The appreciation by epidemiologists that focusing attention on interventions against low risk factors that involve large numbers of people, as opposed to focusing on the small number of people at high risk, was an important advance. Later, it led to the definition of how important environmental agents may interact with one another—the increased risk of death from tuberculosis in smokers in India, for example.

A substantial amount of work has gone into identifying risk factors for other diseases, such as hypertension, obesity and its accompaniments, and other forms of cancer. Risk factors defined in this way, and from similar analyses of the pathological

role of environmental agents such as unsafe water, poor sanitation and hygiene, pollution, and others, form the basis of *The World Health Report 2002* (WHO 2002c), which sets out a program for controlling disease globally by reducing 10 conditions: underweight status; unsafe sex; high blood pressure; tobacco consumption; alcohol consumption; unsafe water, sanitation, and hygiene; iron deficiency; indoor smoke from solid fuels; high cholesterol; and obesity. These conditions are calculated to account for more than one-third of all deaths worldwide.

The epidemiological approach has its limitations, however. Where risk factors seem likely to be heterogeneous or of only limited importance, even studies involving large populations continue to give equivocal or contradictory results. Furthermore, a major lack of understanding, on the part not just of the general public but also of those who administer health services, still exists about the precise meaning and interpretation of *risk*. The confusing messages have led to a certain amount of public cynicism about risk factors, thus diminishing the effect of information about those risk factors that have been established on a solid basis. Why so many people in both industrial and developing countries ignore risk factors that are based on solid data is still not clear; much remains to be learned about social, cultural, psychological, and ethnic differences with respect to education about important risk factors for disease. Finally, little work has been done regarding the perception of risk factors in the developing countries (WHO 2002c).

A more recent development in the field of clinical epidemiology—one that may have major implications for developing countries—stems from the work of Barker (2001) and his colleagues, who obtained evidence suggesting that death rates from cardiovascular disease fell progressively with increasing birthweight, head circumference, and other measures of increased development at birth. Further work has suggested that the development of obesity and type 2 diabetes, which constitute part of the metabolic syndrome, is also associated with low birthweight. The notion that early fetal development may have important consequences for disease in later life is still under evaluation, but its implications, particularly for developing countries, may be far reaching.

The other major development that arose from the application of statistics to medical research was the development of the randomized controlled trial. The principles of numerically based experimental design were set out in the 1920s by the geneticist Ronald Fisher and applied with increasing success after World War II, starting with the work of Hill, Doll, and Cochrane (see Chalmers 1993; Doll 1985). Variations on this theme have become central to every aspect of clinical research involving the assessment of different forms of treatment. More recently, this approach has been extended to provide broad-scale research syntheses to help inform health care and research. Increasing the numbers of patients involved in trials and applying meta-analysis and electronic technology for

updating results have made it possible to provide broad-scale analyses combining the results of many different trials. Although meta-analysis has its problems—notably the lack of publication of negative trial data—and although many potential sources of bias exist in the reporting of clinical trials, these difficulties are gradually being addressed (Egger, Davey-Smith, and Altman 2001).

More recent developments in this field come under the general heading of evidence-based medicine (EBM) (Sackett and others 1996). Although it is self-evident that the medical profession should base its work on the best available evidence, the rise of EBM as a way of thinking has been a valuable addition to the development of good clinical practice over the years. It covers certain skills that are not always self-evident, including finding and appraising evidence and, particularly, implementation—that is, actually getting research into practice. Its principles are equally germane to industrial and developing countries, and the skills required, particularly numerical, will have to become part of the education of physicians of the future. To this end, the EBM Toolbox was established (Web site: <http://www.ish.ox.ac.uk/ebh.html>). However, evidence for best practice obtained from large clinical trials may not always apply to particular patients; obtaining a balance between better EBM and the kind of individualized patient care that forms the basis for good clinical practice will be a major challenge for medical education.

Partial Control of Infectious Disease. The control of communicable disease has been the major advance of the 20th century in scientific medicine. It reflects the combination of improved environmental conditions and public health together with the development of immunization, antimicrobial chemotherapy, and the increasing ability to identify new pathogenic organisms. Currently, live or killed viral or bacterial vaccines—or those based on bacterial polysaccharides or bacterial toxoids—are licensed for the control of 29 common communicable diseases worldwide. The highlight of the field was the eradication of smallpox by 1977. The next target of the World Health Organization (WHO) is the global eradication of poliomyelitis. In 1998, the disease was endemic in more than 125 countries. After a resurgence in 2002, when the number of cases rose to 1,918, the numbers dropped again in 2003 to 748; by March 2004, only 32 cases had been confirmed (Roberts 2004).

The Expanded Program on Immunization (EPI), launched in 1974, which has been taken up by many countries with slight modification, includes *Bacillus Calmette-Guérin* (BCG) and oral polio vaccine at birth; diphtheria, tetanus, and pertussis at 6, 10, and 14 weeks; measles; and, where relevant, yellow fever at 9 months. Hepatitis B is added at different times in different communities. By 1998, hepatitis B vaccine had been incorporated into the national programs of 90 countries, but an estimated 70 percent of the world's hepatitis B carriers still live in

countries without programs (Nossal 1999). Indeed, among 12 million childhood deaths analyzed in 1998, almost 4 million were the result of diseases for which adequate vaccines are available (WHO 2002a).

The development of sulfonamides and penicillin in the period preceding World War II was followed by a remarkable period of progress in the discovery of antimicrobial agents effective against bacteria, fungi, viruses, protozoa, and helminths. Overall, knowledge of the pharmacological mode of action of these agents is best established for antibacterial and antiviral drugs. Antibacterial agents may affect cell wall or protein synthesis, nucleic acid formation, or critical metabolic pathways. Because viruses live and replicate in host cells, antiviral chemotherapy has presented a much greater challenge. However, particularly with the challenge posed by HIV/AIDS, a wide range of antiviral agents has been developed, most of which are nucleoside analogues, nucleoside or nonnucleoside reverse-transcriptase inhibitors, or protease inhibitors. Essentially, those agents interfere with critical self-copying or assembly functions of viruses or retroviruses. Knowledge of the modes of action of antifungal and antiparasitic agents is increasing as well.

Resistance to antimicrobial agents has been recognized since the introduction of effective antibiotics; within a few years, penicillin-resistant strains of *Staphylococcus aureus* became widespread and penicillin-susceptible strains are now very uncommon (Finch and Williams 1999). At least in part caused by the indiscriminate use of antibiotics in medical practice, animal husbandry, and agriculture, multiple-antibiotic-resistant bacteria are now widespread. Resistance to antiviral agents is also occurring with increasing frequency (Perrin and Telenti 1998), and drug resistance to malaria has gradually increased in frequency and distribution across continents (Noedl, Wongsrichanalai, and Wernsdorfer 2003). The critical issue of drug resistance to infectious agents is covered in detail in chapter 55.

In summary, although the 20th century witnessed remarkable advances in the control of communicable disease, the current position is uncertain. The emergence of new infectious agents, as evidenced by the severe acute respiratory syndrome (SARS) epidemic in 2002, is a reminder of the constant danger posed by the appearance of novel organisms; more than 30 new infective agents have been identified since 1970. Effective vaccines have not yet been developed for some of the most common infections—notably tuberculosis, malaria, and HIV—and rapidly increasing populations of organisms are resistant to antibacterial and antiviral agents. Furthermore, development of new antibiotics and effective antiviral agents with which to control such agents has declined. The indiscriminate use of antibiotics, both in the community and in the hospital populations of the industrial countries, has encouraged the emergence of resistance, a phenomenon exacerbated in some of the

developing countries by the use of single antimicrobial agents when combinations would have been less likely to produce resistant strains. Finally, public health measures have been hampered by the rapid movement of populations and by war, famine, and similar social disruptions in developing countries. In short, the war against communicable disease is far from over.

Pathogenesis, Control, and Management of Noncommunicable Disease. The second half of the 20th century also yielded major advances in understanding pathophysiology and in managing many common noncommunicable diseases. This phase of development of the medical sciences has been characterized by a remarkable increase in the acquisition of knowledge about the biochemical and physiological basis of disease, information that, combined with some remarkable developments in the pharmaceutical industry, has led to a situation in which few noncommunicable diseases exist for which there is no treatment and many, although not curable, can be controlled over long periods of time.

Many of these advances have stemmed from medical research rather than improved environmental conditions. In 1980, Beeson published an analysis of the changes that occurred in the management of important diseases between the years 1927 and 1975, based on a comparison of methods for treating these conditions in the 1st and 14th editions of a leading American medical textbook. He found that of 181 conditions for which little effective prevention or treatment had existed in 1927, at least 50 had been managed satisfactorily by 1975. Furthermore, most of these advances seem to have stemmed from the fruits of basic and clinical research directed at the understanding of disease mechanisms (Beeson 1980; Comroe and Dripps 1976).

Modern cardiology is a good example of the evolution of scientific medicine. The major technical advances leading to a better appreciation of the physiology and pathology of the heart and circulation included studies of its electrical activity by electrocardiography; the ability to catheterize both sides of the heart; the development of echocardiography; and, more recently, the development of sophisticated ways of visualizing the heart by computerized axial tomography, nuclear magnetic resonance, and isotope scanning. These valuable tools and the development of specialized units to use them have led to a much better understanding of the physiology of the failing heart and of the effects of coronary artery disease and have revolutionized the management of congenital heart disease. Those advances have been backed by the development of effective drugs for the management of heart disease, including diuretics, beta-blockers, a wide variety of antihypertensive agents, calcium-channel blockers, and anticoagulants.

By the late 1960s, surgical techniques were developed to relieve obstruction of the coronary arteries. Coronary bypass

surgery and, later, balloon angioplasty became major tools. Progress also occurred in treatment of abnormalities of cardiac rhythm, both pharmacologically and by the implantation of artificial pacemakers. More recently, the development of microelectronic circuits has made it possible to construct implantable pacemakers. Following the success of renal transplantation, cardiac transplantation and, later, heart and lung transplantation also became feasible.

Much of this work has been backed up by large-scale controlled clinical trials. These studies, for example, showed that the early use of clot-dissolving drugs together with aspirin had a major effect on reducing the likelihood of recurrences after an episode of myocardial infarction (figure 5.1). The large number of trials and observational studies of the effects of coronary bypass surgery and dilatation of the coronary arteries with balloons have given somewhat mixed results, although overall little doubt exists that, at least in some forms of coronary artery disease, surgery is able to reduce pain from angina and probably prolong life. Similar positive results have been obtained in trials that set out to evaluate the effect of the control of hypertension (Warrell and others 2003).

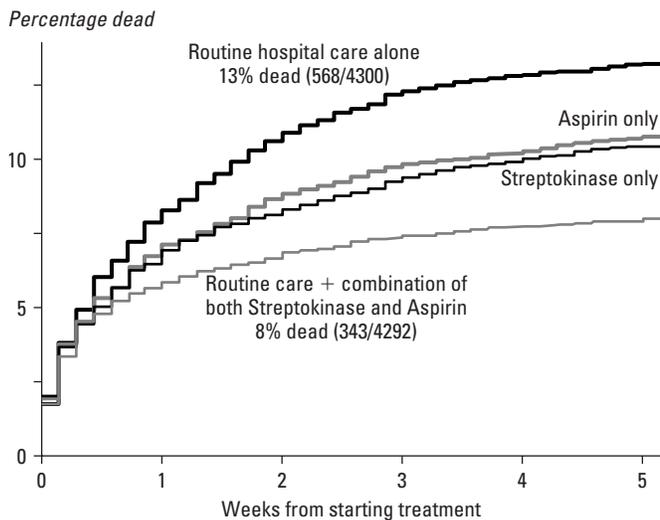

The management of other chronic diseases, notably those of the gastrointestinal tract, lung, and blood has followed along similar lines. Advances in the understanding of their pathophysiology, combined with advances in analysis at the structural and biochemical levels, have enabled many of these diseases to be managed much more effectively. The pharmaceutical industry has helped enormously by developing agents

such as the H₂-receptor antagonists and a wide range of drugs directed at bronchospasm. There have been some surprises—the discovery that peptic ulceration is almost certainly caused by a bacterial agent has transformed the management of this disease, dramatically reducing the frequency of surgical intervention. Neurology has benefited greatly from modern diagnostic tools, while psychiatry, though little has been learned about the cause of the major psychoses, has also benefited enormously from the development of drugs for the control of both schizophrenia and the depressive disorders and from the emergence of cognitive-behavior therapy and dynamic psychotherapy.

The second half of the 20th century has witnessed major progress in the diagnosis and management of cancer (reviewed by Souhami and others 2001). Again, this progress has followed from more sophisticated diagnostic technology combined with improvements in radiotherapy and the development of powerful anticancer drugs. This approach has led to remarkable improvements in the outlook for particular cancers, including childhood leukemia, some forms of lymphoma, testicular tumors, and—more recently—tumors of the breast. Progress in managing other cancers has been slower and reflects the results of more accurate staging and assessment of the extent and spread of the tumor; the management of many common cancers still remains unsatisfactory, however. Similarly, although much progress has been made toward the prevention of common cancers—cervix and breast, for example—by population screening programs, the cost-effectiveness of screening for other common cancers—prostate, for example—remains controversial.

Many aspects of maternal and child health have improved significantly. A better understanding of the physiology and disorders of pregnancy together with improved prenatal care and obstetric skills has led to a steady reduction in maternal mortality. In an industrial country, few children now die of childhood infection; the major pediatric problems are genetic and congenital disorders, which account for about 40 percent of admissions in pediatric wards, and behavioral problems (Scriver and others 1973). Until the advent of the molecular era, little progress was made toward an understanding of the cause of these conditions. It is now known that a considerable proportion of cases of mental retardation result from definable chromosomal abnormalities or monogenic diseases, although at least 30 percent of cases remain unexplained. Major improvements have occurred in the surgical management of congenital malformation, but only limited progress has been made toward the treatment of genetic disease. Although a few factors, such as parental age and folate deficiency, have been incriminated, little is known about the reasons for the occurrence of congenital abnormalities.

In summary, the development of scientific medical practice in the 20th century led to a much greater understanding

Figure 5.1 Effects of a One-hour Streptokinase Infusion Together with Aspirin for One Month on the 35-Day Mortality in the Second International Study of Infarct Survival Trial among 17,187 Patients with Acute Myocardial Infarction Who Would Not Normally Have Received Streptokinase or Aspirin, Divided at Random into Four Groups to Receive Aspirin Only, Streptokinase Only, Both, or Neither

of deranged physiology and has enabled many of the common killers in Western society to be controlled, though few to be cured. However, although epidemiological studies of these conditions have defined a number of risk factors and although a great deal is understood about the pathophysiology of established disease, a major gap remains in our knowledge about how environmental factors actually cause these diseases at the cellular and molecular levels (Weatherall 1995).

Consequences of the Demographic and Epidemiological Transitions of the 20th Century. The period of development of modern scientific medicine has been accompanied by major demographic change (Chen 1996; Feachem and others 1992). The results of increasing urbanization, war and political unrest, famine, massive population movements, and similar issues must have had a major effect on the health of communities during the 20th century, but there has been a steady fall in childhood mortality throughout the New World, Europe, the Middle East, the Indian subcontinent, and many parts of Asia during this period, although unfortunately there has been much less progress in many parts of Sub-Saharan Africa. Although much of the improvement can be ascribed to improving public health and social conditions, the advent of scientific medicine—particularly the control of many infectious diseases of childhood—seems likely to be playing an increasingly important part in this epidemiological transition. Although surveys of the health of adults in the developing world carried out in the 1980s suggested that many people between the ages of 20 and 50 were still suffering mainly from diseases of poverty, many countries have now gone through an epidemiological transition such that the global pattern of disease will change dramatically by 2020, with cardiorespiratory disease, depression, and the results of accidents replacing communicable disease as their major health problems.

Countries undergoing the epidemiological transition are increasingly caught between the two worlds of malnutrition and infectious disease on the one hand and the diseases of industrial countries, particularly cardiac disease, obesity, and diabetes, on the other. The increasing epidemic of tobacco-related diseases in developing countries exacerbates this problem. The global epidemic of obesity and type 2 diabetes is a prime example of this problem (Alberti 2001). An estimated 150 million people are affected with diabetes worldwide, and that number is expected to double by 2025. Furthermore, diabetes is associated with greatly increased risk of cardiovascular disease and hypertension; in some developing countries the rate of stroke is already four to five times that in industrial countries. These frightening figures raise the questions whether, when developing countries have gone through the epidemiological transition, they may face the same pattern of diseases that are affecting industrial countries and whether

such diseases may occur much more frequently and be more difficult to control.

Partly because of advances in scientific medicine, industrial countries have to face another large drain on health resources in the new millennium (Olshansky, Carnes, and Cassel 1990). In the United Kingdom, for example, between 1981 and 1989, the number of people ages 75 to 84 rose by 16 percent, and that of people age 85 and over by 39 percent; the current population of males age 85 or over is expected to reach nearly 0.5 million by 2026, at which time close to 1 million females will be in this age group. Those figures reflect the situation for many industrial countries, and a similar trend will occur in every country that passes through the epidemiological transition. Although data about the quality of life of the aged are limited, studies such as the 1986 General Household Survey in the United States indicate that restricted activity per year among people over the age of 65 was 43 days in men and 53 days in women; those data say little about the loneliness and isolation of old age. It is estimated that 20 percent of all people over age 80 will suffer from some degree of dementia, a loss of intellectual function sufficient to render it impossible for them to care for themselves. Scientific medicine in the 20th century has provided highly effective technology for partially correcting the diseases of aging while, at the same time, making little progress toward understanding the biological basis of the aging process. Furthermore, the problems of aging and its effect on health care have received little attention from the international public health community; these problems are not restricted to industrial countries but are becoming increasingly important in middle-income and, to a lesser extent, some low-income countries.

Although dire poverty is self-evident as one of the major causes of ill health in developing countries, this phenomenon is emphatically not confined to those populations. For example, in the United Kingdom, where health care is available to all through a government health service, a major discrepancy in morbidity and mortality exists between different social classes (Black 1980). Clearly this phenomenon is not related to the accessibility of care, and more detailed analyses indicate that it cannot be ascribed wholly to different exposure to risk factors. Undoubtedly social strain, isolation, mild depression, and lack of social support play a role. However, the reasons for these important discrepancies, which occur in every industrial country, remain unclear.

Economic Consequences of High-Technology Medicine

The current high-technology medical practice based on modern scientific medicine must steadily increase health expenditures. Regardless of the mechanisms for the provision of health care, its spiraling costs caused by ever more sophisticated technology and the ability to control most chronic illnesses, combined with greater public awareness and demand for

medical care, are resulting in a situation in which most industrial countries are finding it impossible to control the costs of providing health care services.

The U.K. National Health Service (NHS) offers an interesting example of the steady switch to high-technology hospital practice since its inception 50 years ago (Webster 1998). Over that period, the NHS's overall expenditure on health has increased fivefold, even though health expenditure in the United Kingdom absorbs a smaller proportion of gross domestic product than in many neighboring European countries. At the start of the NHS, 48,000 doctors were practicing in the United Kingdom; by 1995 there were 106,845, of whom 61,050 were in hospital practice and 34,594 in general (primary care) practice. Although the number of hospital beds halved over the first 50 years of the NHS, the throughput of the hospital service increased from 3 million to 10 million inpatients per year, over a time when the general population growth was only 19 percent. Similarly, outpatient activity doubled, and total outpatient visits grew from 26 million to 40 million. Because many industrial countries do not have the kind of primary care referral program that is traditional in the United Kingdom, this large skew toward hospital medicine seems likely to be even greater.

The same trends are clearly shown in countries such as Malaysia, which have been rapidly passing through the epidemiological transition and in which health care is provided on a mixed public-private basis. In Malaysia, hospitalization rates have steadily increased since the 1970s, reflecting that use is slowly outstripping population growth. The number of private hospitals and institutions rose phenomenally—more than 300 percent—in the same period. In 1996, the second National Health and Morbidity Survey in Malaysia showed that the median charge per day in private hospitals was 100 times higher than that in Ministry of Health hospitals. Those figures reflect, at least in part, the acquisition of expensive medical technology that in some cases has led to inefficient use of societal resources. As in many countries, the Malaysian government has now established a Health Technology Assessment Unit to provide a mechanism for evaluating the cost-effectiveness of new technology.

Those brief examples of the effect of high-technology practice against completely different backgrounds of the provision of health care reflect the emerging pattern of medical practice in the 20th century. In particular, they emphasize how the rapid developments in high-technology medical practice and the huge costs that have accrued may have dwarfed expenditure on preventive medicine, certainly in some industrial countries and others that have gone through the epidemiological transition.

A central question for medical research and health care planning is whether the reduction in exposure to risk factors that is the current top priority for the control of common diseases in both industrial and developing countries will have a major effect on this continuing rise of high-technology hospi-

tal medical practice. The potential of this approach has been discussed in detail recently (WHO 2002c). Although the claims for the benefits of reducing either single or multiple risk factors are impressive, no way exists of knowing to what extent they are attainable. Furthermore, if, as seems likely, they will reduce morbidity and mortality in middle life, what of later? The WHO report admits that it has ignored the problem of competing risks—that is, somebody saved from a stroke in 2001 is then “available” to die from other diseases in ensuing years. Solid information about the role of risk factors exists only for a limited number of noncommunicable diseases; little is known about musculoskeletal disease, the major psychoses, dementia, and many other major causes of morbidity and mortality.

The problems of health care systems and improving performance in health care delivery have been reviewed in *World Health Report 2000—Health Systems: Improving Performance* (WHO 2000). Relating different systems of health care to outcomes is extremely complex, but this report emphasizes the critical nature of research directed at health care delivery. As a response to the spiraling costs of health care, many governments are introducing repeated reforms of their health care programs without pilot studies or any other scientific indication for their likely success. This vital area of medical research has tended to be neglected in many countries over the later years of the 20th century.

Summary of Scientific Medicine in the 20th Century

The two major achievements of scientific medicine in the 20th century—the development of clinical epidemiology and the partial control of infectious disease—have made only a limited contribution to the health of developing countries. Although in part this limited effect is simply a reflection of poverty and dysfunctional health care systems, it is not the whole story. As exemplified by the fact that of 1,233 new drugs that were marketed between 1975 and 1999, only 13 were approved specifically for tropical diseases, the problem goes much deeper, reflecting neglect by industrial countries of the specific medical problems of developing countries.

For those countries that have gone through the epidemiological transition and for industrial countries, the central problem is quite different. Although the application of public health measures for the control of risk factors appears to have made a major effect on the frequency of some major killers, those gains have been balanced by an increase in the frequency of other common chronic diseases and the problems of an increasingly elderly population. At the same time, remarkable developments in scientific medicine have allowed industrial countries to develop an increasingly effective high-technology, patch-up form of medical practice. None of these countries has worked out a way to control the spiraling costs of health care, and because of their increasing aged populations, little sign exists

that things will improve. Although some of the diseases that produce this enormous burden may be at least partially preventable by the more effective control of risk factors, to what extent such control will be achievable is unclear, and for many diseases these factors have not been identified. In short, scientific medicine in the 20th century, for all its successes, has left a major gap in the understanding of the pathogenesis of disease between the action of environmental risk factors and the basic disease processes that follow from exposure to them and that produce the now well-defined deranged physiology that characterizes them.

These problems are reflected, at least in some countries, by increasing public disillusion with conventional medical practice that is rooted in the belief that if modern medicine could control infectious diseases, then it would be equally effective in managing the more chronic diseases that took their place. When this improvement did not happen—and when a mood of increasing frustration about what medicine could achieve had developed—a natural move occurred toward trying to find an alternative answer to these problems. Hence, many countries have seen a major migration toward complementary medicine.

It is against this rather uncertain background that the role of science and technology for medical care in the future has to be examined.

SCIENCE, TECHNOLOGY, AND MEDICINE IN THE FUTURE

Before considering the remarkable potential of recent developments in basic biological research for improvements in health care, we must define priorities for their application.

Priorities for Biomedical Research in the Future

In the setting of priorities for biomedical research in the future, the central objective is to restore the balance of research between industrial and developing countries so that a far greater proportion is directed at the needs of the latter. In the 1990s, it was estimated that even though 85 percent of the global burden of disability and premature mortality occurs in the developing world, less than 4 percent of global research funding was devoted to communicable, maternal, perinatal, and nutritional disorders that constitute the major burden of disease in developing countries (WHO 2002b).

The second priority is to analyze in much more detail methods of delivery of those aspects of health care that have already been shown to be both clinically effective and cost-effective. It is vital that the delivery of health care be based on well-designed, evidence-based pilot studies rather than on current fashion or political guesswork. It is essential to understand why there are such wide discrepancies in morbidity and mortality

between different socioeconomic groups in many industrial countries and to define the most effective approaches to educating the public about the whole concept of risk and what is meant by risk factors. In addition, a great deal more work is required on mechanisms for assessing overall performance of health care systems.

The third priority must be to focus research on the important diseases that the biomedical sciences have yet to control, including common communicable diseases such as malaria, AIDS, and tuberculosis; cardiovascular disease; many forms of cancer; all varieties of diabetes; musculoskeletal disease; the major psychoses; and the dementias. Of equal importance is gaining a better understanding of both the biology and pathophysiology of aging, together with trying to define its social and cultural aspects.

In the fields of child and maternal health, the requirements for research differ widely in industrial and developing countries. Industrial countries need more research into the mechanisms of congenital malformation and the better control and treatment of monogenic disease and behavioral disorders of childhood. In developing countries, both child and maternal health pose different problems, mainly relating to health education and the control of communicable disease and nutrition. In many developing countries, some of the common monogenic diseases, notably the hemoglobin disorders, also require urgent attention.

In short, our priorities for health care research come under two main heads: first, apply knowledge that we already have more effectively; second, apply a multidisciplinary attack on diseases about which we have little or no understanding. These issues are developed further in chapter 4.

New Technologies

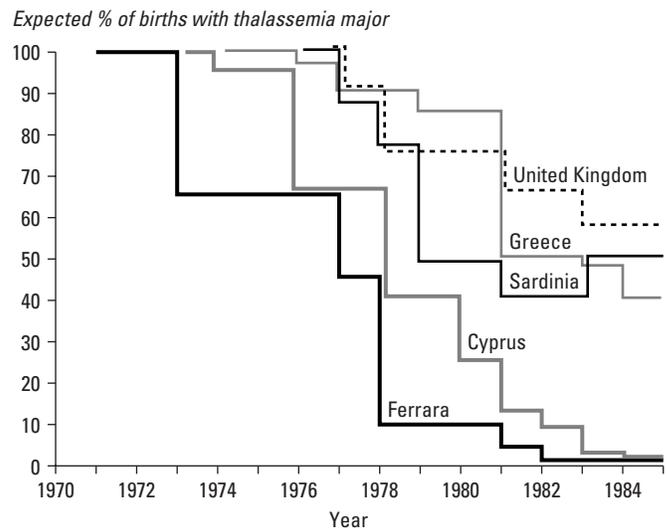

The sections that follow briefly outline some examples of the new technologies that should help achieve these aims.

Genomics, Proteomics, and Cell Biology. Without question the fields of molecular and cell biology were the major developments in the biological sciences in the second half of the 20th century. The announcement of the partial completion of the human genome project in 2001 was accompanied by claims that knowledge gained from this field would revolutionize medical practice over the next 20 years. After further reflection, some doubts have been raised about this claim, not in the least the time involved; nevertheless, considerable reason for optimism still exists. Although the majority of common diseases clearly do not result from the dysfunction of a single gene, most diseases can ultimately be defined at the biochemical level; because genes regulate an organism's biochemical pathways, their study must ultimately tell us a great deal about pathological mechanisms.

The genome project is not restricted to the human genome but encompasses many infectious agents, animals that are extremely valuable models of human disease, disease vectors, and a wide variety of plants. However, obtaining a complete nucleotide sequence is one thing; working out the regulation and function of all the genes that it contains and how they interact with each other at the level of cells and complete organisms presents a much greater challenge. The human genome, for example, will require the identification and determination of the function of the protein products of 25,000 genes (*proteomics*) and the mechanisms whereby genes are maintained in active or inactive states during development (*methyloemics*). It will also involve the exploration of the roles of the family of regulatory ribonucleic acid (RNA) molecules that have been discovered recently (Mattick 2003). All this information will have to be integrated by developments in information technology and systems biology. These tasks may take the rest of this century to carry out. In the process, however, valuable fallout from this field is likely to occur for a wide variety of medical applications. Many of these are outlined in a recent WHO report, *Genomics and World Health 2002* (WHO 2002a).

The first applications of DNA technology in clinical practice were for isolating the genes for monogenic diseases. Either by using the candidate gene approach or by using DNA markers for linkage studies, researchers have defined the genes for many monogenic diseases. This information is being used in clinical practice for carrier detection, for prenatal diagnosis, and for defining of the mechanisms of phenotypic variability. It has been particularly successful in the case of the commonest monogenic diseases, the inherited disorders of hemoglobin, which affect hundreds of thousands of children in developing countries (Weatherall and Clegg 2001a, 2001b). Through North-South collaborations, it has been possible to set up screening and prenatal diagnosis programs for these conditions in many countries, resulting in a marked decline in their frequency, particularly in Mediterranean populations (figure 5.2). Gene therapy, that is, the specific correction of monogenic diseases, has been fraught with difficulties, but these are slowly being overcome and this approach seems likely to be successful for at least some genetic diseases in the future.

From the global perspective, one of the most exciting prospects for the medical applications of DNA technology is in the field of communicable disease. Remarkable progress has been made in sequencing the genomes of bacteria, viruses, and other infective agents, and it will not be long before the genome sequence of most of the major infectious agents is available. Information obtained in this way should provide opportunities for the development of new forms of chemotherapy (Joët and others 2003) and will be a major aid to vaccine development (Letvin, Bloom, and Hoffman 2001). In the latter case, DNA technology will be combined with studies of the basic immune mechanisms involved in individual infections in an attempt to

Figure 5.2 Decline in Serious Forms of Thalassemia in Different Populations after the Initiation of Prenatal Diagnosis in 1972 Following the Development of North-South Partnerships.

find the most effective and economic approach. Recombinant DNA technology was used years ago to produce pure antigens of hepatitis B in other organisms for the development of safe vaccines. More recently, and with knowledge obtained from the various genome projects, interest has centered on the utility of DNA itself as a vaccine antigen. This interest is based on the chance observation that the direct injection of DNA into mammalian cells could induce them to manufacture—that is, to express—the protein encoded by a particular gene that had been injected. Early experiences have been disappointing, but a variety of techniques are being developed to improve the antigens of potential DNA-based vaccines.

The clinical applications of genomics for the control of communicable disease are not restricted to infective agents. Recently, the mosquito genome was sequenced, leading to the notion that it may be possible to genetically engineer disease vectors to make them unable to transmit particular organisms (Land 2003). A great deal is also being learned about genetic resistance to particular infections in human beings (Weatherall and Clegg 2002), information that will become increasingly important when potential vaccines go to trial in populations with a high frequency of genetically resistant individuals.

The other extremely important application of DNA technology for the control of communicable disease—one of particular importance to developing countries—is its increasing place in diagnostics. Rapid diagnostic methods are being developed that are based on the polymerase chain reaction (PCR) technique to identify pathogen sequences in blood or tissues. These approaches are being further refined for identifying

Box 5.1

Chronic Myeloid Leukemia: The Path from Basic Science to the Clinic

1960 An abnormal chromosome, named the *Philadelphia chromosome*, was found in the white cells of most patients with chronic myeloid leukemia (CML).

1973 By the use of specific dyes to label chromosomes, notably quinocrone fluorescence and Giemsa staining, the Philadelphia chromosome was found to be the result of a translocation between chromosomes 9 and 22: t(9:22)(q34;q11).

1983 It was found that the translocation that causes the Philadelphia chromosome juxtaposes the *c-abl* oncogene from chromosome 9 with a breakpoint cluster (*bcr*) region on chromosome 22, resulting in an abnormal *bcr/abl* gene. The product of this gene, an abnormal tyrosine kinase, has increased tyrosine kinase activity compared with the product of the normal *c-abl* gene, a major fact in causing the uncontrolled white cell proliferation characteristic of CML.

1996 A selective inhibitor of the abnormal tyrosine kinase produced by the *bcr/abl* gene product was developed that

results in a high remission rate in patients with CML and other tumors.

A major advance in the understanding of the mechanisms of malignant transformation followed the discovery that many forms of cancer result from the acquisition of mutations in cellular oncogenes—that is, normal housekeeping genes of cells that are involved in a variety of regulatory functions. In some cases, we may be born with a mutation of this kind, but the vast majority of cancers seem to be attributable to acquired mutations involving one or more oncogenes. The discovery of a drug that was able to interfere specifically with the activity of the product of an abnormal oncogene was a major advance in oncology, offering the hope that future research will make it possible to tailor-make agents directed at abnormal oncogene activity for the treatment of cancer.

Source: Bartram and others 1983; Druker and others 1996; Klein and others 1982; Nowell and Hungerford 1960; Rowley 1973.

organisms that exhibit drug resistance and also for subtyping many classes of bacteria and viruses. Although much remains to be learned about the cost-effectiveness of these approaches compared with more conventional diagnostic procedures, some promising results have already been obtained, particularly for identification of organisms that are difficult to grow or in cases that require a very early diagnosis (Harris and Tanner 2000). This type of technology is being widely applied for the identification of new organisms and is gaining a place in monitoring vaccine trials (Felger and others 2003). The remarkable speed with which a new corona virus and its different subtypes were identified as the causative agent of SARS and the way this information could be applied to tracing the putative origins of the infection are an example of the power of this technology (Ruan and others 2003).

Genomics is likely to play an increasingly important role in the control and management of cancer (Livingston and Shivdasani 2001). It is now well established that malignant transformation of cell populations usually results from acquired mutations in two main classes of genes:

- First are *oncogenes*—genes that are involved in the major regulatory processes whereby cells interact with one

another, respond to environmental signals, regulate how and when they will divide, and control the other intricate processes of cell biology (box 5.1).

- Second are *tumor suppressor genes*; loss of function by mutation may lead to a neoplastic phenotype.

In the rare familial cancers, individuals are born with one defective gene of this type, but in the vast majority of cases, cancer seems to result from the acquisition during a person's lifetime of one or more mutations of oncogenes. For example, in the case of the common colon cancers, perhaps up to six different mutations are required to produce a metastasizing tumor. The likelihood of the occurrence of these mutations is increased by the action of environmental or endogenous carcinogens.

Array technology, which examines the pattern of expression of many different genes at the same time, is already providing valuable prognostic data for cancers of the breast, blood, and lymphatic system. This technology will become an integral part of diagnostic pathology in the future, and genomic approaches to the early diagnosis of cancer and to the identification of high-risk individuals will become part of clinical practice. It is also becoming possible to interfere with the function or

products of oncogenes as a more direct approach to the treatment of cancer (box 5.1), although early experience indicates that drug resistance may be caused by mutation, as it is in more conventional forms of cancer therapy.

The genomic approach to the study of common diseases of middle life—coronary artery disease, hypertension, diabetes, and the major psychoses, for example—has been widely publicized (Collins and McKusick 2001). Except in rare cases, none of them is caused by a defective single gene; rather, they appear to be the result of multiple environmental factors combined with variation in individual susceptibility attributable to the action of several different genes. The hope is that if these susceptibility genes can be identified, an analysis of their products will lead to a better understanding of the pathology of these diseases and will offer the possibility of producing more definitive therapeutic agents. Better still, this research could provide the opportunity to focus public health measures for prevention on genetically defined subsets of populations.

Pharmacogenomics is another potential development from the genomics revolution (Bumol and Watanabe 2001) (table 5.1). Considerable individual variability exists in the metabolism of drugs; hence, clinical medicine could reach a stage at which every person's genetic profile for the metabolism of common drugs will be worked out and become part of their physicians' toolkit. This information will also be of considerable value to the pharmaceutical industry for designing more effective and safer therapeutic agents.

A word of caution is necessary: Although well-defined genetic variation is responsible for unwanted side effects of drugs, this information is still rarely used in clinical practice; a possible exception is screening for glucose-6-phosphate dehydrogenase (G6PD) deficiency for primaquine sensitivity, though the costs preclude its application in many developing countries. Furthermore, plasma levels after the administration of most common drugs follow a normal distribution, indicating that if genetic variation exists, a number of different genes must be involved. Hence, although the idea of all people having their genetic profile for handling drugs as part of their standard medical care will take a long time to achieve, if it ever happens, no doubt exists that this field will gradually impinge on medical research and clinical practice.

Many other potential applications of genomic research for medical practice wait to be developed. The role of DNA array technology for the analysis of gene expression in tumors has already been mentioned. Advances in bioengineering, with the development of biomicroelectromechanical systems, micro-level pumping, and reaction circuit systems, will revolutionize chip technology and enable routine analysis of thousands of molecules simultaneously from a single sample (Griffith and Grodzinsky 2001), with application in many other fields of research. Although somatic cell gene therapy—that is, the correction of genetic diseases by direct attack on the defective

Table 5.1 Pharmacogenomics

Gene	Drug	Clinical consequence
<i>Drug metabolism</i>		
NAT-2	Isoniazid, hydralazine, procainamide, sulfonamides	Neuropathy, lupus erythematosus
CYP2D6	Beta-blockers, antidepressants, codeine, debrisoquine, antipsychotics, many others	Arrhythmias, dyskinesia with antipsychotics, narcotic effects, changes in efficacy, many others
CYP2C9	Tolbutamide, phenytoin, nonsteroidal anti-inflammatories	Anticoagulant effects of warfarin modified
RYR-1	Halothane and other anesthetics	Malignant hyperthermia
<i>Protection against oxidants</i>		
G6PD	Primaquine, sulfonamides, acetanilide, others	Hemolytic anemia
<i>Drug targets</i>		
ACE	Captopril, enalapril	Modified response to treatment of cardiac failure, hypertension, renal disease
HERG	Quinidine	Cardiac arrhythmia (long Q-T syndrome)
HKCNE2	Clarithromycin	Drug-induced arrhythmia

Source: Modified from Evans and Relling (*Science* 286: 487 [2001], as quoted in WHO 2002a).
 Note: Table shows examples of genetic polymorphisms that cause unwanted effects of drugs or modification of response. Currently, arrays are being developed for the rapid identification of families of polymorphisms related to infection-defense genotypes, drug-metabolism genotypes, and many others. Although many polymorphisms associated with variations to drug response or toxicity have been defined, the bulk of variation of response to drugs follows a multifactorial pattern of inheritance.

The examples shown are as follows: NAT-2 = N-acetyltransferase; CYP = cytochrome P450; RYR-1 = ryanidine receptor; G6PD = Glucose-6-phosphate dehydrogenase; and ACE = angiotensin-converting enzyme. HERG and HKCNE2 are potassium channels.

gene—has gone through long periods of slow progress and many setbacks, the signs are that it will be successful for at least a limited number of monogenic diseases in the long term (Kaji and Leiden 2001). It is also likely to play a role for shorter-term objectives—in the management of coronary artery disease and some forms of cancer, for example. DNA technology has already revolutionized forensic medicine and will play an increasingly important role in this field. Although it is too early to assess to what extent the application of DNA technology to the studies of the biology of aging will produce information of clinical value, considering the massive problem of our aging populations and the contribution of the aging process to their illnesses, expanding work in this field is vital. Current work in the field of evolution using DNA technology seems a long way from clinical practice; however, it has considerable possibilities for helping us understand the lack of

adaptation of present day communities to the new environments that they have created.

Stem Cell and Organ Therapy. Stem cell therapy, or, to use its more popular if entirely inappropriate title, therapeutic cloning, is an area of research in cellular biology that is raising great expectations and bitter controversies. Transplant surgery has its limitations, and the possibility of a ready supply of cells to replace diseased tissues, even parts of the brain, is particularly exciting. Stem cells can be obtained from early embryos, from some adult and fetal tissues, and (at least theoretically) from other adult cells.

Embryonic stem cells, which retain the greatest plasticity, are present at an early stage of the developing embryo, from about the fourth to seventh day after fertilization. Although some progress has been made in persuading them to produce specific cell types, much of the potential for this field so far has come from similar studies of mouse embryonic stem cells. For example, mouse stem cells have been transplanted into mice with a similar condition to human Parkinson's disease with some therapeutic success, and they have also been used to try to restore neural function after spinal cord injuries.

Many adult tissues retain stem cell populations. Bone marrow transplantation has been applied to the treatment of a wide range of blood diseases, and human marrow clearly contains stem cells capable of differentiating into the full complement of cell types found in the blood. Preliminary evidence indicates that they can also differentiate into other cell types if given the appropriate environment; they may, for example, be a source of heart muscle or blood vessel cell populations. Although stem cells have also been found in brain, muscle, skin, and other organs in the mouse, research into characterizing similar cell populations from humans is still at a very early stage.

One of the major obstacles to stem cell therapy with cells derived from embryos or adult sources is that, unless they come from a compatible donor, they may be treated as "foreign" and rejected by a patient's immune system. Thus, much research is directed at trying to transfer cell nuclei from adult sources into an egg from which the nucleus has been removed, after which the newly created "embryo" would be used as a source of embryonic stem cells for regenerative therapy for the particular donor of the adult cells. Because this technique, called *somatic cell nuclear transfer*, follows similar lines to those that would be required for human reproductive cloning, this field has raised a number of controversies. Major ethical issues have also been raised because, to learn more about the regulation of differentiation of cells of this type, a great deal of work needs to be carried out on human embryonic stem cells.

If some of the formidable technical problems of this field can be overcome and, even more important, if society is able to come to terms with the ethical issues involved, this field holds considerable promise for correction of a number of different

intractable human diseases, particularly those involving the nervous system (Institute of Medicine 2002).

Information Technology. The explosion in information technology has important implications for all forms of biomedical research, clinical practice, and teaching. The admirable desire on the part of publicly funded groups in the genomics field to make their data available to the scientific community at large is of enormous value for the medical application of genomic research. This goal has been achieved by the trio of public databases established in Europe, the United States, and Japan (European Bioinformatics Institute, GenBank, and DNA Data Bank of Japan, respectively). The entire data set is securely held in triplicate on three continents. The continued development and expansion of accessible databases will be of inestimable value to scientists, in both industrial and developing countries.

Electronic publishing of high-quality journals and related projects and the further development of telepathology will help link scientists in industrial and developing countries. The increasing availability of telemedicine education packages will help disseminate good practices. Realizing even these few examples of the huge potential of this field will require a major drive to train and recruit young information technology scientists, particularly in developing countries, and the financial support to obtain the basic equipment required.

Minimally Invasive Diagnostics and Surgery: Changes in Hospital Practice. Given the spiraling costs of hospital care in industrial countries and the likelihood of similar problems for developing countries in the future, reviewing aspects of diagnostics and treatment that may help reduce these costs in the future is important. Changes in clinical practice in the latter half of the 20th century have already made some headway on this problem. In the U.K. NHS, the number of hospital beds occupied daily halved between 1950 and 1990 even though the throughput of the service, after allowance for change of definition, increased from 3 million to 10 million inpatients per year. Remarkably, by 1996, of 11.3 million finished consultant episodes, 22 percent were single-day cases. How can this efficient trend be continued? A major development with this potential is the application of minimally invasive and robotic surgery (Mack 2001). Advances in imaging, endoscopic technology, and instrumentation have made it possible to convert many surgical procedures from an open to an endoscopic route. These procedures are now used routinely for gall bladder surgery, treatment of adhesions, removal of fibroids, nephrectomy, and many minor pediatric urological procedures. The recent announcement of successful hip replacement surgery using an endoscopic approach offers an outstanding example of its future potential. Although progress has been slower, a number of promising approaches exist for the use of these techniques in cardiac surgery and for their augmentation by

the introduction of robotics into surgical practice. Transplant surgery will also become more efficient by advances in the development of selective immune tolerance (Niklason and Langer 2001).

These trends, and those in many other branches of medicine, will be greatly augmented by advances in biomedical imaging (Tempany and McNeil 2001). Major progress has already been made in the development of noninvasive diagnostic methods by the use of MRI, computer tomography, positron imaging tomography, and improved ultrasonography. Image-guided therapy and related noninvasive treatment methods are also showing considerable promise.

Human Development and Child and Maternal Health.

Among the future developments in molecular and cell biology, a better understanding of the mechanisms of human development and the evolution of functions of the nervous system offer some of the most exciting, if distant, prospects (Goldenberg and Jobe 2001). In the long term, this field may well have important implications for reproductive health and birth outcomes. The role of a better understanding of the monogenic causes of congenital malformation and mental retardation was mentioned earlier in this chapter. Already thoughts are turning to the possibility of the isolation and clinical use of factors that promote plasticity of brain development, and specific modulators of lung and gut development are predicted to start to play an increasing role in obstetric practice. A better understanding of the mechanisms leading to vasoconstriction and vascular damage as a cause of preeclampsia has the potential for reducing its frequency and thus for allowing better management of this common condition. Similarly, an increasing appreciation of the different genetic and metabolic pathways that are involved in spontaneous preterm births should lead to effective prevention and treatment, targeting specific components of these pathways and leading to reduction in the frequency of premature births. An increasing knowledge of the mode of action of different growth factors and promoters of gut function will enhance growth and development of preterm infants.

Neuropsychiatry. Particularly because depression and related psychiatric conditions are predicted to be a major cause of ill health by 2020 and because of the increasing problem of dementia in the elderly, neuropsychiatry will be of increasing importance in the future (Cowan and Kandel 2001). Developments in the basic biomedical sciences will play a major role in the better diagnosis and management of these disorders. Furthermore, the application of new technologies promises to lead to increasing cooperation between neurology and psychiatry, especially for the treatment of illnesses such as mental retardation and cognitive disorders associated with Alzheimer's and Parkinson's diseases that overlap the two disciplines.

The increasing application of functional imaging, together with a better understanding of biochemical function in the brain, is likely to lead to major advances in our understanding of many neuropsychiatric disorders and, hence, provide opportunities for their better management. Early experience with fetally derived dopaminergic neurons to treat parkinsonism has already proved to be successful in some patients and has raised the possibility that genetically manipulated stem cell treatment for this and other chronic neurological disorders may become a reality. Promising methods are being developed for limiting brain damage after stroke, and there is increasing optimism in the field of neuronal repair based on the identification of brain-derived neurotrophic growth factors. Similarly, a combination of molecular genetic and immunological approaches is aiding progress toward an understanding of common demyelinating diseases—notably multiple sclerosis.

Strong evidence exists for a major genetic component to the common psychotic illnesses—notably bipolar depression and schizophrenia. Total genome searches should identify some of the genes involved. Although progress has been slow, there are reasonable expectations for success. If some of these genes can be identified, they should provide targets for completely new approaches to the management of these diseases by the pharmaceutical industry. Recent successes in discovering the genes involved in such critical functions as speech indicate the extraordinary potential of this field. Similarly, lessons learned from the identification of the several genes involved in familial forms of early-onset Alzheimer's disease have provided invaluable information about some of the pathophysiological mechanisms involved, work that is having a major effect on studies directed at the pathophysiology and management of the much commoner forms of the disease that occur with increasing frequency in aged populations.

Nutrition and Genetically Modified Crops. By 2030, the world's population is likely to increase by approximately 2.5 billion people, with much of this projected growth occurring in developing countries. As a consequence, food requirements are expected to double by 2025. However, the annual rate of increase in cereal production has declined; the present yield is well below the rate of population increase. About 40 percent of potential productivity in parts of Africa and Asia and about 20 percent in the industrial world are estimated to be lost to pathogens.

Given these considerations, the genetic modification (GM) of plants has considerable potential for improving the world's food supplies and, hence, the health of its communities. The main aims of GM plant technologies are to enhance the nutritional value of crop species and to confer resistance to pathogens. GM technology has already recorded several successes in both these objectives.

Controversy surrounds the relative effectiveness of GM crops as compared with those produced by conventional means, particularly with respect to economic issues of farming in the developing world. Concerns are also expressed about the safety of GM crops, and a great deal more research is required in this field. The results of biosafety trials in Europe raise some issues about the effects of GM on biodiversity (Giles 2003).

Plant genetics also has more direct potential for the control of disease in humans. By genetically modifying plants, researchers hope it will be possible to produce molecules toxic to disease-carrying insects and to produce edible vaccines that are cheaper than conventional vaccines and that can be grown or freeze dried and shipped anywhere in the world. A promising example is the production of hepatitis B surface antigen in transgenic plants for oral immunization. Work is also well advanced for the production of other vaccines by this approach (WHO 2002a).

Social and Behavioral Sciences, Health Systems, and Health Economics. As well as the mainstream biomedical sciences, research into providing health care for the future will require a major input from the social and behavioral sciences and health economics. These issues are discussed in more detail in chapter 4.

The *World Health Report 2002* (WHO 2002c) emphasizes the major gaps in public perception of what is meant by health and, in particular, risk factors, in both industrial and developing countries. Epidemiological studies have indicated that morbidity and mortality may be delayed among populations that are socially integrated. Increasing evidence of this kind underlines the importance of psychosocial factors in the development of a more positive approach to human health, clearly a valuable new direction for research on the part of the social sciences.

Neither developing nor industrial countries have come to grips with the problems of the organization and delivery of health care. Learning more about how to build effective health delivery strategies for developing countries is vital. Similarly, the continuous reorganization of the U.K. NHS, based on short-term political motivation and rarely on carefully designed pilot studies, is a good example of the requirement for research into the optimal approaches to the provision of health care in industrial countries. Indeed, across the entire field of health provision and the education of health care professionals, an urgent requirement exists for research into both methodology and, in particular, development of more robust endpoints for its assessment.

Similar problems exist with respect to research in health economics. Many of the parameters for assessing the burden of disease and the cost-effectiveness of different parameters for the provision of health care are still extremely crude and controversial, and they require a great deal more research and

development. These problems are particularly relevant to the health problems of the developing countries.

One of the main barriers to progress in these fields is the relative isolation of the social sciences and health care economics from the mainstreams of medical research and practice. Better integration of these fields will be a major challenge for universities and national and international health care agencies.

Integration of the Medical Sciences: Organizational Priorities for the Future

From these brief examples of the likely direction of biomedical research in the future, some tentative conclusions can be drawn about its effects on the pattern of global health care.

The control of communicable disease will remain the top priority. Although this goal can be achieved in part by improving nutrition and sanitation and applying related public health measures in developing countries, the search for vaccines or better chemotherapeutic agents must also remain a high priority. However, although optimism that new vaccines will become available is well founded, many uncertainties still exist, particularly in the case of biologically complex diseases like malaria. It is vital that a balance be struck between the basic biomedical science approach and the continued application of methods to control these diseases by more conventional and well-tried methods.

For the bulk of common noncommunicable diseases, the situation is even less clear. Although much more humane, cost-effective, and clinically effective approaches to their management seem certain to be developed, mainly by high-technology and expensive procedures, the position regarding prevention and a definitive cure is much less certain. Hence, the program for reducing risk factors, as outlined in the *World Health Report 2002* (WHO 2002c), clearly should be followed. However, a strong case exists for a partnership of the public health, epidemiological, and genomic sciences to develop pilot studies to define whether focusing these programs on high-risk subsets of populations will be both cost-effective and more efficient. For those many chronic diseases for which no risk factors have been defined, strategies of the same type should be established to define potential environmental factors that may be involved. Although surprises may arise along the way, such as the discovery of the infective basis for peptic ulceration, the multilayered environmental and genetic complexity of these diseases, combined with the ill-understood effects of aging, suggests that no quick or easy answers to these problems will present themselves; future planning for global health services must take this factor into consideration.

Given these uncertainties, an important place exists for the involvement and integration of the social sciences and health economics into future planning for biomedical research. Major gaps in knowledge about public perceptions and

understanding of risk factors, a lack of information about the social and medical problems of aging populations, and widespread uncertainty about the most cost-effective and efficient ways of administering health care—both in developing countries and in those that have gone through the epidemiological transition and already have advanced health care systems—still exist.

In short, the emerging picture shows reasonable grounds for optimism that better and more definitive ways of preventing or curing communicable diseases will gradually become available; only the time frame is uncertain. Although there will be major improvements in management based on extensive and increasingly high-technology practice, the outlook for the prevention and definitive cure of the bulk of noncommunicable diseases is much less certain. Hence, it is vital that research in the basic biomedical sciences be directed at both the cause and the prevention of noncommunicable diseases, and that work in the fields of public health and epidemiology continues to be directed toward better use of what is known already about their prevention and management in a more cost-effective and efficient manner.

New Technologies and Developing Countries

The role of genomics and related high-technology research and practice in developing countries is discussed in detail in *Genomics and World Health 2002* (WHO 2002a). The central question addressed by the report was, given the current economic, social, and health care problems of developing countries, is it too early to be applying the rather limited clinical applications of genomic and related technology to their health care programs? The report concluded that it is not too early, and subsequent discussion has suggested that this decision was right. Where DNA technology has already proven cost-effective, it should be introduced as soon as possible (Weatherall 2003). Important examples include the common inherited disorders of hemoglobin (see chapter 34) and, in particular, the use of DNA diagnostics for communicable disease. The advantage of this approach is that it offers a technical base on which further applications can be built as they become available. It also provides the impetus to develop the training required, to initiate discussions on the many ethical issues that work of this type may involve, and to establish the appropriate regulatory bodies. The way this type of program should be organized—through North-South collaboration, local networking, and related structures, monitored by WHO—was clearly defined in the report.

For the full benefits of genomics to be made available to developing countries—and for these advances not to widen the gap in health care provision between North and South—the most pressing and potentially exciting developments from the new technologies of science and medicine will have to

be exploited by current scientific research in the industrial countries.

This need is particularly pressing in the case of the major communicable killers: malaria, tuberculosis, and AIDS. Similarly—and equally important—if developing countries are to make the best use of this new technology for their own particular disease problems, partnerships will have to be established between both academia and the pharmaceutical industries of the North and South.

Although this approach should be followed as a matter of urgency, that developing countries build up their own research capacity is equally important. *Genomics and World Health 2002* (WHO 2002a) includes some encouraging accounts of how this capacity is being achieved in Brazil, China, and India. The establishment of the Asian-Pacific International Molecular Biology Network is a good example.

It is important that work start now to apply the advances stemming from the basic biological sciences for the health of the developing world. This beginning will form a platform for the integration of future advances into health care programs for these countries. However, because of uncertainties of the time involved, more conventional public health approaches to medical care must not be neglected, and a balance should be struck between research in this area and research in the emerging biomedical sciences.

Economic Issues for Future Medical Research

The central economic issues regarding medical research in the future are how it is to be financed and how its benefits are to be used in the most cost-effective way in both industrial and developing countries. Currently, research is carried out in both private and public sectors (table 5.2). Work in the private sector is based mainly in the pharmaceutical industry and, increasingly, in the many large biotechnology companies that evolved rapidly following the genomic revolution. In the public sector, the major sites of research are universities, government research

Table 5.2 Estimated Global Health Research and Development Funding for 1998

Type of funding	Total (US\$ billions)	Percentage
Public funding: high-income and transition countries	34.5	47
Private funding: pharmaceutical industry	30.5	42
Private not-for-profit funding	6.0	8
Public funding: low- and middle-income countries	2.5	3
Total	73.5	100

Source: WHO 2002b.

institutes, and centers—either within the universities or freestanding—that are funded through a variety of philanthropic sources. The input of philanthropic sources varies greatly between countries. In the United Kingdom, the Wellcome Trust provides a portion of funding for clinical and basic biomedical research that approaches that of the government, and in the United States, the Howard Hughes organization also plays a major, though proportionally less important, role in supporting medical research. Similarly, the Bill & Melinda Gates Foundation and other large international philanthropic foundations are contributing a significant amount of funding for medical research. In developing countries, such research funding as is available comes from government sources. For example, Thailand and Malaysia spend US\$15.7 million and US\$6.9 million each year, representing 0.9 percent and 0.6 percent of their health budgets, respectively (WHO 2002b).

As examined in the report of the WHO Commission on Macroeconomics and Health (WHO 2001), considerable discussion is taking place about how to mobilize skills and resources of the industrial countries for the benefit of the health of the developing world. However, how this international effort should be organized or, even more important, funded is still far from clear. A number of models have been proposed, including the creation of a new global institute for health research and a global fund for health research with an independent, streamlined secretariat analogous to the Global Fund to Fight AIDS, Tuberculosis, and Malaria. Recently, a number of large donations have been given—either by governments or by philanthropic bodies—to tackle some of the major health problems of the developing world. Although many of these approaches are admirable, those that involve single donations raise the critical problem of sustainability. People with experience in developing interactions between the North and South will have no doubts about the long period of sustained work that is often required for a successful outcome.

Because of the uncertainties about sustainability and the efficiency of large international bodies, it has been suggested that a virtual global network for health research be established in which the leading research agencies of the North and South take part, together with a coordinating council (Keusch and Medlin 2003). In this scheme or in a modified form (Pang 2003), both government funding agencies and philanthropic bodies would retain their autonomy and mechanisms of funding while at the same time their individual programs would be better integrated and directed toward the problems of global health.

A central problem of both private and public patterns of funding for medical research is that industrial countries have tended to focus their research on their own diseases and have, with a few exceptions, tended to ignore the broader problems of developing countries, a trend that has resulted in the well-known 10/90 gap in which more than 90 percent of the world's

expenditure on health research is directed at diseases that, numerically, affect a relatively small proportion of the world's population. If the enormous potential of modern biomedical research is not to result in a widening of the gap in health care between North and South, this situation must be corrected. The governments of industrial countries may be able to encourage a more global view of research activity on the part of their pharmaceutical and biotechnology industries by various tax advantages and other mutually beneficial approaches. Progress in this direction seems likely to be slow, however. For this reason, moving quickly toward a virtual global network for research that would bring together the research agencies of the North and South holds many attractions. Although those of the North that rely on government and charitable funding may find it equally difficult to convince their governments that more of their budget should be spent on work in the developing world, they vitally need to move in this direction, possibly by turning at least some proportion of their overseas aid to this highly effective approach to developing North-South partnerships.

In short, to produce the funding required for medical research in the future and to ensure that it takes on a much more global view of its objectives, a complete change in attitude is called for on the part of the industrial countries. This transformation, in turn, will require a similar change of outlook on the part of those who educate doctors and medical scientists. The introduction of considerable sums of research monies into the international scene by governments or philanthropic bodies as single, large donations, while welcome, will not form the basis for the kind of sustainable research program that is required. Rather, the attitudes of both government funding agencies and charitable bodies in industrial countries will have to change, with a greater proportion of their funding being directed at diseases of the developing world in the future. Achieving this end will require a major program of education on the global problems of disease at every level, including governments, industry, universities, charitable organizations, and every other body that is involved in the medical research endeavor.

Issues requiring the assessment of the economic value of medical research are discussed in chapter 4.

Education

The central theme of the previous sections is that the potential fruits of the exciting developments in the biomedical sciences will be achieved only if a complete change in attitude occurs on the part of industrial countries, with the evolution of a much more global attitude to the problems of medical research and health care. Change will have to start in the universities of the industrial countries, which will need to incorporate a more global perspective in medical education so that the next generation of young people is more motivated to develop research

careers that take a more international view of the problems of medical research. A major change of emphasis in education will be required and will be difficult to achieve unless those who control the university education and research programs can be convinced that funding is available for further development in these new directions (Weatherall 2003). Excellent examples of the value of the development of North-South partnerships between universities and other academic institutions do already exist.

An effective approach to increasing global funding for internationally based research is through virtual global networks involving the leading research agencies in the North and South. Hence, a similar effort will be required to educate these agencies and their governments that this approach to improving the level of health globally is cost-effective. In particular, it will be vital to persuade them that this approach may constitute an effective use of their programs of aid for developing countries. Carrying out a number of pilot studies showing the economic value of North-South partnerships in specific areas of medical research may be necessary. Indeed, a number of these partnerships have already been formed in several countries and information of this type almost certainly exists (WHO 2002a).

Of course, much broader issues involving education need to be resolved for the better exploitation of medical research. The problems of educating the public so that developing countries can partake in the advancements of the genome revolution were set out in detail in *Genomics and World Health 2002* (WHO 2002a), but a great deal of work along these lines is also required for industrial countries. People are increasingly suspicious of modern biological science and of modern high-technology medicine, a factor that, together with concerns over the pastoral skills of today's doctors, is probably playing a role in driving many communities in industrial countries toward complementary medicine (see Horton 2003). These trends undoubtedly are attributable to inadequacies of medical education and the way that science is taught in schools—reflected by the lack of scientific literacy both in the general public and in governments. If trust is to be restored between the biomedical sciences and the public, significant efforts will have to be made to improve the level of scientific literacy, and a much more open dialogue will need to be developed between scientists and the community. This requirement will be increasingly important as work on basic biomedical sciences impinges on areas such as gene therapy, stem cell research, and the collection of large DNA databases to be used for both research and therapeutic purposes in the future.

The difficulties in achieving a more global view of medical research and health care on the part of industrial countries for the future should not be underestimated. Without a major attempt to solve these difficulties, the potential of modern biomedical sciences seems certain to simply widen the gap in health care between North and South.

Ethical Issues

Few advances in scientific medicine have not raised new ethical issues for society. The genomics era has encountered many problems in this respect, and although many of the initial fears and concerns have been put to rest by sensible debate and the development of effective control bodies, new problems continue to appear (WHO 2002a). The ill-named field of therapeutic cloning is still full of unresolved issues regarding human embryo research, the creation of embryos for research purposes, and other uncertainties, but these questions should not be overemphasized at a time when most societies face even more onerous ethical issues. For example, as the size of our aging population increases, many societies may have to face the extremely difficult problem of rationing medical care. The theme recurring throughout both industrial and developing countries is how to provide an adequate level of health care equally to every income group.

Many developing countries still lack the basic structure for the application of ethical practices in research and clinical care, including the development of institutional ethics committees, governmental regulatory bodies, and independent bioethical research bodies. Every country requires a completely independent bioethics council that can debate the issues uninhibited by pressures from government, commerce, or pressure groups of any kind. Our approaches to developing a more adequate ethical framework for much of medical decision making, whether it involves preventive medicine, clinical practice, or research, constitute another neglected area that requires research input from many different disciplines.

The important question of the ethical conduct of research in the developing countries by outside agencies has been reviewed in detail recently (Nuffield Council on Bioethics 2002).

Why Do We Need Research?

It is important to appreciate that considerable public suspicion exists about both the activities and the value of biomedical research. Suspicion has been generated in part by the field's exaggerated claims over recent years, an uneasy feeling that research is venturing into areas that would best be avoided, and a lack of understanding about the complexity of many of the problems that it is attempting to solve. At the same time, many government departments that run national health care programs, the private sector (with the exception of the pharmaceutical industry), and many nongovernmental organizations set aside extremely small fractions of their overall expenditure for research. For many of those organizations, research seems irrelevant as they deal with the stresses of daily provision of programs of health care and with crisis-management scenarios that have to follow rapid change or major failures in providing health care.

One of the major challenges for the biomedical research community will be to better educate the public about its activities and to restore their faith in and support for the medical research endeavor. Educating many governments and nongovernmental organizations about the critical importance of decision making based on scientifically derived evidence will be vital. Medical care will only get more complex and expensive in the future; its problems will not be solved by short-term, politically driven activity. The need for good science, ranging from studies of molecules to communities, has never been greater.

SUMMARY

Clearly, the most important priorities for medical research are development of more effective health delivery strategies for developing countries and control of the common and intractable communicable diseases. In this context, the argument has been that much of the medical research that has been carried out in industrial countries, with its focus on noncommunicable disease and its outcomes in high-technology practice, is completely irrelevant to the needs of developing countries. This view of the medical scene, however, is short term. Although some redistribution of effort is required, every country that passes through the epidemiological transition is now encountering the major killers of industrial countries. Learning more about those killers' basic causes, prevention, and management is crucial. Although the initial costs of providing the benefits of this research are often extremely high, they tend to fall as particular forms of treatment become more widely applied. Hence, because we cannot completely rely on our current preventive measures to control these diseases, medical research must continue.

Research in basic human biology and the biomedical sciences is entering the most exciting phase of its development. However, it is difficult to anticipate when the gains of this explosion in scientific knowledge will become available for the prevention and treatment of the major killers of mankind. Thus, medical research must strike a balance between the well-tried approaches of epidemiology, public health, and clinical investigation at the bedside with the application of discoveries in the completely new fields of science that have arisen from the genome revolution.

If this balanced approach toward the future provision of health care is not to continue to worsen the gap between North and South, however, a complete change of attitude is necessary toward health care research and practice on the part of the industrial countries. A major effort will be required to educate all parties—international nongovernmental organizations, governments, universities, and the private sector—in global health problems (Weatherall 2003). Equally important will be a major change of emphasis in the universities of industrial countries toward education programs in science and medicine

to provide medical scientists of the future with a more global perspective of health and disease. If this transformation can be achieved—if it can form the basis for the establishment of networks for sustainable research programs between universities and related bodies in the North and South—much progress will be made toward distributing the benefits of biomedical research and good practice among the populations of the world. However, the great potential of advances in the biomedical sciences for global health will not come to full fruition without much closer interaction between the fields of basic and clinical research and the fields of public health, health economics, and the social sciences.

Chapter 6

Product Development Priorities

Adel Mahmoud, Patricia M. Danzon, John H. Barton,
and Roy D. Mugerwa

The overall goal of this chapter is to introduce the multistep process that leads to new product development and use and to outline the economic and institutional context for products developed specifically for major global diseases. In addition, it attempts to define the major financial efforts under way to help stimulate the process. Because product development is integrally related to intellectual property issues and to regulatory and liability concerns, these topics are also included. Data on product development for the developing countries are not systematically available. We have, therefore, used information based on analyses for developed countries and, when possible, made comparisons.

INTRODUCTION

In recent decades, scientific advances in many disciplines, particularly molecular biology, genomics, and medicinal chemistry, opened the way for developing new therapeutic agents, several vaccines, and enhanced diagnostic capabilities. The central questions for the purpose of this chapter are what drives research, discovery, and development and what institutional and financing arrangements are necessary to promote research and development (R&D) for global diseases? Medical needs and public health imperatives constitute the logical answer to the first question; however, our armamentarium for combating major global diseases suffers from certain fundamental gaps. Innovation or discovery in the health fields is the process whereby the findings of many sciences are translated from basic findings into approaches to protect health (vaccines) or reverse disease (therapeutic and diagnostic products).

Even though investigators have explored the conceptual framework for understanding how knowledge may be translated into products over the years, consensus is lacking on the specific drivers of the process or on the effects of alternative institutional arrangements.

Several features of the innovation process and its environment are essential for product development (Hilleman 2000; Nederbragt 2000; Schmid and Smith 2002). Innovation advances through a sequence of steps from discovery, through process development, to animal and human testing—a sequence with many overlapping features. Discovery may come in two ways: in a nonlinear, quantum-leap fashion that results in findings of an unexpected or unpredictable nature or in a linear fashion that builds on existing knowledge. Nonlinear processes are characteristically random despite many efforts to inject varying degrees of predictability or goal definitions (Webber and Kremer 2001). By contrast, the goal of linear innovation is defined improvement of a known process or mechanism.

Discovery

Product development is fundamentally anchored to the discovery process. In modern societies, discovery represents a societal capability that involves multiple institutions and constituents. The concept of networks of innovation has been introduced to describe one of the processes of discovery that leads to the development of pharmaceutical products or vaccines (Galambos and Sewell 1995, 272). Original scientific observations are made in organizations widely distributed across society, such as academic environments, government laboratories, biotechnology companies, or the large organizations dedicated

to R&D. Because of the multiplicity of these settings and the traditions of open scientific communications, combined with the high costs of research and the importance of incentives, intellectual property issues must be taken into account.

The outcome is appreciably complex. Therefore, prescribing in a systematic way how to develop products along a planned pathway—particularly those intended for use in developing countries—is challenging. Recent decades have witnessed many attempts to develop specific drugs or vaccines to meet developing countries' needs, and the process has been difficult. Examples include pharmaceuticals to treat major global killers such as malaria and African trypanosomiasis and vaccines for most of the diarrheal diseases and respiratory infections (Nossal 2000).

Development Cycles

Discovery may set in motion a series of steps that eventually leads to the deployment of a product suitable for human use. The next step following discovery is process definition to map the steps of manufacturing and scalability to optimize the size of manufacturing. This process involves translating an idea discovered anywhere in the multiplicity of settings defined earlier, including mobilizing the energies of many sciences, to come up with a product. For instance, for a discovery in the therapeutic field to be translated into a drug, the sciences of medicinal chemistry, structural biology, and structure-function relationships are fundamental to the process. More recently, the product development process has begun using genomics and proteomics to bring about a more focused approach to defining clinical candidate products. Only then are pharmacology, toxicology, and bioavailability used in the next phase of therapeutic evaluation.

The capabilities for process definition and scalability have traditionally been concentrated in the research-based pharmaceutical industry, but several recent successful efforts in public-private partnerships (PPPs) have expanded these capabilities, such as the Medicines for Malaria Venture (MMV) and Global Alliance for TB Drug Development (GATB). Developing countries such as Brazil, India, and the Republic of Korea are now undertaking major efforts to achieve similar capabilities (Biehl 2002; Lohray 2003).

Therapeutic evaluation may begin at an *in vitro* or molecular level before proceeding to animal testing and the usual three phases of human assessment (Hilts 2003). The scientific disciplines of clinical research, epidemiology, and biostatistics have progressed at a significant pace in recent decades. In parallel, ethical and societal concerns about research involving human subjects and its standards, particularly across countries, cultures, and capabilities, are being extensively debated (Agre and Rapkin 2003; Barrett and Parker 2003; Emanuel and others 2004; McMillan and Conlon 2004).

The engineering aspects of product development are the next major step. Optimizing manufacturability and assessing

market needs to determine the level of investment required for plant construction and operation are the two fundamental components of this phase.

One important feature of discovery and development is the length of time it takes. Estimates indicate that the average time for a new chemical entity (NCE) or vaccine to proceed from discovery through preclinical testing, human clinical trials, and regulatory approval is longer than a decade (Garber, Silvestri, and Feinberg 2004; Hilleman 1996; Rappuoli, Miller, and Falkow 2002), including the time spent on unsuccessful attempts. This timeline imposes certain pressures on how decisions are made, on the investment needed, and on competing priorities.

Development Institutions

As indicated previously, innovation and discovery occur in a multiplicity of settings. Although these settings have been concentrated in developed countries and have served the process of product development well, the challenges of developing new products for the developing world are considerable. Many countries, such as Brazil, India, and Singapore, are initiating a new wave of fundamental research institutions (Ahmad 2001; Jayaramann 2003). Their involvement in the discovery of products necessary for the health needs of developing countries is a fundamental paradigm shift. Along with the developing world's emerging biotechnology industry, a movement toward product discovery and development is under way. In addition, multiple PPPs—for example, the MMV (2002) and the GATB (2001)—are adding to the total global effort (Lyles 2003; Widdus 2001). The major feature of these new settings is their ability to focus on the immediate needs of developing countries. The challenge, however, lies in sustaining their funding and ensuring their ability to proceed from discovery to development and manufacturing, possibly with appropriate partners.

Finally, the evaluation of a product's pharmacological, biological, and toxicological properties may be carried out in developed or developing countries. Indeed, the evaluation of the safety and efficacy of products intended for developing countries should occur in those settings. Although quality control standards should be applied globally (Milstien and Belgharbi 2004), specific efforts must be directed at protecting the rights of human subjects (Agre and Rapkin 2003; Barrett and Parker 2003; Emanuel and others 2004; McMillan and Conlon 2004). In general, clinical development is heavily regulated in developed countries, and additional mechanisms exist for monitoring other aspects of product development, such as animal experimentation, use of controlled substances, and so on, but the global situation varies considerably. The time is ripe to consider the development of a global coordinated effort that involves uniform standards and reciprocity.

The analysis in the following sections focuses on the costs of developing drugs, vaccines, and diagnostics. The emphasis on

drugs and vaccines reflects both the available evidence and the fact that regulatory requirements and costs are much greater for drugs and vaccines than for devices and diagnostics.

PHARMACEUTICAL PRODUCTS

The costs of developing new medicines and diagnostics reflect both the technical complexities of product development and costs related to regulatory approval, which requires clinical trials to establish product safety and efficacy. Although the relative contributions of these two components are difficult to distinguish empirically—and even conceptually—there is general consensus that increasing regulatory requirements have contributed to the rising costs of new product development in the United States. In considering the costs of new product development for diseases prevalent in low-income countries (LICs), we attempt to identify those costs that might be influenced by regulatory policy as opposed to the unavoidable costs resulting from the hard science of new product development.

R&D Costs for Drugs for Industrial Countries

The most detailed evidence on the cost of developing new drugs is from DiMasi, Hansen, and Grabowski (2003), who estimate the cost of bringing a compound to market at US\$802 million in 2000 dollars. Their estimate is based on U.S. data from 10 major companies for a randomly selected sample of 68 compounds that entered human testing between 1983 and 1994 and reached approval between 1990 and 2001. The 68 compounds include 61 small molecule chemical entities, 4 recombinant proteins, 2 monoclonal antibodies, and 1 vaccine. Together, the 10 companies accounted for 42 percent of R&D by U.S. companies. The cost estimates are based on project-level data obtained from the companies for the period 1980–99. The sample was restricted to compounds that originated within these companies to avoid omitted costs of in-licensed products.

Earlier studies using similar data and methods found significantly lower R&D costs for drugs launched in the 1970s and 1980s (DiMasi and others 1991; Hansen, 1979). For the 1980s drug cohort, the estimate was US\$359 million per NCE (U.S. Congress, Office of Technology Assessment 1993). Thus, the estimate for the 1990s drug cohort of US\$802 million represents a significant increase over and above inflation.

Three main factors contribute to this high and rising cost of R&D. Understanding the contribution of each of these factors is important to understanding whether drug R&D costs might be lower in developing countries.

First, the inputs into pharmaceutical R&D are costly, including highly trained scientists, highly specialized capital equipment, expensive animal studies, and clinical trials involving thousands of human subjects that are often coordinated across

multiple countries. Clinical trial out-of-pocket costs reflect expenditures on patients' medical treatment and monitoring, data collection, and analysis. In the study by DiMasi, Hansen, and Grobowski (2003), the average expected clinical cost, adjusted for the probability of entering each clinical phase, was US\$60.6 million per compound entering human trials. In addition, the authors estimated that the out-of-pocket costs of drug discovery and preclinical development account for 30 percent of overall R&D costs, raising the total expected out-of-pocket cost to US\$86.8 million per compound entering clinical trials. The average number of clinical trial patients per compound was 5,303, and the average cost per patient was US\$23,500 before adjusting for the probability of entering each clinical phase.

Second, in the United States, the Food and Drug Administration (FDA) approves only roughly one in five compounds that enter human clinical trials.¹ The costs incurred for the four out of five compounds that failed must be included as costs of bringing one new compound to market. Failures occur because of safety concerns, lack of significant efficacy, and poor economic prospects. Even though the new technologies of drug discovery should eventually improve predictive accuracy for both safety and efficacy, success rates were no better in the 1990s than in the 1980s (DiMasi, Hansen, and Grabowski 2003; DiMasi and others 1991). Adjusting for failure rates raises the total out-of-pocket cost from US\$86.8 million to US\$403 million per approved compound.

Third, the US\$802 million total cost estimate includes the opportunity cost of capital over the roughly 12-year investment period. Using an 11 percent real (net of inflation) cost of capital, DiMasi, Hansen, and Grabowski (2003) estimate the total cost of capital at US\$399 million. This figure represents the return that shareholders would have received had they invested in activities that yielded immediate returns rather than in the lengthy drug discovery process. If pharmaceutical R&D is financed by—and hence must compete for—private equity capital, shareholders must be compensated for this opportunity cost. Thus, the cost of capital is appropriately included as a cost of R&D if the R&D is undertaken in commercial firms and financed by equity capital. As discussed later, if not-for-profit organizations finance R&D, the opportunity cost of capital may be lower. If we assume financing by private equity, adding the US\$399 million cost of capital to the US\$403 million out-of-pocket cost yields US\$802 million as the capitalized cost at launch, before taxes, per approved compound. The after-tax estimate is considerably lower because, like any business expense, R&D expenses are tax deductible, plus R&D tax credits may be available in certain circumstances. However, for purposes of comparing the costs of R&D to the revenues a commercial firm would require to cover these costs, if costs are measured net of tax, then revenues must also be measured net of tax, in which case adjusting for tax makes little difference. Hereafter we use the before-tax R&D cost estimates to facilitate

comparison with other estimates of R&D costs. The before-tax estimates are also most relevant to not-for-profit firms and PPPs that are not subject to taxes.

If commercial firms facing a commercial cost of capital and with no in-kind contributions (see the next section) undertake R&D, they might be able to save roughly 10 to 20 percent of their costs by conducting trials in developing countries and possibly more if they adhere to the countries' regulatory requirements, which may permit fewer and shorter trials than are normal for the FDA. Whether firms could realize those potential savings may be a matter of judgment depending on perceived liability risks. If commercial firms conduct R&D for LIC diseases in not-for-profit spinoffs, they may realize tax advantages and a lower cost of capital, which would further reduce their cost below the US\$802 million estimate.

R&D Costs for Drugs for Developing Countries

Recent studies by two PPPs that focus on new product development for diseases in developing countries yield much lower cost estimates for drugs in their portfolios than those in the previous section. The GATB and the MMV estimate the costs of R&D at US\$150 million (MMV 2002) and US\$178 million (midpoint of the range of US\$115 million to US\$240 million) (GATB 2001, 101) or less than a quarter of DiMasi, Hansen, and Grabowski's (2003) estimate of US\$802 million. The reasons for these large differences are instructive.

First, the GATB and MMV estimates reflect only out-of-pocket costs, with no allowance made for the opportunity cost of capital. Nevertheless, the estimates of out-of-pocket cost are less than half of the US\$403 million out-of-pocket cost estimated by DiMasi, Hansen, and Grabowski (2003). This difference in out-of-pocket costs primarily reflects two factors: (a) fewer clinical trials and, hence, fewer patients in trials—namely, 1,368 patients per drug for the GATB compared with 5,303 in the DiMasi, Hansen, and Grabowski (2003) study—and (b) lower costs per patient of US\$1,000 to US\$3,000 for the GATB for trials run in developing countries compared with US\$23,500 per patient in the DiMasi, Hansen, and Grabowski (2003) study.

Some drugs for LICs may require fewer trials, fewer patients, or both per trial because of differences in drug types and trial objectives and different regulatory requirements. For example, some of the drugs in the two PPPs' portfolios are modifications of existing drugs for which some data have been established. R&D costs for LIC drugs may also be lower to the extent that these drugs are tested for fewer indications, with less within-sample stratification by patient subgroup and less need to test for drug interactions. Clinical effects for infectious and parasitic diseases may also be greater than for chronic diseases, which permit smaller trial sizes.² The lower trial cost per patient for LIC drugs partly reflects the lower costs of conducting trials in developing countries, with much lower costs of medical care and

personnel than in the United States. The trial duration may also be shorter because the target diseases are acute rather than chronic. To the extent that the lower out-of-pocket clinical costs in the GATB and MMV studies reflect fewer patients in trials and lower cost per patient, such savings could, in principle, apply to LIC drugs regardless of whether these drugs are developed by not-for-profit or commercial enterprises.³

Another factor contributing to the lower out-of-pocket costs reported by the MMV and the GATB is that these PPPs benefit from in-kind contributions of personnel, technologies, and other resources supplied by their industry and academic partners. The MMV estimates these in-kind contributions as equivalent to its own incurred costs. Thus, if these in-kind contributions are included, the full social cost for developing LIC drugs increases to US\$250 million to US\$300 million per compound, or only 25 to 35 percent less than the DiMasi, Hansen, and Grabowski (2003) estimate of US\$403 million. However, as long as such in-kind contributions are available without charge to PPPs, the actual budget cost to PPP funders is only US\$150 million to US\$178 million, or less than half DiMasi, Hansen, and Grabowski's (2003) estimate.⁴

The second major determinant of R&D costs is failure rates. The GATB and MMV estimates show overall drug failure rates similar to those in DiMasi, Hansen, and Grabowski's (2003) study. Indeed, there is no obvious reason to expect significant differences in failure rates if LIC drugs face similar scientific challenges and are reviewed by the FDA or the European Medicines Evaluation Agency applying the same safety, efficacy, and risk-benefit tradeoff standards as are applied to drugs for the industrial countries. However, if the regulatory review of LIC drugs uses risk-benefit tradeoffs that reflect conditions in developing countries, then success rates might be higher, implying a lower budget cost per approved compound for LIC drugs.

Finally, the third major contributor to R&D costs is the opportunity cost of capital, which accounts for US\$399 million, or almost half of DiMasi, Hansen, and Grabowski's (2003) US\$802 million cost per compound. The GATB and MMV estimates do not include the cost of capital. Whether the cost of capital should be included in estimating the cost of R&D for LIC drugs depends on the circumstances and the perspective. If LIC drugs are to be developed by commercial firms that must generate a competitive return for their shareholders, then the cost estimates appropriately include a cost of capital at roughly 11 percent, as in the DiMasi, Hansen, and Grabowski (2003) study. However, if LIC drugs are developed by PPPs or other not-for-profit institutions with financing from philanthropic or governmental agencies, the opportunity cost of capital may be lower if these funders typically do not require a rate of return on their investment to compensate them for the forgone alternative uses of the funds during the investment period. For example, government investments sometimes assume a social opportunity cost of capital of about 5 percent. Using a 5 percent cost of

capital for financing from philanthropic or governmental agencies implies a roughly 50 percent markup over out-of-pocket R&D costs to reflect the cost of capital rather than the roughly 100 percent estimated by DiMasi, Hansen, and Grabowski (2003), assuming the same time flow of investments.

Applying this markup to the US\$150 million to US\$178 million estimated out-of-pocket R&D cost for the MMV and the GATB yields a total capitalized R&D cost of roughly US\$250 million for LIC drugs if they are developed by PPPs with foundation or government funding, assuming that in-kind contributions are at current levels and that trials are conducted in developing countries. Alternatively, these funders might choose to use a zero cost of capital, reflecting the importance that they attach to developing new medicines to treat currently untreatable diseases and to replace existing drugs that are increasingly ineffective because of resistance. In that case, the appropriate capitalization cost is zero, and the out-of-pocket costs of US\$150 million to US\$178 million are the full R&D costs per new compound for LIC diseases.

Economics of Vaccine Discovery and Development

In discussions of the economics of vaccine development, comparing the findings with those obtained for pharmaceuticals is useful. Note, however, that the two product categories are different in many fundamental and practical aspects. Pharmaceuticals are used to treat an existing clinical condition with the ultimate aim of reversing the course of disease. By contrast, vaccines are used to prevent a future threat. In addition, pharmaceuticals may be administered over a prolonged time frame and, in many chronic conditions, may be taken from the time of diagnosis for the rest of the patient's life, whereas most vaccines are administered once or a few times.

The costs of vaccine production consist of the traditional components of discovery, process development, scale-up, and manufacturing, as well as the costs pertaining to regulatory requirements, liability, and postlicensing studies (Andre 2002; Grabowski 1997). Furthermore, the economic framework for disease prevention (Kou 2002) raises many questions that are less clear than calculating the cost of treatment of a specific pathological condition in an individual or setting priorities for government budgets. Finally, the financing of vaccine purchasing and immunization programs has traditionally been separated from the totality of health care financing. Although this practice may have appeared to be advantageous at some point globally or in individual countries, the current outcome is less than satisfying in that the financing of vaccines is fragmented (Institute of Medicine 2004) and competes at a less favorable level with other budgetary priorities.

Costs of Vaccine R&D

The decision to develop a new vaccine is usually based on medical need, scientific feasibility, and market conditions. Because

most currently available vaccines have been developed over relatively long periods and multiple organizations have been involved in their discovery, our cost estimates are based on historical data and on many assumptions that are probably changing rapidly (Agre and Rapkin 2003; Barrett and Parker 2003; Emanuel and others 2004; McMillan and Conlon 2004). The cost elements are similar to those for pharmaceutical R&D except for the specific regulatory procedures for vaccines, such as the completion of plant construction before phase 3 trials.

As noted earlier, estimates indicate that an NCE costs US\$403 million to US\$802 million in 2000 dollars (DiMasi, Hansen, and Grabowski 2003). Clarke (2002) estimates that a vaccine costs approximately US\$700 million by the time the product is marketed, including not only the actual costs of products, but also such items as the cost of failures and the cost of funds (Grabowski 1997). In addition, the size of phase three clinical trials has recently escalated along with costs.

The Institute of Medicine (2004) estimates that total expenditure on vaccine R&D in 1995 was US\$1.4 billion. The large pharmaceutical companies accounted for approximately 50 percent of the total (Mercer Management Consulting 1995). However, the current situation is more complex for vaccine research than for drug R&D. In 2004, only five major multinational companies were investing in vaccine R&D and production (Institute of Medicine 2004). In addition, a multitude of smaller, new biotechnology organizations in both developed and developing countries are pursuing multiple vaccine targets that are of considerable value (Nossal 2004). Since September 11, 2001, U.S. government funding for microbial threats that can be used as agents of terror has increased: Project Bioshield is devoting more than US\$5 billion during the next 10 years to discovering and producing vaccines and other therapeutics (Herrera 2004). These initiatives may have spillover benefits for vaccines and therapeutics for developing countries.

Another barrier, in addition to complexity and costs that may directly or indirectly affect investment in vaccine R&D, is the condition of the vaccine market. Even though experts anticipate healthy growth in the total global vaccine market from approximately US\$6 billion in 2004 to US\$20 billion in 2009, the number of large private pharmaceutical companies involved in vaccine research is down to five (Mercer Management Consulting 2002). As a recent Institute of Medicine report (2004) demonstrates, other significant barriers also stand in the way of a well-functioning vaccine research and production system. These barriers include the difficulties of entering the field and of financing research, plus in the United States they include the government's role in determining pricing in relation to the government's purchase of a significant proportion of vaccines. Similar situations arise in other countries. All lead to an underappreciation of the value of vaccines and reduce the incentives for investment in future vaccine products.

As noted earlier, whether the cost of R&D for drugs or vaccines intended for use in developing countries is less than for products targeted to high-income markets is questionable. Certainly, developing vaccines for LICs requires investment from both industrial and developing countries and participation by scientists from both industrial and developing countries. In the case of vaccines, discovery similar to pharmaceuticals is a costly process. Therefore, a research infrastructure has to be supported in academic institutions and private sector and government laboratories for new ideas to emerge and to be tested. The capabilities needed to discover a new HIV or malaria vaccine are different and far more complex than those used to manufacture traditional vaccines such as whole-cell pertussis. Indeed, the technological know-how needed to discover new vaccines is embedded in the advancing edge of science.

Alternative mechanisms of financing and managing the development of new vaccines for the developing world must be identified and may require governmental, international, and philanthropic funding. Appropriate new institutions or alliances could evolve from the multiple PPPs now being pursued. The case has repeatedly been made for a massive infusion of funds and global coordination if vaccines against great killer diseases such as HIV/AIDS are to be developed (Klausner and others 2003).

Effect and Cost of Vaccination Programs

The major societal and health effect of vaccines are realized mainly when immunization programs reach a significant proportion of individuals in a society (Mahmoud 2004). The effect of vaccines in interrupting or preventing the transmission of infectious agents depends on two concepts: inducing resistance in healthy individuals before exposure and extending the umbrella of prevention to the majority of the target population to achieve herd immunity (Anderson and May 1990). When deciding to mount a vaccination program, health professionals face scientific, public health, and financial considerations. The ultimate outcome is a cost structure that has to compete against well-established budgetary constraints and comparisons. The subject of the cost-effectiveness of vaccination programs has been examined at multiple levels and in many settings (Miller and Hinman 1999). The overall conclusion derived from most quantitative techniques—for example, cost-benefit analysis, cost-effectiveness analysis, and cost utility and decision analysis—indicates that vaccination was one of the most effective health measures of the 20th century (CDC 1999).

DIAGNOSTICS

Evidence-based disease control strategies are now in place for most of the major infectious diseases affecting developing countries. Implementing these strategies depends on accurate

diagnostic methods. Progress has been made in securing adequate drug supplies to treat or prevent diseases such as tuberculosis (TB), and in many instances, the most pressing need is for improved diagnostics to ensure wider and wiser use of effective therapies. Thus, an urgent need exists to develop diagnostic tests that are simple, cost-effective, and robust enough to be used in resource-constrained settings with endemic diseases.

Diagnostics Development Priorities for Developing Countries

The top priorities for developing new diagnostic methods pertain to HIV, TB, and malaria. In the field of HIV/AIDS, where the goal is to simplify the diagnosis of HIV, the need is for a noninvasive, inexpensive, and simple but highly sensitive and specific HIV test for saliva, sputum, urine, or other body secretions, as well as tests for monitoring highly active antiretroviral therapy.

In diagnosis of mycobacterium TB, the limited sensitivity of microscopy and the diagnostic challenges posed by smear-negative, extrapulmonary, and pediatric TB emphasize the need to find an alternative approach. In this context, the Gen-Probe Amplified Mycobacterium Tuberculosis Direct Test (Coll and others 2003; O'Sullivan and others 2002) and nucleic acid amplifications assays, as well as serological tests (Perkins 2000), have great potential. Diagnosing latent mycobacterium TB infection using tuberculin skin testing has major limitations, including the inability to differentiate latent TB from active TB. The QuantiFERON-TB test (Mazurek and Villarino 2003), which was approved by the FDA for detecting latent mycobacterium TB infection, and the MPB64 patch test (Perkins 2000), a mycobacterial antigen test (Nakamura and others 1998) specific to the mycobacterium TB complex, are promising and should undergo further evaluation.

For specific diagnosis of malaria, the most useful approach would be a rapid test to determine whether patients who present with fever have malaria. If this rapid test has the capability of estimating parasite density, it may help predict those at higher risk of progression to severe disease or treatment failure.

For the major noncommunicable diseases—for instance, cardiovascular diseases—portable imaging devices, such as radiographic or ultrasound machines, are becoming the new standard for diagnosis. Adaptation of these technologies to settings in developing countries is urgently needed.

Economics of Diagnostics R&D

R&D for new drugs and vaccines poses major challenges in developing countries because of financial constraints and lack of infrastructure. By contrast, both the timelines and the costs of developing diagnostics are significantly lower even though the process of developing diagnostics is in many respects similar to

the development of drugs or vaccines. Whereas the costs related to clinical trials and the opportunity cost of funds are lower, the process does have additional engineering requirements. For diseases with relatively large at-risk populations, large and small biotechnology companies have been sufficiently attracted to invest in diagnostic R&D and stand to generate adequate commercial returns even for inexpensive products. For less common diseases or diagnostic indications, industry investment has been minimal, and direct R&D investment by the Special Programme for Research and Training in Tropical Diseases (TDR) (<http://www.who.int/tdr>) and other public sector agencies or PPPs will be needed if products are to be developed.

Diagnostics activity in the TDR's Product Research and Development Unit currently focuses on two disease areas through work carried out by the TB Diagnostics Initiative (<http://www.who.int/tdr/diseases/tb/tbdi.htm>) and the Sexually Transmitted Diseases Diagnostic Initiative. This work is done in partnership with academic researchers, disease control experts, public health officials from disease-endemic countries, and industry. The TDR has recently invested substantially in its capacity to support the clinical development and registration of new diagnostics and will work closely with industry, regulatory agencies, and ministries of health in industrial countries and disease-endemic countries to improve the quality and standardization of diagnostic trials and to facilitate the implementation and appropriate use of proven technologies. As an example, the mission of the TB Diagnostics Initiative is to work

closely with interested parties to stimulate interest; identify obstacles; and facilitate the development, evaluation, approval, and appropriate use of new diagnostics for TB in LICs (<http://www.who.int/tdr/about/resources/contributions.htm>). Current activities include research on new diagnostic targets and methodologies, product development programs to facilitate commercial and noncommercial R&D, and formal laboratory and field product evaluation trials. The Sexually Transmitted Diseases Diagnostic Initiative is a 10-year-old collaborative project established in recognition of the critical need for improved diagnostic tools for common sexually transmitted diseases. Its mission is to promote the development, evaluation, and application of diagnostic tests appropriate for use in primary health care settings in developing countries, with a focus on syphilis, chlamydia, and gonorrhoea.

Cost Estimates of Diagnostics R&D

No systematic estimates of the costs of developing diagnostics are available that are comparable to the studies for pharmaceuticals. The costs of developing new diagnostics depend on the type of tool; the duration from discovery to approval; and the technicalities involved in technology acquisition, patent fees, market research, laboratory and field trials, marketing and product launch, and support costs. Table 6.1 summarizes costs related to the development of selected diagnostics for TB. Note that these are out-of-pocket costs and do not include the

Table 6.1 Costs of Developing Selected TB Diagnostics (US\$)

Item	Type of test				
			Nucleic acid amplification	Screening test	Drug susceptibility testing
Location of company	Rest of world	United States and European Union	United States and European Union	United States and European Union	United States and European Union
Market research costs	10,000	100,000	50,000	500,000	500,000
Technology acquisition and patent fees		275,000	250,000	50,000	200,000
Development of prototype		3,775,000	4,000,000	4,662,000	2,825,000
Consumables used during development		1,575,000		75,000	150,000
Scale-up and validation			600,000	200,000	200,000
Total product development costs	575,000	5,625,000	4,850,000	4,987,000	3,375,000
Total costs of clinical trials (location of study sites)	180,000 (disease-endemic countries)	1,450,000 (United States and European Union)	2,000,000 (United States and European Union)	294,000 (disease-endemic countries)	
Regulatory approval costs (agencies)	100,000 (FDA, European Union)	800,000 (United States)	454,000		
Marketing and launch support costs	80,000	1,500,000	200,000		
Product support costs for one year	50,000	1,125,000	20,000		
Total	995,000	10,600,000	7,574,000	5,781,000	3,875,000

opportunity cost of capital (<http://www.who.int/tdr/about/resources/contributions.htm>).

FINANCING AND INSTITUTIONAL ARRANGEMENTS FOR NEW PRODUCT DEVELOPMENT

Research that contributes to the discovery and development of drugs, vaccines, and diagnostics occurs in public, private, and mixed settings, each with different funding mechanisms.

Public Sector

In most high-income countries (HICs), government funding from tax revenues is generally targeted to basic research—that is, research that advances understanding of underlying disease processes but is unlikely to yield commercially viable products in the near term. The research may be done in government institutions or in academic and other not-for-profit research institutions. Governments also stimulate private sector R&D through tax credits.

Private For-Profit Sector

Applied research that targets specific products is generally undertaken by the private sector using equity financing. Firms that rely on equity financing must provide a return to their investors comparable to returns on other potential investments, hereafter referred to as a competitive return. This requirement applies for multinational pharmaceutical companies, for biotechnology firms, and for firms in developing countries, unless they receive public subsidies. Start-up firms in HICs generally rely on equity capital from venture capitalists and other private investors, whereas established firms issue shares in the broadly based public equity markets but finance most of their R&D from retained earnings on existing products. The need to provide a competitive return to shareholders means that commercial firms can invest only in products that they expect will generate sufficient revenues to cover all costs, including the costs of R&D. In practice, commercial firms have focused on products with a potential market in industrial countries because of their residents' ability to pay prices sufficient to cover costs.

Differential, or “Tiered,” Pricing. For global products—that is, products targeting diseases that occur in all countries, such as cardiovascular diseases—revenues generated in HICs and in the more affluent sectors of middle-income countries are sufficient to recoup the investment in R&D to the extent that, ideally, prices in LICs need to cover only the incremental or marginal costs of production for these countries.

Even with pricing at marginal cost, medicines may still be unaffordable for the poorest populations, particularly for drugs with high manufacturing costs, in which case additional subsidies may be necessary. However, the important conclusion is that for drugs for global diseases, the existence of a market in industrial countries attracts private sector investment in R&D; thus, differential (tiered) pricing provides a finance mechanism for developing new drugs that can achieve both dynamic efficiency (appropriate incentives for R&D) and static efficiency (appropriate incentives for use of existing products) (Danzon and Towse 2005).

By contrast, for drugs and vaccines that target diseases that occur predominantly in LICs, no HIC market exists in which to recoup the costs of R&D, and patents and differential pricing will not suffice to attract R&D for products that cannot expect to generate sufficient revenue to cover their development costs. In 2002, annual per capita spending on drugs alone in member states of the Organisation for Economic Co-operation and Development was US\$279, while developing countries typically spent less than US\$20 per capita for all health services (Sachs 2001; Troullier and others 2002). Per capita health spending on drugs by the poorest individuals, who may be the majority of patients for communicable diseases, is even lower. Thus, for products that target LIC-only diseases, even if millions of patients are in need, expected revenues are insufficient to attract private sector investment for developing new products without additional public subsidies.

For HIV/AIDS, even though the majority of the disease burden is in LICs, the markets in HICs have been sufficient to attract private sector companies to develop several drugs and to undertake considerable investment in an AIDS vaccine, albeit with little success to date. In 2001, the GATB increased the estimated size of the TB market from US\$150 million to US\$450 million per year, with the potential to grow to US\$700 million per year (GATB 2001). This amount is within the range normally considered necessary to attract private investment. However, estimated potential revenues for anti-malarials and treatments for other LIC diseases are still well below this threshold. In addition to the limited ability to pay, some developing countries still lack the health care infrastructure necessary for conducting clinical trials and for delivering medicines and vaccines effectively, which further reduces incentives for R&D investment.

Given the low potential revenues and lack of necessary infrastructure, R&D for tropical diseases and TB for the past 25 years has been far less, relative to need, than for global diseases. The number of NCEs per million disability-adjusted life years lost (a proxy for research relative to need) was 0.55 for infectious and parasitic diseases but roughly 1.25 to 1.44 for cardiovascular system diseases (Troullier and others 2002). Between 1975 and 1999, just 16 of the 1,393 NCEs registered were for tropical diseases or TB (Troullier and others 2002).⁵

Several of these products were fortuitous by-products of commercial research efforts initially intended for the oncology or veterinary market (Ridley 2003).

Multinational companies appear to be showing some signs of increasing their investment in tropical disease R&D. For example, GlaxoSmithKline, AstraZeneca, and Novartis have recently announced or established research centers devoted to tropical disease. AstraZeneca's facility in Bangalore, India, will focus on TB treatments and receive a commitment of personnel and US\$40 million in investment during 2003–8. The non-profit Novartis Institute for Tropical Diseases in Singapore is a US\$122 million joint venture between Singapore and Novartis that will focus on dengue fever and TB. GlaxoSmithKline has established a research institute for TB and malaria in Spain ("Drugs for the Poor" 2003).

Orphan Drug Acts. Orphan drug acts provide additional stimulus for private sector R&D for diseases that afflict only small populations in HICs. The U.S. Orphan Drug Act grants orphan status to drugs to treat diseases that affect 200,000 or fewer patients per year in the United States. Orphan drug status provides additional R&D tax credits and seven years of market exclusivity, during which the FDA cannot approve another drug to treat the same condition unless it uses a novel mechanism of action. Such market exclusivity enhances the orphan drug's market power, enabling the developer to charge high prices that to some extent offset the low sales volumes, thereby covering the costs of R&D. The U.S. act has stimulated a sharp increase in the number of drugs developed to treat orphan conditions since its passage. The European Union recently adopted similar legislation.

The potential for orphan status in the United States and the European Union may provide some additional stimulus for commercial firms to develop drugs and vaccines for LIC diseases, but the effects are likely to be minor for several reasons. First, after one product has acquired market exclusivity, firms have few incentives to develop other products to treat the same disease. Second, the value of orphan drug status in terms of annual revenue per patient is greatest for drugs to treat chronic diseases that require daily or weekly treatment. Potential revenues for treatments for acute diseases, for which each patient needs only a short course of treatment, are likely to be smaller. Thus, though orphan drug acts may create some additional stimulus for R&D for LIC diseases, other institutional and financing mechanisms are essential. Of these, PPPs are the most promising.

"Pull" Financing Mechanisms. Since the late 1990s, organizations such as the Bill & Melinda Gates Foundation and the Rockefeller Foundation have increased their funding commitments to fight diseases in developing countries. This new funding, including funding coordinated through the Global Fund to

Fight AIDS, Tuberculosis, and Malaria, is allocated primarily to paying for vaccinations and treatment. By paying for vaccines and drugs, such financing could provide additional revenues to suppliers of these products and, hence, stimulate R&D. However, for the financing of vaccines and therapeutics to serve as an effective pull mechanism for future R&D, such financing must be sustained and must pay originators enough that they can recoup the costs of R&D. Thus, purchasers such as the United Nations Children's Fund or the Global Fund face a tradeoff between paying the lowest possible prices so as to maximize their ability to supply existing medicines to current patients and paying somewhat higher prices so as to create incentives for future R&D.

Creating effective pull financing incentives for R&D is probably best done by means of explicit purchasing commitments for specific products. Some progress has been made in identifying the contractual and legal requirements of such commitments to enter into future contracts. The most promising candidates for initial implementation would be products or vaccines that are already in late stages of development or have been approved for industrial countries but for which additional purchasing commitments are needed to induce the investment necessary to undertake clinical trials and build the manufacturing capacity required to extend these products to LICs. Possible candidates are the pneumococcal vaccine and the rotavirus vaccine. For both these products, accelerated development and introduction plans have been created in the Global Alliance for Vaccines and Immunization to address the many practical issues surrounding the implementation of an advance purchase contract. When advance purchasing commitments have been successfully demonstrated on products in the late stages of development, extending this promising approach to products at earlier stages of development may be possible.

Public-Private Partnerships

In recent years, a growing number of initiatives involving partnerships between industry and government, nonprofit, and philanthropic organizations have been set up to stimulate tropical disease R&D. One of the oldest is the World Health Organization, World Bank, and United Nations Development Programme TDR, which has worked with industry, academia, and research institutions to spur R&D and has contributed to half the new drugs developed for neglected tropical diseases during the past 25 years (Ridley 2003; Troullier and others 2002) (see table 6.2 for examples of the program's initiatives). The TDR is a relatively small program, with contributions of US\$30 million in 2002.

Since the late 1990s, increased government and foundation funding, particularly from the Rockefeller Foundation and the Bill & Melinda Gates Foundation, has stimulated the growth of product development PPPs, giving a "push" stimulus to R&D

Table 6.2 Selected Initiatives of the TDR

Disease	Product	Partner	Status
Uncomplicated malaria	Lapdap	GlaxoSmithKline	Dossier submitted (2002)
	Lapdap, artesunate	GlaxoSmithKline	Phase 1
	Pyronaridine, artesunate	Shin Poong	Preclinical trials
Severe malaria	Intramuscular artemether	Artecef	Registered (2000)
	Rectal artesunate	Under discussion	FDA approval letter received
Visceral leishmaniasis	Miltefosine	Zentaris	Registered (2002)
	Paromomycin	Institute for OneWorld Health	Phase 3 studies
Sleeping sickness	Intravenous eflornithine	Aventis	Registered (2001)
River blindness	Ivermectin	Merck	Registered (1989)

(Varmus and others 2004). According to the Initiative on Public-Private Partnerships for Health, about 20 PPPs were involved in product development as of 2004. Although a few focus on a specific project, most adopt a portfolio approach with multiple candidates. The latter include five targeting HIV/AIDS vaccines or microbicides; three working with malaria therapeutics or vaccines; three investigating TB therapeutics, vaccines, or diagnostics; and at least six targeting drugs for other neglected diseases (Widdus 2004).

The PPPs are heterogeneous in terms of their objectives, structure, and financing. In general, their goal is to develop products for use in developing countries with a public health rather than a commercial goal. Their sources for promising compounds include modifications of existing compounds; continued development of compounds previously abandoned because of a lack of commercial potential; and totally new initiatives coming out of academia, industry, or government laboratories. If a PPP acquires a product from another firm, the other firm typically retains patent rights in HICs and middle-income countries, and the PPP commits to noncommercial pricing in developing countries.

PPPs draw on financing from foundations and, to a lesser extent, from governments. They work closely with private industry, including large pharmaceutical and biotechnology firms, obtaining a range of in-kind contributions, including promising compounds; useful technologies; patent rights; and expertise and advice on discovery, clinical trials, manufacturing, market estimation, regulatory requirements, and so on. They operate largely as “virtual” firms, usually contracting out actual operations to other firms or to contract research or service organizations. As compounds move into human trials, PPPs must also liaise closely with disease-endemic countries regarding clinical trials, regulatory requirements, and product delivery. Thus, they face significant scientific, managerial, financing, and operational challenges.

Table 6.3 lists the leading product development PPPs and their committed funding as of early 2004. Several have received

grants of US\$50 million or less, with significantly larger amounts for the International AIDS Vaccine Initiative and the Malaria Vaccine Initiative. Several of the organizations rely heavily on the Bill & Melinda Gates Foundation and the Rockefeller Foundation for both their initial and continued funding (Widdus 2004). Note that the dollar funding amounts shown exclude in-kind contributions from industry and other sources, whose worth is difficult to calculate because the value to the PPPs is presumably greater than the cost to the donor.

Table 6.4 shows the product development PPPs’ portfolios of products as of early 2004. The percentage of products still in preclinical development is higher for vaccines than for drugs, which may reflect the scientific challenges of developing vaccines for LIC diseases. In general, comparing funding amounts with the number of products in development across PPPs is inappropriate as an indicator of performance because the different PPPs target different problems and have received varying in-kind contributions. Also, some products are modest extensions of existing therapies, whereas others are more innovative and, hence, more risky approaches.

As table 6.3 shows, aggregate committed funding for the product development PPPs as of early 2004 was US\$1.2 billion, excluding in-kind contributions. A comparison of these funding amounts to the costs per NCE suggests that current rates of investment will produce some progress, but not rapid advances. Assuming optimistically that future funding for PPPs will be US\$300 million per year, that private industry will invest similar amount, and that other sources will provide US\$100 million a year (all of which are probably generous estimates) would imply total investment of US\$700 million per year. If this level of investment were sustained over time, it might result in two or three NCEs per year, using the conservative cost estimates of US\$200 million to US\$300 million per NCE. This development level would be significant progress, although it still leaves a large shortfall, given the number of diseases for which no good treatment or vaccine is available and the threat of resistance developing to existing treatments. It is

Table 6.3 Selected Endeavors by Product Development PPPs, 2004

Disease	Number of people killed annually by the disease	Number of new cases per year	PPP	Focus	Committed funds raised to date (US\$ millions)

a. The Drugs for Neglected Diseases Initiative has two malaria drugs in phase 3 that are partly financed by the European Union.

b. The GATB anticipates a portfolio of three phase 1 trials and expects its current phase 2 trial will enter phase 3 before 2007. Its portfolio also includes platform-related investments.

c. The South African AIDS Vaccine Initiative does not yet have any of its own products at phase 1 but is collaborating on two projects that are at this stage.

also far short of the Commission on Macroeconomics and Health's target for 2006 of US\$3 billion in R&D spending for diseases in developing countries (Sachs 2001).

Industry in Developing Countries

Pharmaceutical firms in developing countries have traditionally focused on the generic sector, making use of their expertise in engineering and other skills needed for efficient drug manufacturing. More recently, the adoption of product patents has created incentives for LIC firms to invest in R&D. For example, India adopted product patents as of 2005, and several leading generic firms are already developing new products. However, assuming that these firms will focus their efforts on developing drugs for tropical diseases would be a mistake. As for-profit firms, they face similar incentives to those of commercial firms in any country, which means focusing on the global diseases that offer the greatest expected net revenues rather than diseases specific to LICs. Nonetheless, several policies might help target R&D efforts in these countries toward tropical diseases. These policies include collaboration with the product development PPPs, provision of special government funding or tax credits for products that target LIC diseases, and provision of subsidies targeting the development and scientific testing of products derived from local products and other traditional medicines.

Other Proposed Mechanisms for Increasing Affordability

In evaluating other proposals for making drugs or vaccines available in developing countries, distinguishing proposals to stimulate new product development from proposals to increase the affordability of existing drugs is critical. One proposal pertaining to affordability is that multinational companies should voluntarily license production rights to LIC producers. Experience with generic markets across countries indicates that necessary conditions for such out-licensing to reduce prices to consumers are (a) the existence of competition between multiple licensees, (b) the licensees having lower production costs than the originator firms, and (c) a mechanism that prevents middlemen and retailers from capturing any potential savings. In practice, these conditions may not be met. The more probable scenario of licensing to only one local generic manufacturer is unlikely to reduce prices to consumers.

Another proposal is that governments should purchase patent rights, paying the originator firm the estimated value of the drug (net of production costs) and then selling the product to consumers at the marginal cost of production. This proposal has several disadvantages. First, because the government would presumably have to raise taxes to pay for the patents, the tax-induced efficiency loss could offset any efficiency gain in the pharmaceutical market, so the net effect on efficiency is

unclear. Second, the presumption that patents result in suboptimal drug consumption because of monopoly pricing ignores the widespread prevalence of insurance in HICs and middle-income countries, so that, in practice, consumers face out-of-pocket prices that are already close to marginal cost. Third, and most important, is the difficulty of estimating the value of a product before its use in the market, because both positive features (additional uses) and negative features (side effects) may be discovered. In addition, distortions in the amounts paid for patent rights would distort incentives for R&D. Moreover, the proposal would reduce originator firms' incentives to invest in postlaunch improvements.

INTELLECTUAL PROPERTY

The issue of intellectual property is involved in the debate about the perceived conflict between patents and access.

The Role of Patents in Drug Development

Under a patent system, an inventor is entitled to a limited monopoly for a period of time, typically 20 years. This exclusivity may permit high prices and, consequently, an increased economic return that serves as an incentive to develop new products. The system has worked quite effectively in the pharmaceutical area, where the incentives deriving from exclusivity have resulted in important new drugs. The first generation of patients pays a higher price than subsequent generations, which provides compensation for the large research costs involved in developing a new drug. When the patent expires, the price normally falls as generic competitors enter the market.

Even though this approach has been extremely successful in the developed world, it does not generally work for products for which the main market is limited to the developing world. The total magnitude of the market in the developing world for products for HIV, malaria, TB, or less widespread diseases is likely to be too small to provide an adequate incentive for the private sector. This fact, together with the fact that patents are likely to result in higher prices, has raised important concerns in the developing world.

The Drug Access Debate

The Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) entered into force on January 1, 1995.⁶ This agreement requires the members of the World Trade Organization (WTO), which include nearly all major trading nations, to live up to defined standards of intellectual property protection. TRIPS was part of a much broader international trade package negotiated during the Uruguay Round, one of a series of international trade negotiations that have

taken place since World War II. The United States and European nations, which were the strong proponents of TRIPS, were responding to pressure from their pharmaceutical, copy-right content, and trademark-based industries.

The pharmaceutical industry's concern was that a number of developing nations had made deliberate decisions to deny patent protection to pharmaceutical products and to grant protection only to processes for producing pharmaceuticals. These nations believed that inexpensive access to pharmaceutical products was so important that these products should not be patented. In its 1970 patent law, for example, India excluded pharmaceuticals from product patent protection, effectively choosing to provide low-cost pharmaceuticals for its people at the expense of eliminating incentives to create new products. This law was one of the reasons the Indian generic pharmaceutical industry was able to evolve to make and market copies of drugs that were still on patent in wealthier nations. Another concern for the pharmaceutical industry arose from the compulsory license process, a legal process available in some nations to authorize the use of a patented technology under some circumstances even over the patent holder's objection. In practice, compulsory licenses are rarely granted but are instead used as a threat to negotiate lower prices for the technology or pharmaceutical involved.

The United States was determined to change these laws and in TRIPS achieved important requirements for expanding patent protection. The most important TRIPS provision relevant to pharmaceuticals is article 27, which includes a requirement that "patents shall be available for any inventions, whether products or processes, in all fields of technology." (U.K. Commission on Intellectual Property Rights 2002). The clear intent of this language was to prohibit exclusions of pharmaceutical products as in the Indian law. Article 31 established careful procedural limitations on when a nation could grant a compulsory license. As part of the political compromise, transitional provisions gave developing nations extra time to comply with the treaty's requirements and also set up arrangements for the remaining parts of patent terms to be made available for products developed during the transition period. Because of these transitional provisions, developing nations were not generally required to provide product patents on pharmaceuticals until January 1, 2005 (a date that has since been extended to 2016 for the least developed countries).

During the years following the entry into force of TRIPS, a substantial and bitter debate over access to pharmaceutical products in developing countries focused largely on access to antiretroviral agents for HIV patients in Sub-Saharan Africa. A group of nongovernmental organizations argued that patents on these drugs in the developing world raise the prices of the products necessary to help such patients survive. The research-based pharmaceutical industry countered that many of the relevant products are not covered by patents in the nations

involved and that the problem is not patents but the inadequacy of the countries' medical infrastructure.

An area of convergence has begun to emerge in relation to differential pricing: prices should be lower in developing nations than in developed nations, permitting pharmaceutical firms to recover their research expenditures in the developed world while making products available at near marginal production cost to the poor in the developing world. This differential pricing is justified because potential sales in poor nations are so small that the market provides only a minimal incentive: total sales in the poorest nations account for only about 1 percent of global pharmaceutical sales. The research-based pharmaceutical industry would prefer to achieve this differential pricing by means of a donation program or simply by charging different prices. Critics would prefer that the patent monopoly not be available to raise prices in the developing world, thereby opening up markets to local generic producers.

Movement toward agreement on differential pricing was reflected in the Doha Declaration on TRIPS agreement and public health, reached at a November 2001 WTO meeting of trade ministers. This declaration affirmed that TRIPS "should be interpreted and implemented in a manner supportive of WTO members' right to protect public health and, in particular, to promote access to medicines for all" (TRIPS, paragraph 4, 2001). It affirmed the right of nations to use the exceptions to TRIPS to address public health concerns, specifically stating that "public health crises, including those related to HIV/AIDS, tuberculosis, malaria and other epidemics, can represent a national emergency" and, thus, facilitate the right to use compulsory licensing (WTO 2003).

The Doha Declaration left an issue unresolved: the manufacture of drugs under compulsory license for nations that do not have the capability to manufacture the drugs themselves. The problem arises from the compulsory licensing article of TRIPS, which contains a provision, article 31(f), requiring that the manufacture of products under compulsory license be predominantly for the domestic market. Thus, a small Sub-Saharan African nation clearly has the right to grant a compulsory license but may have no local industry able to manufacture the product. If it asks a foreign firm to manufacture the product, that firm would be manufacturing the product primarily for export, a violation of TRIPS.

The Doha negotiators did not find a way to resolve this problem, and article 6 of the Doha Declaration called for members of the TRIPS Council (a group of national representatives) to find a solution by the end of 2002. By that time, all member countries except the United States had agreed to a procedure for waiving article 31(f). The new agreement covered products needed to address public health problems recognized in the Doha Declaration, but the United States feared that it would be expanded to a variety of other products and was unwilling to accept it. Finally, a compromise was reached in August 2003.

The United States accepted the 2002 document, provided that the General Council chairperson of the WTO made an appropriate parallel statement. The chair made the statement, which included language that the agreement would be used “in good faith to protect public health” and not be “an instrument to pursue industrial or commercial policy objectives,” and recognized the need to respond to the industry’s concern that products produced under this agreement would not be exported to major developed world markets (WTO 2003; see also UNAIDS 2003).

This agreement represents a step forward for access and will certainly place pressure on the research-based pharmaceutical industry to provide products in the developing world at low prices. It leaves several important problems only partly resolved, however. One is the need to prevent importation of the low-priced products into the developed world. Such imports would cut into the patent-protected market and affect incentives to develop new products. A second is political backlash. When the general public becomes aware that a product is available to the poor in a developing nation at a price far below that which patients in developed nations must pay, the political backlash for the pharmaceutical industry in the developed world may be severe.

Most important, resolving the legal problem of article 31(f) does not resolve the economic problem. It confirms that there will be no patent incentive for the development of drugs for diseases endemic to the developing nations and that public funds will be needed for this purpose. Such funds are currently inadequate.

The Research Tool Issue

Another important problem arises from the changing nature of medical research and of patenting practice. This is the research tool problem: many of the basic tools used in medical research are now themselves patented. For example, the research use of certain genetically modified mice is patented in the United States, as are the uses of many gene sequences and protein crystal coordinates. In the case of the malaria antigen merozoite surface protein 1, some 39 patent families cover various aspects of the protein (U.K. Commission on Intellectual Property Rights 2002).

Such patents can significantly complicate research and make it more expensive. Each one that might affect a particular research program requires legal analysis to determine whether it is valid and actually applies to the planned research program. If relevant, a license must be sought or the research program must be redesigned. The more patents are involved, the greater the likelihood that a patent holder will refuse to grant a license or will demand an exorbitant sum. Even though Walsh, Arora, and Cohen’s (2003) study finds no cases of research programs being canceled midstream because of this problem, it finds

many cases of efforts to avoid the problem by, for example, modifying the research; conducting the research offshore in locations where the relevant patents are not in force; or, in some cases, simply ignoring the patent.

REGULATORY AND LIABILITY ISSUES

Developing and registering new products are generally lengthy and complicated processes (Abraham and Reed 2002; Baylor and McVittie 2003; FDA 2004) that are regulated both at the national level and, in some circumstances, at the international level. The role of the regulatory system extends beyond the launch of a new product to manufacturing and compliance standards and to postmarketing surveillance for clinical effects and potential untoward outcomes. For products that are intended to be deployed in global markets, manufacturers have to comply with regulatory requirements in the country of origin as well as the requirements of each country where the product may be marketed. One exception is the mutual recognition systems used currently by European Union countries (Pignatti, Boone, and Moulon 2004). The situation may be different for products intended for use only in developing countries; however, for legal and liability reasons, manufacturers in developed countries have refrained from working with two different sets of regulatory requirements.

The best example for illustrating this process is the FDA (2004). Over the years, FDA regulations have developed into a clear pathway. The process is initiated through an application by the manufacturer and a step-by-step approach toward licensing. The agency gets involved in every phase of the development process and approves in advance the experimental design, assays, and endpoints for clinical trials. After it has collected all the information, the agency examines the materials submitted and reaches a decision. The FDA process extends through regulating and approving marketing materials and postlicensing collection of efficacy data and information about possible side effects.

The FDA approval process differs somewhat for pharmaceutical products and vaccines. One of the main differences is the obligation of vaccine manufacturers to prepare materials for use in phase 3 trials in the final and approved production facility. This requirement means that the firm must invest in completing the manufacturing plant well ahead of launching a specific product, a process that can take three to six years. The regulatory process for vaccines also dictates batch release for every batch ready for deployment in the marketplace. This part of the regulatory process, although it ensures quality control, adds to costs and to the timeline.

In 1996, the European Union adopted a centralized procedure for applications and approvals through the European Medicines Evaluation Agency and through a mutual

recognition process (Pignatti, Boone, and Moulon 2004). In many ways, the procedure parallels the FDA process, with several differences reflecting the fact that the European Union consists of many countries, each with a country-based process that remains as an alternative or an addition to the communitywide process. The International Conference on Harmonization of Technical Requirements for Regulation of Pharmaceuticals for Human Use was established to achieve coordination of the process of drug development between industry, Japan, the United States, and the European Union (Abraham and Reed 2002; Ohno 2002). The conference's activities have improved understanding of the regulatory process and reduced duplication.

In contrast, the absence of a unified or harmonized approach to product registration and approval at the global level adds multiple layers of complexity. National systems consist of complex processes with differing thresholds and interpretations and with changing requirements in addition to differing Global Manufacturing Program standards and enforcement. A number of recent attempts have been made to resolve the issue. First among these is the World Health Organization's effort to expand its prequalification system, to develop technical standards earlier in the approval process, and to expand the availability of reference reagents for international calibration (Milstien and Belgharbi 2004). These efforts aim at injecting a higher level of quality control and transparency into the global regulatory system. The effort may have the potential to provide a global process that transcends national borders. Such a process should provide a simplified, systematic, and disciplined system that would reduce costs and speed up market access for new products.

The issue of liability in relation to harm to individuals receiving pharmaceutical products has been extremely significant in U.S. product development. It is entirely appropriate for those developing new products to be sued if they are negligent in their research or product development, but in some cases pharmaceutical firms have been sued for side effects of drugs that may have been unforeseeable or may not even have been the result of the product. This type of liability can be a barrier to product development. Although perhaps a less serious concern since the 1993 *Daubert v. Merrell Dow Pharmaceuticals* lawsuit in the United States, a case that has been interpreted to restrict the presentation to juries of evidence determined not to be "scientific," the issue is still significant. It may also be part of the reason the U.S. vaccine industry has shrunk significantly, and it has certainly affected the direction of investment, pushing it away, for example, from products such as vaccines that are used in one or a few doses in healthy people toward products used repetitively by those who already have a chronic disease (Institute of Medicine 2004). It, thus, provides pressure directly contrary to public health priorities, which emphasize prevention and, therefore, the use of vaccines.

Whether or how this trend in the United States will affect the developing world is unclear. Europe has moved toward a liability system somewhat similar to that of the United States, but many developing nations may not have such a tort liability system. Even if they do not have such a system, groups participating in pharmaceutical development might be sued in the United States for harm occurring in the developing world. Doctrines exist that restrict such suits, but firms may fear that these doctrines are insufficiently effective. Hence, recognizing the potential costs of protecting against liability and, at the same time, ensuring that products are designed and manufactured to the highest standards will be important.

NOTES

1. The phase transition probabilities in DiMasi, Hansen, and Grabowski (2003) and the overall success probability of 0.215, conditional on entering human trials, are estimated from a larger sample of 538 investigational compounds first tested in humans between 1983 and 1994.

2. The size of trial required to estimate statistical significance depends on the magnitude of the drug effect; the extent of stratification within the total sample by patient age, condition, and so on; the required statistical confidence; and other factors.

3. DiMasi, Hansen, and Grabowski's (2003) data for average cost and average number of patients are based on actual, retrospective cost data, whereas the GATB estimates are prospective estimates (best guesses) based on prior clinical trials for tuberculosis drugs in the United States and a survey of clinical trial experts to determine administrative and data management costs.

4. The MMV estimate of in-kind contributions does not include the value of basic research conducted by universities and foundations from which it obtains its lead compounds. Similarly, commercial firms also benefit from such basic research and it is omitted from the DiMasi, Hansen, and Grabowski (2003) estimates, so comparisons are not necessarily biased by this exclusion.

5. Tropical diseases include parasitic diseases (malaria, African trypanosomiasis, Chagas disease, schistosomiasis, leishmaniasis, lymphatic filariasis, onchocerciasis, and intestinal nematode infections); leprosy; dengue fever; Japanese encephalitis; trachoma; and infectious diarrheal diseases.

Chapter 7

Economic Approaches to Valuing Global Health Research

David Meltzer

Health research has contributed tremendously to advancing health and welfare throughout the world. Gains in health have already been attained, and health research continues to have great potential to contribute to the well-being of persons in both low-income and high-income countries. The “10/90” reports of the Global Forum on Health Research (GFHR) have helped highlight that, although the burden of disease attributable to morbidity and mortality is greatest in developing countries, most health research has focused on the needs of developed countries and relatively little on the needs of lower-income countries (GFHR 2003). Despite the relative dearth of health research focused specifically on their most important health problems, lower-income countries have also benefited from health research, often as much from research originally motivated to serve high-income countries as from research specifically designed to address the needs of low-income countries.

In the future, health research aimed primarily at addressing the needs of affluent countries is likely to continue to produce benefits for lower-income countries, even in the absence of efforts to manage scientific research in the interest of lower-income nations. Indeed, as lower-income countries increase in income, their health problems will likely come to resemble more closely the health problems of higher-income countries. However, “trickle-down” approaches are not an efficient way of producing knowledge to advance the health and well-being of the populations of lower-income nations. Instead, a rational approach is needed that appreciates both the value of health in lower-income nations and the potential for rational scientific management to efficiently allocate resources for scientific research. The work of the GFHR and other organizations in this regard is an important step in this direction. Moreover,

recent advances in understanding about the value of improvements in health and in approaches to the value and priorities of health research provide powerful theoretical tools to address these issues.

Although the application of these principles is still in its infancy, these tools provide a valuable framework for determining the value of health research relevant to low-income countries and for maximizing the value of research that aims to promote health in those countries. In the following section, recent innovations in determining the value of health research at an aggregate level are reviewed. The conclusion is that the value of health research has been immense and is likely to increase dramatically in coming years, especially in lower-income countries. In deriving these conclusions, not only health-oriented measures of improved health, such as life years, disability-adjusted life years (DALYs), or quality-adjusted life years (QALYs), were considered, but also how increases in income may increase the value of such improvements. In a later section, recent methods that can be used to estimate the value of specific research projects are reviewed. The application of such methods promises to better identify the value of health research in specific instances, which can enhance the case for research spending to improve health in developing countries and can increase the efficiency with which available research funds are spent.

THE VALUE OF HEALTH RESEARCH

Health research can be valuable for a variety of reasons. The most obvious reason is simply the value that people place on improvements in health. Those health improvements may be

reflected in increased length of life or quality of life. Other reasons that health research can be valuable include the improvements in productivity, decreases in medical care costs, and greater ability to plan for and invest in the future when health improves. Health research can also sometimes decrease costs independent of any effects on health—for example, when a lower-cost treatment can replace a higher-cost treatment of similar efficacy.

A large body of work has attempted to assess and quantify the economic value of health from these perspectives. The goal of some of this literature is a comprehensive assessment of the cost of illness (for example, Rice 1994). Such comprehensive assessments are often attempted in order to assess the cost-effectiveness of medical or public health interventions, which are frequently measured in terms of quality-adjusted life expectancy (Gold and others 1996) or DALYs (WHO 1994; World Bank 1993). Other aspects of this literature focus on single dimensions of the economic value of health. For example, Ram and Schultz (1979) performed an early analysis showing the effects of malaria eradication on productivity. Similarly, Meltzer (1992) attempted to identify the effects of mortality on investment in education, the demographic transition, and the onset of sustained economic growth. In that work, it was suggested that health can increase income because increasing life expectancy raises returns to investment in education, in turn encouraging decreases in family size and further increases in investment in the education of children and a transition to sustained human capital-based economic growth. These and other mechanisms, including shifts in the ratio of productive adults to dependents and changes in savings rates with increasing life expectancy, have been suggested to produce positive effects of health on per capita income in both the short and the long run (Bloom, Canning, and Jamison 2004).

Although some evidence suggests the importance of all these effects, recent work on the value of health in developed countries has focused primarily on the value that people place on improvements in their health. Such studies for the United States have suggested that increases in longevity over the past several decades are valued in the tens of trillions of dollars, indeed, contributing about as much to increasing welfare over the period as increases in per capita income. Subsequently, similar findings have been reported for other countries, and cross-national studies have found that the value of growth in life expectancy compared with the value of income growth has been even greater for low-income countries (Becker, Philipson, and Soares 2003). These studies have been influential in developing a broad consensus that the returns to health research are large and in producing dramatic increases in the budget for the National Institutes of Health (NIH) in the United States. The conclusions of these studies in the United States have been based on assessments of both the high value of health and the role that health research has played in improvements in health.

Although both the connection of health research to health and the valuation of health differ in important ways between lower-income and higher-income countries, these studies provide a useful framework for understanding the past and likely future value of health research in lower-income countries.

The Value of Improved Health

Several authors have contributed to the literature on the value of improvements in health: Becker, Philipson, and Soares (2003); Cutler and others (1997); Murphy and Topel (2003); and Nordhaus (2003). Although these studies differ somewhat in the analytic framework they use, the basic form of their analyses is quite similar. In essence, they all use estimates of the value of longevity on the basis of revealed preference techniques and multiply these values by the increases in longevity that have been observed to determine the value of improvements in health. Revealed preference estimates of the value of life are most commonly derived by assessing the wage premium required by workers to accept riskier jobs. This idea dates back at least to the work of Adam Smith, but the modern treatment of this issue stems primarily from the work of Thaler and Rosen (1975). For example, if the lifetime earnings of a risky mining job that has a 1/1,000 increased risk of death compared with another mining job is US\$1,000, then the statistical value of a life would be said to be US\$1,000,000, since paying 1,000 workers would result in one extra death on average and require that the employer pay wages equal to 1,000 workers \times US\$1,000/worker = US\$1,000,000.

A simple example considering the value of increases in life expectancy in the United States from 1970 to 2000 illustrates well how these sorts of estimates have been used to estimate the value of increased longevity. From 1970 to 2000, life expectancy at birth for Americans grew by a little more than 5 years, from about 75 years to about 80 years. With about 300 million Americans living during this period, this increase constitutes about 1.5 billion life years. Using a conservative revealed preference estimate of about US\$4 million as the statistical value of a life (Viscusi and Aldy 2003), assuming a life expectancy of 75 to 80 years, and assuming discounting is somewhere between 0 and 3 percent annually, one gets a value of about US\$50,000 to US\$100,000 per life year saved. Multiplying this gain in life years and the estimate of the value of a life year, one gets a value of increased longevity over this period of about US\$75 trillion to US\$150 trillion, or about US\$2 trillion to US\$4 trillion per year. The average of these numbers translates into almost US\$10,000 per person per year, which is about as large as the increase in per capita income in the United States during this period. In essence, this analysis is a simplified form of that performed by Murphy and Topel (2003).

An alternative approach to obtaining a similar number may help some readers better understand the intuition behind these

effects. Over this 30-year period, the 5-year increase in life expectancy that occurred raised life expectancy by about two months (or one-sixth year) per year. With each life year valued at about US\$75,000, these gains in life years are readily seen to be worth about US\$10,000 per person per year.

Understanding the value of improvements in health in lower-income countries requires data both on increase in longevity and on how such increases in longevity might be valued. Data on increases in longevity are relatively easy to obtain for most countries and vary substantially across countries over time. For example, many countries that had low income in 1950, including the Arab Republic of Egypt, Mexico, and Thailand, have had an increase in life expectancy since 1950 of more than 20 years, or about three months per year, which is about 50 percent greater than the rate of growth in life expectancy in the United States. Although some countries that had low incomes in 1950 and did not experience much economic growth during this period did not increase in life expectancy over this period, the vast majority of countries with low incomes in 1950 experienced increases in life expectancy far exceeding the rate of increase in the United States and other developed countries. This fact suggests that the potential for increases in life expectancy is greater for lower-income countries than for higher-income ones, so the increase in life expectancy for lower-income countries might be expected to slow in coming years. If the rate of change in the value of health gains were determined primarily by the rate of increase in life expectancy, growth in the value of health in lower-income countries would be expected to slow in the future.

Assessing the importance of changes in life expectancy relative to changes in the value of increased life expectancy in influencing the value of health requires data on the value of increased longevity. Such data on the value of mortality reductions are limited but do exist. Viscusi and Aldy (2003) reviewed the literature on the statistical value of life across countries that vary in income. One key finding is that the statistical value of life increases with income, with an elasticity of approximately 0.5 to 0.6, so that a 100 percent increase in income leads to a 50 to 60 percent increase in the statistical value of life.

One implication of this finding is that economic growth is likely to result in increases in welfare through improved health, both because economic growth improves health and because the value of those health improvements increases as income increases. This statement can be assessed formally by analyzing change over time in the value of life ($VL = VLY \times LY$), where VLY is the value of a life year, and LY is life expectancy. Such numbers easily show the value of health gains that have been achieved. For example, India is the poorest country for which calculations of revealed preference estimates of the statistical value of life have been done (Viscusi and Aldy 2003). This study suggests a statistical value of life of US\$0.6 million, or about US\$10,000 to US\$20,000 per life year saved. With

gains in life expectancy of about 25 years since 1950 and a population in 2000 of about 1 billion persons, the gains in life expectancy in India alone over the period are worth about US\$400 trillion, or US\$8 trillion per year, equivalent to about US\$800 per person per year.

Thus, as large as the US\$75 trillion to US\$150 trillion estimate for the health gains for the United States is, such gains are only about one-fourth as large as the gains for India. The value of the gains for India is larger for several reasons. One is just the longer period considered—30 years for the United States compared with 50 for India—although, in fact, gains in the United States were small enough between 1950 and 1970 that the longer period explains relatively little of the difference. Much larger factors are the fivefold greater increase in life expectancy in India than in the United States over the period (25 years compared with 5 years) and a population about five times as large. Thus, if health gains are valued in U.S. dollars, the value of such gains for India over this period far exceeds that for the United States. Given the 5:1 size of India and the gains in life expectancy, the ratio of those gains would be more like 25:1 than 4:1 (US\$400 trillion as opposed to US\$75 trillion to US\$150 trillion) were it not that the statistical value of life in the United States is greater than that in India. Even if one does not feel comfortable assigning differential valuation to lives across countries, the fact that the valuation of gains in India is so much larger than the valuation of the gains in the United States using this method provides a powerful reminder of certain basics of the value of improving health in lower-income versus higher-income countries: many more people live in low-income than in high-income countries, and the potential for large increases in life expectancy is thus far greater.

Such statistics provide some insights into the value of historical improvements in health, but in terms of considering future investments, considering what can be said about the growth of the value of health in lower- versus higher-income countries in the future is useful. To do so, one finds it useful to decompose growth in the value of health into growth in life expectancy and growth in the value of longevity (growth in the value of life years). We begin with $VL = VLY \times LY$ and differentiate to obtain the finding that growth rates can be decomposed to find that $g_{VL} = g_{VLY} + g_{LY}$, so that the growth in the value of life is the sum of the growth in the value of a life year and growth in life expectancy.

To understand the meaning of this relationship, one finds it useful to consider the Viscusi and Aldy (2003) estimate of the elasticity of the value of life with respect to income. Substituting this elasticity income in the above equation, $g_{VL} = 0.5 g_Y + g_{LY}$, where g_Y is the growth rate in per capita income. The relative magnitude of these two components is instructive. In developed countries such as the United States, where growth in life expectancy has been on the order of two months per year from a base of 75 or so years, the growth in

life expectancy is $(2/12)/75 = 0.2$ percent per year. This rate is substantially smaller than the component of increased value of life related to growth in the valuation of gains in life, even with long-run real growth rates of only 2 to 3 percent, so the component attributable to growth in the value of life is $0.5 \times (2 \text{ to } 3 \text{ percent}) = 1 \text{ to } 2$ percent per year. In lower-income countries in which growth in life expectancy is greater and baseline life expectancy is lower, life expectancy growth may be more important but is still not likely to exceed the effects of growth in per capita income. For example, Mali experienced dramatic growth in life expectancy of 1 percent per year (from 30 to 45 years from 1950 to 1990), but growth in per capita income in Mali from 1980 to 2000 was about 3 percent annually, translating into effects on the value of life of 1.5 percent annually. More striking perhaps is China, where growth in life expectancy from 40 to 70 years from 1950 to 1990 represented an increase of about 2 percent per year, whereas growth in per capita income (from 1980 to 2000) was about 8 percent per year (translating into effects on the value of life of about 4 percent per year). Two implications are immediately obvious:

- First, the growth in the overall value of health over the period has been large—about 2 to 6 percent annually for these initially low-income countries.
- Second, the major driver of the value of health over time has not been an increase in health per se but, instead, increases in income that produce increases in how health is valued. This finding is likely to be even more true as life expectancy increases so that continuing large increases in life expectancy become more difficult to achieve.

As noted previously, estimates such as these of the statistical value of life can understandably be criticized on the basis of associating a greater value with saving lives of wealthier persons than saving lives of poorer persons. Nevertheless, it is striking to note that in India—the only relatively low-income country for which data on the statistical value of life are available—the total value of recent health gains far exceeds even the immense gains in the United States. Data on the value of life for other low-income countries would help reinforce this finding, but the combination of the greater potential for large increases in life expectancy and for greater growth in per capita income in low-income countries in the future suggests that the total value of health gains for such countries may far exceed those of higher-income countries. Indeed, it bears emphasis that, in attempting to value health in monetary terms rather than merely health terms, such as life years or QALYs or DALYs, an important new avenue is opened by which the value of health research can increase over time even as gains in life expectancy slow with increasing life expectancy, as they have in developed countries. Despite the concern that economic approaches undervalue the health of persons with lower incomes, such

valuations clearly suggest that the potential value of health research for these countries is immense. That this discussion has focused only on the value of mortality reductions and neglected those of reductions in morbidity even further reinforces the potential gains from health research.

Not only is the magnitude of the value of these improvements in health immense in regard to how people value being healthier, but the total value of health also includes increased productivity, decreased medical care costs, and increased ability to plan for and invest in the future when health improves. Although these effects are often not easy to quantify, they may prove to be important components of the total economic value of improvements in health.

The Connection between Gains in Health and Health Research

To move from the finding that gains in health are highly valued to the finding that health research is highly valued, gains in health must be connected to health research. Making such associations is difficult even in high-income countries, but it has been done with some success. For example, Cutler and Kadiyala (2003) argue that the major recent gains in life expectancy in the United States have come from reductions in cardiovascular disease, about two-thirds of which can be tied to advances that have resulted from medical research as opposed to secular trends in nonmedical factors that promote health, such as per capita income and education. Similar calculations for lower-income countries have not been done. Nevertheless, although growth in income and education seem more likely to be important in producing increases in life expectancy for such countries, the major role of reductions in childhood infectious disease in recent gains in life expectancy suggests the great value of the research that has produced such innovations as childhood immunizations, improved sanitation, and oral rehydration therapy. Similarly, the high burden of cardiovascular disease in lower-income countries will be expected to decline in the coming years if the benefits of research can be applied in those settings.

Such conclusions speak to the value of health research as a whole for lower-income countries, and they reflect the gains that come both from research done initially to benefit higher-income countries and from research done to benefit lower-income countries. Although both of these classes of research may produce benefits for lower-income countries, discussion of their differences is in order. In the case of research done initially with the needs of high-income countries in mind, clearly some types of research benefit low-income countries more than others. For example, research that has demonstrated the power of relatively inexpensive medications to reduce mortality from cardiovascular disease (for example, aspirin in acute myocardial infarction) has much greater potential to produce large benefits for lower-income countries in the foreseeable

future than does research that advances techniques for expensive acute treatments, such as cardiac catheterization. In this particular case of cardiovascular disease, estimates summarized by Cutler and Kadiyala (2003) suggest that higher-income countries have also benefited more from research that advanced such low-technology treatments than from research on high-technology treatments.

Such patterns may not be maintained across other health conditions, but they do hold out the tantalizing thought that health research initiated by high-income countries in their own interest may sometimes be directed toward work of greater value if issues of cost and generalizability to lower-income settings are reflected more greatly in decisions about research priorities. When research directed toward the needs of lower-income countries is considered, cost and feasibility must, of course, receive great attention. However, the immense reductions in mortality that have come from advances in knowledge about public health efforts—such as efficient and effective sanitation, immunization, and oral rehydration programs, all of which were developed primarily with the needs of low-income countries in mind—suggest the value of research targeted toward the needs of lower-income countries. Rigorous studies of the value of these innovations akin to those studies done to assess the value of health research for the United States are sorely needed to inform potential funders of the potential returns to such research.

METHODS OF ASSESSING THE VALUE OF HEALTH RESEARCH PROJECTS

Although the aggregate value of health research has unquestionably been large, not all health research projects are sufficiently valuable to justify their costs. Some of these latter projects are inevitable because the outcome of research is intrinsically unpredictable. However, even if one abstracts from such uncertainty by considering the expected returns from a project before one embarks on it, research projects clearly vary in their likely value relative to their cost. Such assessments are obviously difficult to make, yet they are routinely done as part of the process of deciding the allocation of research funds. These assessments have traditionally been done rather informally, even in the most closely structured settings in which research funding is sought, such as the NIH study sections in the United States that review research proposals for NIH funding.

An active discussion over the past decade has helped to identify valuable strategies for priority setting in global health research and determine their implications for research priorities in the field. The 2004 report on health research of the GFHR summarized the major contributions to this discussion (GFHR 2003). The approaches that are described date back to as early as 1990 with the work of the Commission on Health Research

for Development. They include the essential national research approach developed by the Council on Health Research for Development and approaches developed by the Ad Hoc Committee on Health Research, the Advisory Committee on Health Research, and the GFHR's own Global Forum combined matrix approach. The 2004 report compares these approaches along several dimensions that include the following:

1. Objective of priority setting
2. Focus at global or national level
3. Strategies or principles (especially relating to the process for participation by stakeholders)
4. Criteria for priority setting:
 - Burden of disease
 - Analysis of determinants of disease burden
 - Cost-effectiveness of interventions (resulting from proposed research)
 - Effect on equity and social justice
 - Ethical, political, social, and cultural acceptability
 - Probability of finding a solution
 - Scientific quality of research proposed
 - Feasibility (availability of human resources, funding, facilities)
5. Contribution to capacity strengthening.

In addition to describing the dimensions considered in these approaches to priority setting, the 2004 report also summarizes several efforts to apply these approaches in individual countries or for individual diseases or disease areas (see, for example, Remme and others 2002). The priorities identified include many of those identified in chapter 4 in this volume.

Examining these dimensions of priority setting, one finds that some are intrinsically qualitative in nature but quantitative analysis also sometimes plays an important role. For example, several approaches, including the GFHR's combined matrix approach, use DALYs to quantify the number of healthy years of life lost to the disease toward which the research is directed.

Looking forward, one may find additional quantitative approaches helpful in assessing the value of research. For example, new methods based on value-of-information (VOI) techniques have begun to be proposed to better inform such assessments. In essence, VOI techniques model the uncertainty in the outcomes of research and the value of research contingent on that uncertainty in order to assess the expected value of the research. For example, a research project that has a 5 percent chance of success that it would produce health gains worth US\$100 million and a 95 percent chance of failure, would have an expected value of $(0.05 \times \text{US\$100 million}) + (0.95 \times \text{US\$0}) = \text{US\$5 million}$. Although these techniques have rich roots in statistical and economic theory, they are often difficult to apply well because of the difficulty in valuing health outcomes and modeling the uncertain outcomes of research. As a

result, these methods often can provide only loose bounds on the value of a research project (Meltzer 2001). Indeed, in the worst-case scenarios, in which the available information about the likely outcomes of research is essentially uninformative, VOI techniques only reproduce information on the burden and costs of illness. Nevertheless, in settings where more structure can be put into the problem, these techniques have begun to be applied successfully to specific research questions, such as the prioritization of research in Alzheimer's disease (Claxton and others 2001). In general, the more remote the connection of the research to health outcomes, the harder it is to gain meaningful information from a VOI approach. Thus VOI approaches are far better at providing information on the value of applied research than they are at providing information on the value of basic research.

For lower-income countries, this ability to illustrate the value of applied work may be especially valuable because often a technology has already been developed and the question is

how best to apply it in a given setting. With the limited funds that have traditionally been available for research in lower-income countries and the high value that appears to be placed on improvements in health in these countries, VOI studies, as discussed previously, seem likely to frequently show that the benefits of research in lower-income countries far exceed the costs. It is hoped that such findings may be used to increase the pool of funds available for research in these settings. However, even if VOI techniques do not lead to increases in the total funding available for research in low-income countries, they may be helpful in informing resource allocation decisions, given available resources. In the context of a fixed research budget in which some research projects whose expected benefit exceeds their costs could still not be funded, rigorous data on the high rates of return on projects that did not make the funding line would then serve to highlight the returns to greater research in these settings. Because VOI calculations need not be complex (see box 7.1), the most important barriers to their

Box 7.1

Value of Information

Although VOI calculations can be quite complex (for example, Claxton and others 2001), they need not be. For a researcher seeking funding, much simpler calculations may be sufficient to build a compelling case for funding. For example, quantifying the burden of illness in life years, QALYs, or DALYs lost and converting this into a burden or cost-of-illness measure in economic terms using an estimate of the statistical value of life may even be sufficient. To take a simple example, imagine a research program in a country with a statistical value of life of US\$0.6 million (for example, the estimate for India) for a disease that currently kills 1,000 people per year. If one abstracts from issues such as the age of death and how one might differentially value deaths at different ages, this would have a potential value of US\$0.6 billion per year. If the research study were viewed as having a 10 percent chance of preventing 50 percent of those deaths, its expected value would be $P(\text{success}) \times \text{percent efficacy} \times \text{statistical value of life} = 0.1 \times 0.5 \times \text{US\$0.6 billion} = \text{US\$30 million per year}$. Potential annual productivity gains produced by a successful treatment and annual costs of the treatment could be added to, or subtracted from, these US\$0.6 billion annual benefits as well. One could go further, arguing that the research would be valuable into the future, and discount an infinite stream of those annual returns. At a discount rate (R) of 10 percent, this stream would have a value of $\text{US\$20 million}/R = \text{US\$200 million}$. This result

suggests that a research program costing up to this amount would be worthwhile if it could be expected to have this likelihood of success and percent efficacy. Even if those probabilities could not be reliably estimated, minimum values could be calculated at which the research program would continue to be worthwhile.

As in their use in affluent countries, such calculations are likely to suggest that health research is of great value, often being predicted to return value many times its cost even accounting for uncertainty. In the preceding example, for instance, even an immense US\$100 million research program would have an expected return 20 times as large. Such results would reflect the immense value in health research but would also suggest caution: with limited research funds, not all programs whose benefits exceed their costs should be funded if more valuable projects remain unfunded. In this area, funding agencies can be helpful to the research community by highlighting how they have used calculations such as these and publicizing the ratio of research costs to returns for those projects they have been able to fund. Even when a project is not funded despite a favorable ratio of expected returns to research costs, reporting the missed opportunity will serve as a reminder to the world community of the potential of health research for lower-income countries that remains unrealized and thereby, perhaps, promote greater investment in health research to benefit the people of these countries.

useful application to research in developing countries are the lack of awareness and acceptance of these methods on the part of researchers and funders focused on these settings. Organizations concerned with international health can exercise valuable international leadership by exposing these researchers and funders to these methods and encouraging their use.

CONCLUSIONS

Improvements in health in recent decades have been of great value in both high- and low-income countries. Furthermore, future improvements in health are likely to be highly valued as the value of health increases with continuing growth in income. Health research has played a major role in the advances in health that have occurred, and the great potential value of future gains in health suggests that health research continues to merit increasing investment. New tools to prospectively assess the value of research offer the promise of even greater returns from health investment, especially for more applied research that can be closely connected to measurable benefits at the population level. Because low-income countries may often particularly benefit from applied research, these techniques to assess the value of research may be especially helpful in ensuring that the value of applied research in these settings is recognized. Providing researchers and policy makers in low- and high-income countries with the analytic tools needed to better identify and advocate for valuable opportunities for health research may be an important avenue to increasing the level and effectiveness of spending for health research.

Chapter 8

Improving the Health of Populations: Lessons of Experience

Carol Ann Medlin, Mushtaque Chowdhury, Dean T. Jamison,
and Anthony R. Measham

In the past 50 years, the world has experienced enormous and unprecedented gains in the health of human populations. Progress has been especially apparent in developing countries. Average life expectancy has risen by more than 60 percent, from 40 years in 1950 to 65 years today. In 1950, roughly 28 percent of children died before their fifth birthday, but by 1990, this number had fallen to 10 percent. Furthermore, many of the world's most deadly and debilitating diseases, including leprosy, measles, poliomyelitis (polio), and many childhood illnesses, have been effectively contained in most areas and virtually eliminated in others. Smallpox, a highly contagious and deadly disease that affected more than 50 million people a year prior to 1950, has been completely eradicated.

Researchers have identified economic growth, rising incomes, and better living conditions brought about by rapid social and political transformations in many societies as major contributors to these impressive health gains. However, in recent years, the role of scientific and technological progress has emerged as a crucial, but little understood, factor underlying these gains. As Davis (1956, 306–7) observes, “It seems clear that the great reduction of mortality in underdeveloped areas since 1940 has been brought about mainly by the discovery of new methods of disease treatment applicable at reasonable cost [and] by the diffusion of these new methods.”

New research has sought to validate, and indeed quantify, this basic intuition. For example, Jamison, Lau, and Wang (2005) show that technological progress (which is broadly defined as the generation or adoption of new technologies), together with education, has been a far more important contributor to declining infant mortality rates in developing

countries than income growth. Furthermore, improvements in health brought about by investments in technological progress generate an important and positive feedback loop favoring economic growth and development in these countries.

An important question that follows is what can be done to further consolidate these gains and ensure that the fruits of scientific and technology progress are placed in the hands of the people in developing countries who stand to benefit most? Because the work of the Disease Control Priorities Project (DCPP) focuses primarily on identifying the most cost-effective interventions for diseases and conditions affecting the health of populations in developing countries, this work provides the starting point for analysis. The goal is to isolate the critical factors—in particular those “actionable” through specific public policies—that have contributed to the effective deployment and scaling up of proven cost-effective technologies and services in low-income settings.

To address this question, the DCPP joined forces with the What Works Working Group of the Global Health Policy Research Network, an initiative led by the Center for Global Development in Washington, D.C., and funded by the Bill & Melinda Gates Foundation. DCPP authors were asked to identify outstanding examples of successful implementation of programs and projects geared toward the deployment of proven cost-effective interventions in their respective fields of international health and to speculate on what kinds of programmatic aspects and broader public policy decisions might have contributed to their success.

From an initial set of nominations, the What Works Working Group selected a subset of cases that conformed to strict

selection criteria, researched them thoroughly, and produced a report to be widely disseminated to policy makers and leading health experts in both developed and developing countries. In parallel, the DCPD initiated a systematic review of the case materials to identify commonalities or factors that may have contributed to the deployment and scaling up of those interventions. The objective was to identify a set of specific policy levers and programmatic decisions that could facilitate the transplantation of those and other cost-effective interventions to new and different settings. This chapter presents the results of that study.

RESEARCH METHODS

The study consisted of a qualitative analysis of a set of case studies selected to help illustrate how proven, cost-effective interventions have been successfully deployed and brought to scale with dramatic results in low- and middle-income countries in Africa, Asia, and Latin America and the Caribbean. We examined evidence culled from interviews, peer-reviewed articles published in journals, and official project evaluations and attempted to organize this information in a way that would allow us to reach tentative conclusions about the most significant elements associated with the interventions' success.

The study thus followed one of Mill's (1843) five methods of experimental reasoning: the method of agreement. Such a method postulates that "if two or more instances of the phenomenon (A) . . . have only one circumstance (B) in common, the circumstance (B) in which alone all the instances agree is the cause (or effect) of the given phenomenon (A)." For this study, the phenomenon (A) is represented by success. Cases that qualified as successes had to conform to the following five criteria:

- *Scale.* All cases selected for study involved a national, regional, or global scale. Pilot projects or interventions implemented on a subnational scale were not considered.
- *Importance.* Selected cases addressed a problem of major public health significance that could be expressed, at the program's inception, in terms of disability-adjusted life years, a composite measure of mortality and morbidity caused by the disease.
- *Health impact.* Selected cases had documented evidence of a clear and measurable effect on the health of the population targeted by the intervention. Process indicators, including immunization coverage rates, were not considered an acceptable substitute for health impact data.
- *Duration.* All cases selected for study had a life span of at least five consecutive years.
- *Cost-effectiveness.* Selected cases relied on interventions that had been proven to be cost-effective at a threshold of approximately US\$100 per disability-adjusted life year saved.

The unabashed focus on success meant that the study ignored potentially important information about factors that may be associated with programmatic failures or not-so-successful cases that did not meet the strict criteria described above. However, the inclusion of less-than-successful cases was not an option in light of time, resource constraints, and paucity of available documentation. Thus, a significant limitation of our study results from the lack of variance in the outcome observed. This type of selection bias is a common problem that may result from the nonrandom selection of cases in qualitative research.

Although bias cannot be eliminated without expanding the study to include unsuccessful examples, working skillfully with the presumption of bias to increase the level of confidence in the findings is possible. First, counterfactual examples, even if purely speculative (what would have happened if . . . ?), can be used to further substantiate the hypothesis that circumstance (B) has directly contributed to the observed phenomenon (A). Second, theorizing in a constructive way about what the direction of the bias might be and, therefore, minimizing its impact on the results of the study are also possible. For example, any potential bias more than likely results from overdetermining causality rather than overlooking or ignoring key factors related to success. In a related point, the study design makes discerning the relative contributions of the various factors difficult, because weights cannot be assigned easily.

Remarkably few rigorous studies of this sort attempt to track the implementation of proven, cost-effective interventions in the field. Although we have a good understanding of the efficacy of the available arsenal of interventions for treating and preventing diseases specific to low-income countries, we often know little about the range of programmatic and policy options that are needed to support these interventions in the real world. This study represents the first major contribution toward the development of a body of knowledge in that area, and the preliminary conclusions reached should be understood in that context (Collier and Brady 2004).

CASES

From an initial set of nominations received from DCPD authors as well as from other international health researchers, we selected a subset of 17 cases for study. We could not consider many cases that were nominated because of the absence of reliable data. Thus, the 17 cases selected are merely a subset of the many successes in international health that have been achieved during the past 50 years, not the full universe. Nonetheless, the cases draw from all three continents of the developing world—Africa, Asia, and Latin America and the Caribbean—and involve both communicable and noncommunicable diseases as well as curative and preventive care. Most

cases are national-level programs, but a few involve regional initiatives, and one is global.

Many near misses did not make the cut. The reasons for this exclusion varied. For example, a program in Costa Rica, El Salvador, and Guatemala to promote hand washing appears to have resulted in a dramatic decline in child morbidity and mortality but did not meet the duration criterion because it was fully operational for only three years (1996–99). In another example, the evidence of a health impact was mixed: a successful schistosomiasis control program in the Arab Republic of Egypt that included treatment of blood flukes in infected individuals was later linked to high prevalence rates of hepatitis C caused by the use of improperly sterilized syringes (Frank and others 2000). Nonetheless, the most common rationale for excluding a case from this study had to do with a lack of consistent documentation and of analysis of the health impact of the program in question. Thus, a reasonable conclusion is that the true universe of cases is much larger than the subset of cases we examined.

Each case reviewed here illustrates how a discrete health intervention or combination of interventions was successfully brought to scale in a specific context. To gain insight into this process, we can distinguish between the intervention—for example, the tool or technology that has been proven to be cost-effective for the treatment or prevention of a given disease—and the programmatic characteristics and policies that contributed to the successful delivery or deployment of the intervention through specially designed programs or projects.

The following list of cases selected for review describes the programs or projects that were scaled up, identifies the specific intervention or interventions deployed, and summarizes the existing evidence about health outcomes and impact:¹

- **Chagas disease control.** In 1991, seven countries—Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay, and later Peru—joined forces as part of an initiative for the Southern Cone countries led by the Pan American Health Organization to combat Chagas disease through a combination of surveillance activities, house-to-house spraying, and other vector control methods. *Health impact*—Disease incidence had fallen by 94 percent by 2000. By 2001, disease transmission had been halted in Chile, Uruguay, and large parts of Brazil and Paraguay. The project is ongoing.
- **Diarrheal treatment.** In Egypt, the government launched a national program in the early 1980s to promote the use by mothers of locally manufactured oral rehydration salts in a four-part strategy that included tailoring product design and branding to accommodate local preferences and customs; strengthening production and distribution channels, both public and private; training health workers; and using social marketing and a mass media campaign. *Health impact*—Between 1982 and 1987, infant and child mortality

dropped by 36 and 43 percent, respectively. Mortality attributed to diarrhea fell 82 percent among infants and 62 percent among children. The project closed in 1991.

- **Guinea worm eradication.** Twenty countries in Asia and Sub-Saharan Africa began a global campaign to eradicate guinea worm in the mid 1980s. Led by the Carter Center, the United Nations Children’s Fund, the U.S. Centers for Disease Control and Prevention, and the World Health Organization, the campaign promoted improved water safety through deep-well digging, environmental control, and the use of cloth filters for drinking water; health education programs; and case management, containment, and surveillance. *Health impact*—By 1998, 9 million to 13 million cases of guinea worm had been prevented and global prevalence had dropped by 99 percent. The project is ongoing in three countries.
- **Family planning.** In Bangladesh, family planning has been promoted since the 1970s through a door-to-door outreach program conducted by young, married women who provide information about limiting family size or spacing pregnancies along with products. An extensive media campaign accompanied the outreach program. *Health impact*—Contraceptive use among married women in Bangladesh is approximately 50 percent today, compared with only 8 percent in the mid 1970s, and the average number of children per family is 3.3, down from 7 in the mid 1970s. The project is ongoing.
- **Hib vaccination.** Chile began to include the Hib vaccine as part of its national immunization program in 1996. In The Gambia, a similar initiative was introduced in 1997. *Health impact*—In Chile, the prevalence of Hib disease fell by 90 percent, and the incidence of pneumonia and other Hib-related illnesses fell by 80 percent. In The Gambia, the number of children developing Hib meningitis fell from 200 per 100,000 to 21 per 100,000 only 12 months following the introduction of the vaccine. The projects are ongoing in both countries.
- **HIV/AIDS prevention.** Thailand launched the 100 Percent Condom Program in 1991 to address the rising incidence of HIV/AIDS in the country. The program provided boxes of condoms to brothels free of charge, mandated the use of condoms by sex workers, and threatened brothels with penalties and closure for noncompliance. *Health impact*—By 1992, condom use in brothels had risen to more than 90 percent, up from 14 percent in 1989. The number of cases of new sexually transmitted infections fell from 200,000 in 1989 to 15,000 in 2001, and an estimated 200,000 new infections were averted between 1993 and 2000. The project is ongoing.
- **Health improvement of the poor using financial incentives.** In 1997, the Mexican government launched a new social welfare program designed to help lift rural families

out of poverty by providing cash payments in exchange for their participation in nutrition and supplementation programs, their use of prevention and basic health care services, and their children's school attendance. *Health impact*—After five years, the children of participating families were 12 percent less likely to experience illness than those of non-participating families, and their nutritional status had improved. Adult health indicators also improved. The project is ongoing.

- **Maternal health.** The Sri Lankan government relied on professional midwives and sustained investments in the country's health care system, including in rural areas, to improve maternal health. *Health impact*—The maternal mortality ratio fell from approximately 500 per 100,000 live births in 1950 to 60 per 100,000 in 2003. The project is ongoing.
- **Measles elimination.** In 1996, the seven southern African countries agreed to a coordinated immunization strategy, supported by improved surveillance and laboratory capacity, to eliminate measles by including the vaccine as part of routine immunization for all nine-month-old babies and organizing nationwide catch-up and follow-up campaigns for children age nine months to 14 years. *Health impact*—The number of measles cases reported annually in the region fell from 60,000 in 1996 to 117 in 2000. The number of deaths attributed to measles fell from 166 to 0 during the same period. The project is ongoing.
- **Onchocerciasis control.** The discovery of ivermectin (Mectizan) in 1978 and Merck's decision to provide it free of charge to anyone who needed it allowed early successes based on weekly aerial spraying in 11 West African countries to be further consolidated and later expanded to the other 19 endemic countries in Central and East Africa. *Health impact*—In West Africa, disease transmission has been virtually halted, and 1.5 million previously infected people are now symptom free. In Central and East Africa, the program has helped prevent an estimated 40,000 cases of blindness each year. The Onchocerciasis Control Program (OCP) ended in 2002. The African Programme for Onchocerciasis Control is ongoing.
- **Polio elimination.** In 1985, the Pan American Health Organization launched a campaign to eradicate polio from the Americas. National vaccine days were held twice a year and were targeted at children under the age of five, regardless of their immunization status, to increase coverage in countries with weak routine immunization programs. An extensive surveillance system and mop-up campaigns to address outbreaks were crucial during the campaign's final stages. *Health impact*—The last case of polio in the Americas was reported in 1991.
- **Salt fluoridation.** In Jamaica, a formal agreement between the Ministry of Health and the country's only salt producer introduced fluoridation to salt in 1987 to prevent caries. *Health impact*—By 1995, the severity of caries in children between the ages of 6 and 12 had fallen by more than 80 percent. The project is ongoing.
- **Salt iodination.** China launched the National Iodine Deficiency Disorders Elimination Program in 1993. The government requires producers to iodize salt and has stepped up its monitoring and enforcement capacity to ensure compliance. *Health impact*—Total goiter rates among children between the ages of 8 and 10 years fell from 20.4 percent in 1995 to 8.8 percent in 1999. The project is ongoing.
- **Smallpox eradication.** The campaign to eradicate smallpox, led by the World Health Organization and heavily financed by the United States, was launched in the mid 1960s. Strong leadership, dedication, and commitment on the part of the international community and the timely discovery of simple, new technologies—for example, the bifurcated needle and the “ring” strategy of surveillance and containment—characterized the effort. *Health impact*—The World Health Assembly declared smallpox eradicated in May 1980.
- **Tobacco control.** Poland passed groundbreaking legislation in 1995 imposing strong warning labels on cigarette packages, banning smoking from enclosed workplaces, and prohibiting tobacco sales to minors. South Africa passed similar legislation in 1999 to strengthen a previously imposed tax of 50 percent on the retail price of cigarettes. *Health impact*—Cigarette consumption dropped 10 percent between 1990 and 1998, resulting in a 30 percent decline in lung cancer among men age 20 to 44, a nearly 7 percent decline in cardiovascular disease, and a decline in the number of babies with low birthweight. South Africa witnessed a 30 percent decline in cigarette consumption in the 1990s, especially among youths and the poor. The projects are ongoing in both countries.
- **Trachoma control.** The Moroccan National Blindness Control Program, launched in 1991, promoted the use of “SAFE” interventions (surgery, antibiotics to control the infection, facial cleanliness, and environmental improvements), with the goal of eliminating trachoma by 2005. *Health impact*—Overall prevalence rates have fallen by 75 percent since 1999, and the prevalence of active disease in children under the age of 10 has seen a 90 percent reduction since 1997. The project is ongoing.
- **Tuberculosis control.** In 1991, China launched a 10-year program in 13 of its 31 mainland provinces to apply the directly observed therapy short course (DOTS) strategy to tuberculosis (TB) control. Peru, previously one of 23 high-burden countries that collectively account for 80 percent of the world's new TB cases each year, launched a similar effort the same year. *Health impact*—Within two years, China had achieved a 95 percent cure rate for new cases and a cure rate of 90 percent for those patients who had previously completed treatment unsuccessfully. The number of people with

TB declined by more than 37 percent between 1999 and 2000. The project ended in 2001, but important elements have been incorporated in the 10-year National Plan for the Prevention and Control of TB (2001–10). In Peru, disease incidence declined each year by 6 percent. The program achieved a case detection rate of 70 percent and an 85 percent cure rate. The project is ongoing.

GENERAL FINDINGS

Taken as a whole, the cases support four general findings. The first two have special relevance because they serve to disconfirm aspects of the prevailing wisdom about aid effectiveness—or at least present a serious challenge to such wisdom.

First, these cases demonstrate that a wide range of proven, cost-effective interventions exists that can and have been brought to scale in developing countries, even in extremely low-income settings with limited health infrastructure and in challenging macropolicy environments. In West Africa, aerial spraying of the blackflies' breeding sites, part of the strategy promoted by the OCP throughout the 1980s, "continued unabated through wars between member countries and coups that grounded all other aircraft" (Eckholm 1989, 20). In Sudan, despite the difficulties created by the more than 20-year civil war, and in other areas of Sub-Saharan Africa, the campaign to eradicate the guinea worm has made progress. The finding is significant in that it challenges a central tenet of the aid-effectiveness literature: that only countries with a "good" policy environment can benefit from external financial assistance (Devarajan, Dollar, and Holmgren 2001).

The aid-effectiveness literature has tended to focus on a different set of outcomes—for example, macroeconomic and structural reform—rather than on health outcomes, and this focus may partly explain the contradictory conclusions; however, an examination of whether such a conclusion is true goes well beyond the scope of this study. In any event, the cases reviewed for this study displayed a striking degree of variation in the political and economic contexts in which interventions were applied and brought to scale, and no clear pattern of association was apparent between this variation and successful outcomes in relation to health.

Second, the cases provided new evidence of the importance of the public sector to achieving successful health outcomes. This finding was a surprise, especially considering the strength of recent evidence documenting "weak links in the chain between government spending for services to improve health and actual improvements in health status" (Filmer, Hammer, and Pritchett 2000, 199). The specific roles that the public sector played in achieving these outcomes varied tremendously. In some instances, such as promoting maternal health in Sri Lanka and controlling TB in China and Peru, governments were involved in direct service provision. In other instances, the

public sector's regulatory or legislative authority was critical. Governments in Poland and South Africa passed strict laws, despite strong opposition from the tobacco industry, requiring explicit health warnings on cigarette packs, banning smoking in enclosed public places, and prohibiting tobacco media advertisements, among other things. Governments also used their authority creatively to encourage health-promoting behaviors and to discourage risky ones. In Mexico, the government provided direct cash payments to poor families in exchange for visits to health care clinics and school attendance. In Thailand, local police worked in collaboration with health officials to lend credibility to the government's threat to shut down brothels that failed to comply with the no condom, no sex policy, giving teeth to the national campaign.

Third, the cases reviewed for this study share a number of common features or attributes that appear to have contributed to the successful outcomes. Without exception, they enjoyed and managed to reap the benefits of strong leadership, effective management, realistic financing arrangements, country ownership, and openness and receptivity to learning by doing, constantly improving on strategies and processes by incorporating new research findings and technical innovation into program improvements.

For example, successful projects appeared to benefit from a strong champion who could provide the necessary leadership to bring relevant stakeholders together, encourage them to focus and coordinate their activities, and instill in them a sense of purpose and enthusiasm for their work. However, we did find that leadership came packaged in many different shapes and sizes. In Jamaica, the curiosity and persistence of a Ministry of Health dentist led to the identification of the island's only salt producer as the vehicle for fluoridation. In Mexico, President Ernesto Zedillo Ponce de León seized on the innovative proposal of a close adviser, Santiago Levy, then director-general of social security, and launched a program linking education, health, and nutrition as part of an integrated strategy to lift rural families out of poverty, and the program was not abandoned when Zedillo left office. The new Vicente Fox administration, motivated by undeniable evidence of the program's effectiveness, instead sought to expand the program into urban areas and added an educational component. In a less visible but nonetheless critical display of leadership and forward thinking, the sustained investments of the Sri Lankan government over a nearly 50-year period to build a rural health network emphasizing critical elements of maternal health have led to gains in the health of women unparalleled by countries at similar, and higher, income levels.

Strong program management was needed to ensure that plans, once conceived, were implemented effectively. Successful cases had well-delineated goals that were clearly linked to inputs, activities, outputs, and outcomes. This factor was especially evident in the case of global or regional immunization

campaigns, given the many logistical challenges and the need for fluid and effective coordination of many countries and stakeholder groups, often within a highly constrained time frame. However, similar management skills are needed for health service delivery systems, especially when patient referral, tracking, and follow-up are essential components of the intervention. In China, incentive schemes to motivate physicians, extensive training and supervision of health care staff, and substantial investments in local TB dispensaries were all crucial elements in improving management capacity for large-scale rollout of the country's DOTS program, which covered a population of 573 million in 1,208 counties in 13 provinces.

A closely related requirement was having a realistic financing strategy that was compatible with a project's goals. Even when large sums of money were involved, deployment of the intervention yielded tremendous returns at a relatively low cost per disability-adjusted life year. In the case of onchocerciasis control, for which donors have invested US\$560 million over a period of 28 years, transmission has been virtually halted in 20 West African countries, and nearly 600,000 cases of blindness have been averted at an annual cost of only US\$1 per person. In the case of guinea worm control, in which donors have invested approximately US\$88 million over a 12-year period, disease prevalence has fallen by 99 percent, and only 35,000 people remain affected, down from 3.5 million, at a cost of US\$5 to US\$8 per person.

Country ownership was another distinguishing feature of successful programs. A government's willingness to commit scarce funding to scaling up an intervention can be an important indication of this ownership, although not the sole predictor. Despite the extremely constrained budgets of the seven participating countries, the campaign to eliminate measles in southern Africa was almost entirely funded by their ministries of health. The Thai government covered approximately 96 percent of the cost of the 100 Percent Condom Program. In Morocco, the government bore the bulk of the costs for implementing the SAFE strategy to address blindness caused by trachoma, with contributions from the United Nations Children's Fund and the International Trachoma Initiative, an international public-private partnership.

Most of the cases we reviewed benefited from new research findings and technical innovation. Successful cases appear to display the openness and receptivity needed to make good use of new knowledge and to support ongoing research when appropriate or when gaps in knowledge prove to be a hindrance to progress. In Bangladesh, a program to treat childhood diarrhea trained mothers to make their own salt solution when the authorities determined that mass production and distribution of prepackaged oral rehydration salts was unrealistic. Control of Chagas disease in the Southern Cone of Latin America required public health officials in each country to devise and deploy environmental control strategies appropri-

ate to local conditions and vector behavior. Finally, adoption of the ring vaccination strategy marked a crucial turning point in the global campaign to eradicate smallpox, enabling rapid containment of the disease in remote parts of the world without vaccination of every child.

In sum, a small number of features appear to be common to all the successful cases. A reasonable hypothesis suggested by the evidence is that these five attributes represent the known set of necessary, but not sufficient, conditions for successfully implementing cost-effective health interventions in the developing world.

Fourth, despite the obvious limitations of case study methods in hypothesis testing and confirmation, the evidence from the cases sheds important light on two important debates in international health policy. First, the cases suggest that much more is involved than what is currently understood about whether weak policy environments can make good use of carefully selected, strategic investments in health. As the next section indicates, different types of programmatic characteristics and policies are needed for the deployment of different types of interventions. How these characteristics interact with different policy environments—whether strong, weak, or in between—deserves further scrutiny and exploration. Second, evidence from the cases of successful government action should call into question any premature and overly general conclusions about public sector ineffectiveness in developing countries. Even though such a small sample of cases is surely insufficient to close the book on these important policy debates, it should at least encourage further study and refinement of the arguments.

INTERVENTION TYPE, PROGRAMMATIC CHARACTERISTICS, AND POLICIES

Programmatic characteristics and policies associated with successful outcomes appear to vary by intervention type. The starting point for this discussion is the intervention, technology, or tool in question. What allows for the widespread deployment of a proven, cost-effective intervention? What are the steps for converting a proven, cost-effective intervention into a fully fledged health program that has been successfully brought to scale, preferably at the national level? Is it possible to distinguish between the specific health intervention and the programmatic characteristics and public policies associated with its successful deployment?

The cases under review were grouped according to the primary type of intervention deployed by the program or project in question. The types of interventions varied in terms of their emphasis on the delivery of standardized products to a population (product-intensive interventions), the delivery of clinical services (service-intensive interventions), a personal

behavior change (behavioral change interventions), the control of environmental hazards (environmental control interventions), or some combination thereof.

Further scrutiny of subgroupings of cases revealed that certain programmatic characteristics, delivery modalities, and public policy instruments also appeared to vary by intervention type. This finding appeared to substantiate the claim of the first edition of this volume (Jamison 1993, 11) that “commonalities of logistics, policy instruments, and approach” vary by intervention type and play a role in determining whether the intervention or interventions will be deployed successfully.

The typology presented here differs from the one elaborated by *World Development Report 2004: Making Services Work for Poor People* (World Bank 2004), in that the classification depends on characteristics inherent to the intervention in question. By contrast, *World Development Report 2004* identifies three classes of service delivery arrangements: individual-oriented clinical services, population-oriented outreach services, and community- and family-oriented services that support self-care. The focus is on differences in the relationship between provider and client and how these differences interact with market and public sector dynamics.² However, our focus was on how characteristics of the interventions themselves give rise to certain programmatic or policy imperatives that may contribute, ultimately, to successful health outcomes.

This section presents the five intervention types and explores the clusters of programmatic characteristics and policies that appear to support the successful deployment of each intervention type, based on case study analysis.

Product-Intensive Interventions

These types of interventions (box 8.1) involve the simple transfer of a standardized technology to an individual or to an entire population. They can be targeted at either prevention or cure, but the distinguishing feature is standardization. Unlike service-intensive interventions, product-intensive interventions need not be tailored to the unique health care needs of the individual receiving treatment.

To the degree that product-intensive interventions place relatively low technical demands on health care staff at the point of delivery, they may be more easily deployed in low-resource settings than other types of interventions. Compared with service-intensive interventions, they are less transaction intensive, requiring fewer interactions between providers and clients. Also, compared with behavioral-change interventions, they are less dependent on individual compliance, requiring simply that individuals make themselves available for treatment. Product-intensive interventions include mass drug administration (chemotherapy), childhood immunizations, mineral fortification, and nutritional supplementation. (These specific interventions are addressed in detail in chapters 20, 22, and 28.)

Product-intensive interventions are often, though not necessarily, linked to vertical rather than horizontal delivery modalities. According to Gonzalez (cited in Mills 1983, 1972), the vertical approach “calls for the solution of a given health problem through the application of specific measures through single-purpose machinery.” By contrast, the horizontal approach “seeks to tackle . . . health problems on a wide front and on a long-term basis through the creation of a system of permanent institutions commonly known as ‘general health services.’” Where health systems are weak and poorly functioning, vertical programs—in particular, mass campaigns—can be an effective means of rapidly providing coverage to a large population. However, the same approach could result in an unfortunate duplication of effort in countries where the health care system is already strong and functioning properly.

Mass Drug Administration. Of the product-intensive interventions, those that can be delivered in pill or capsule form in standardized doses, often through what is referred to as *mass drug administration*, are perhaps the least complex to deliver and, as a result, may be the least costly. Onchocerciasis, also known as river blindness, can be treated by a single dose of ivermectin administered annually to infected individuals. Lymphatic filariasis can be treated in much the same way using a two-drug combination therapy of albendazole plus either diethylcarbamazine or ivermectin administered annually in

single doses for four to six years (the estimated productive life span of the adult-stage parasite).

The importance of product-intensive therapies can easily be illustrated by reference to the case of onchocerciasis control in most parts of Africa. Although aerial spraying, an environmental control intervention, had been used successfully to slow disease transmission in 11 West African countries, it was not a viable option for 19 countries of East and Central Africa because of geographical differences. However, Merck scientists' discovery of ivermectin in 1978 and the company's generous commitment to provide the drug free of charge to anyone who needed it changed the parameters of what was possible. Seizing the opportunity, the African Programme for Onchocerciasis Control, an international partnership led by the World Bank, the World Health Organization, the United Nations Development Programme, and the Food and Agriculture Organization of the United Nations, was created in 1995 with the goal of eliminating onchocerciasis as a disease of public health and socioeconomic importance in East and Central Africa.

It quickly became apparent that the weak and sometimes nonfunctioning health systems of many African countries were not up to the task; thus, a new approach was tried that took advantage of the fact that the success of the intervention no longer depended on a clinic-based delivery system. Under the supervision of national public health ministries and non-governmental organizations, community volunteers received training on organizing and managing the local ivermectin campaigns. The community-directed approach of treatment with ivermectin has been so successful that it has been considered as a possible model for delivering other types of treatments to remote areas.

Immunizations. Product-intensive interventions may vary in complexity, which has implications for their delivery or deployment. For vaccines, the need to maintain an effective cold chain adds an additional layer of complexity to the delivery system. Other pertinent factors are whether the intervention can be delivered as a single shot or iteratively, whether it can be bundled together with other products or must be delivered separately, and whether the number of distribution points is few or many. In many cases, the characteristics of the disease or condition being addressed may affect the level of complexity.

For example, the overwhelming success of the global effort to eradicate smallpox has been attributed, at least in part, to specific characteristics of the variola virus. Unlike other infectious diseases, such as malaria or yellow fever, smallpox depends solely on the human host and does not have an animal or insect carrier. Unlike polio, smallpox does not produce silent or asymptomatic infection, thereby facilitating diagnosis and surveillance of the disease (Tucker 2001). Other notable differences from other diseases have more to do with the vaccine than the virus. Tucker (2001, 64) explains that “a freeze-dried smallpox

vaccine was available that was easy to manufacture, cost only about a penny a dose, protected for several years with a single inoculation, and was relatively stable in warm climates, reducing the need for refrigeration. Whereas most vaccines took months to induce immunity, the smallpox vaccine acted with remarkable speed, providing nearly total protection within ten to twelve days.” This unique set of characteristics together meant that a “surveillance-containment” approach could replace mass vaccination entirely, in effect reducing the number of distribution points required by the intervention, thereby permitting major strides in the global eradication campaign.

The more complex the intervention, the more challenging—and probably costly—it will likely be to implement. Interventions that can be delivered in a single shot or that can be easily incorporated into routine immunization (bundled) are clearly the easiest to implement. As the case of Hib vaccination in Chile illustrates, delivering the intervention was relatively straightforward after the government got past the hurdle of evaluating its cost-effectiveness relative to other interventions. The government determined that the creation of a combined diphtheria-tetanus-pertussis and Hib vaccine was worthwhile and that the vaccine could be administered as part of an already well-functioning system of routine immunization.

Some of the common complexities associated specifically with immunizations range from the need for multiple inoculations administered at regular intervals, to the need to maintain a reliable cold chain, or to the need for the large population coverage required to achieve “herd immunity”—whereby the likelihood of person-to-person transmission is drastically reduced, even among the unimmunized population. In view of these potential complexities, polio elimination in the Americas represents a remarkable achievement. The oral polio vaccine must be administered in three properly spaced doses, and coverage must be high to prevent “silent” epidemics. In the 1970s, before the campaign was launched, polio caused an estimated 15,000 cases of paralysis and 1,750 deaths each year (Musgrove 1988). However, a carefully orchestrated campaign organized around achieving and maintaining high coverage through routine immunization and national vaccination days, the prompt identification of new cases, and the aggressive control of outbreaks led to the elimination of polio from the Americas in 1991. The creation of the Inter-Agency Coordinating Committee, made up of representatives from the Pan American Health Organization, the United Nations Children's Fund, the U.S. Agency for International Development, the Inter-American Development Bank, Rotary International, and the Canadian Public Health Association, played a key role not only in generating political and financial support, but also in helping address the logistical and managerial challenges inherent to the campaign. The Inter-Agency Coordinating Committee model was so effective that it was quickly duplicated at the country level.

The technical and logistical challenges associated with measles elimination in southern Africa were no less complex. Measles is one of the most contagious of all human diseases. The measles vaccine requires 90 percent coverage to achieve herd immunity and to stop the spread of the virus. Furthermore, it often requires two doses to be effective and must be administered to infants no earlier than nine months of age, or about six months later than other recommended vaccines. If given earlier, the vaccine will fail to trigger an active immune response, because infants are passively protected by their mothers' antibodies until that age. Thus, the vaccination interval falls outside of what most routine immunizations require.

To overcome this challenge, the southern African countries adopted a strategy known as catch up, keep up, and follow up. In each country, beginning with the program's launch in 1996, the strategy involved organizing a national catch-up campaign in which mobile teams vaccinated all children, regardless of their vaccination status, between the approximate ages of 9 months and 14 years; sustained routine coverage; and ran at least one follow-up campaign several years later. The countries also strengthened their surveillance and laboratory capabilities to investigate all suspected measles cases.

Mineral Fortification. A different type of product-intensive intervention, mineral fortification, requires fewer points of delivery and is far less labor intensive. However, potential challenges include the need for a different set of technical capacities than is typical for health sector solutions; the possibility of a need for significant initial investments to modify production processes or manufacturing capabilities; and the involvement of non-health sector entities, such as private industry.

Jamaica's salt fluoridation program beautifully illustrates the simplicity of a single delivery point for an intervention. With the agreement of the island's only salt producer, Alkali Limited, in place, universal coverage was easy to achieve. All that was needed was a complementary legal and regulatory framework to oversee the process. In this case, the start-up costs were small: only US\$3,000 worth or so of new equipment was needed, which the company was easily able to recoup with a slight increase in the price of salt.

In China, salt fortification with iodine was more difficult, involving a larger investment in the production process and a

greater number of potential delivery points. Because salt production is licensed at the provincial level in China, implementing the change involved working with several layers of government bureaucracy; however, perhaps ironically, the system of central control eased the challenge. During a four-year period, 55 salt factories were upgraded and 112 iodination centers were established throughout the country to support the initiative. The government also introduced changes in bulk and retail packaging to help consumers more easily recognize iodized salt. The basic plan achieved nearly 90 percent coverage, but the remaining challenge is to address the numerous delivery points that function outside the national system, for instance, in areas where people live near the sea and produce their own salt.

Summary. In sum, product-intensive interventions can be extraordinarily complex even though they involve fewer transactions between providers and clients and lower technical requirements at the point of delivery than other types of interventions, particularly service-intensive interventions. However, the relative simplicity of deployment when the scientific and technical issues of development and production have been addressed may help explain why product-intensive interventions are perceived to be easier to implement than other types of interventions and why countries experiencing political and economic instability might prefer them.

Service-Intensive Interventions

Service-intensive interventions (box 8.2) include the full range of diagnostic and therapeutic health services usually provided not only in the clinic setting, but also in the home or at school. Unlike product-intensive interventions, service-intensive interventions cannot easily be standardized and may require careful—and time-consuming—monitoring and reporting on patients' progress. Thus service-intensive interventions are highly transaction intensive and typically place high technical demands on the health staff at the point of delivery. Examples range from primary care services, including essential obstetrical care, to surgical procedures, to treatment of communicable and noncommunicable diseases.

The complexity of service-intensive interventions may vary, just as in the case of product-intensive interventions. The more

standardized the treatment protocol, the easier it will be to administer on a large scale. However, standardized or not, the transaction-intensive character of this type of intervention means that its successful deployment depends on the program's or project's ability to overcome potential (and likely) constraints on human resources. A related concern is the overall health system's capacity to effectively manage competing demands on these resources. In contrast to product-intensive interventions, human capacity constraints for service-intensive interventions are harder, but not impossible, to address through community mobilization or the use of volunteers, because of the need for specialized training. Chapter 71 investigates developing countries' experiences with new types of professionals in service delivery settings that have traditionally relied on physicians.

Single-Shot Surgical Services. If the intervention is relatively standardized, it can sometimes be deployed using a vertical modality in a manner similar to the more standardized, single-shot, product-intensive interventions. This was the case of the surgical procedure used in Morocco as part of the broader SAFE strategy to address trachoma. A relatively simple surgical procedure, the bilamellar tarsal rotation procedure, can be used to halt corneal damage to prevent the onset of blindness caused by repeated trachoma infections. Morocco's Ministry of Health organized mobile surgical teams of doctors and nurses to carry out the corrective surgery in small towns and communities throughout the country. In just eight years, the teams carried out more than 26,000 surgeries. The effort required the involvement of 43 physicians and 119 nurses working in 34 clinics. However, despite the relatively standardized nature of this kind of service-intensive intervention, human capacity constraints may slow progress. Compared with product-intensive interventions for which community volunteers can be recruited to assist with distribution, service-intensive interventions require a more specialized workforce. Even when nurses and other health workers with lower-level skills can substitute for more highly trained physicians, constraints on human resource capacity may persist. Morocco faces a backlog of about 15,000 cases, many of which are urgent.

Strengthened Outreach and Referral Systems. If the intervention is not easily standardized, or if it is highly transaction intensive, its successful deployment will also depend on well-developed outreach and referral systems. Outreach systems are needed to ensure that those requiring care will have access to care, and referral systems are needed to route patients requiring additional care toward specialized care and treatment facilities. However, ensuring that such systems are in place for specific programs and projects is a major challenge in countries where the health care system is already weak and under considerable strain.

The cases we reviewed relied on a variety of strategies to address this problem. Although the specific interventions varied, the strategies ranged from traditional investments in public sector provision to improve access, to supply-side incentives to address quality concerns, to demand-side incentives to strengthen the effective demand for health care services. For example, in an effort to improve maternal health even in remote areas, Sri Lanka adopted the traditional model of public sector provision, but with a twist. Instead of a physician-based solution, which would have been extremely costly, Sri Lanka relied instead on professional midwives to provide widespread access to maternal health care, building on a strong health care system that provides free health care. Midwives serve a population of 3,000 to 5,000 each and live locally. They visit pregnant women in their homes, register them for care, and encourage them to attend prenatal clinics (run by doctors). Midwives receive 18 months of training and are backed up by supervision and a well-functioning referral network. Established procedures for service delivery and supervision, along with frequent in-service training, help keep midwives current and delivering high-quality services. Health clinics are supported by a network of cottage hospitals (clinics having doctors as well as nurses assigned to them), rural hospitals, and maternity homes at the secondary level; tertiary provincial hospitals with specialist services; teaching hospitals; and specialist maternity hospitals.

China faced a similar dilemma with regard to establishing an effective system of outreach and referral to address a growing TB problem by scaling up DOTS. Although DOTS is relatively standardized as far as service interventions go (see chapter 16), the treatment protocol is highly transaction intensive, and complicated cases may require specialized treatment. DOTS is thus also highly dependent on well-developed systems of outreach and referral for its success. However, China faced a challenging situation because most village doctors who were needed to conduct patient diagnosis, treatment, and surveillance in rural areas were in private practice and had little incentive to treat patients for whom drugs were now provided free of charge. In response, the government created a financial scheme to provide incentives for these doctors to participate. For each patient enrolled in the treatment program, village doctors received US\$1. They received an additional US\$2 for each smear examination carried out in the county TB dispensary during a two-month period and another US\$4 for each patient who completed treatment. Simultaneously, the government made significant administrative, managerial, and institutional investments. Tens of thousands of staff from TB dispensaries were trained, and supervisory systems were put into place. Furthermore, the government set up a national TB project office and a TB control center to oversee and coordinate the various levels of government involvement.

Demand-Side Incentives. Demand-side incentives can be designed to complement supply-side investments. Indeed, both skeptics and supporters of governments' ability to translate public spending into effective service provision and positive health outcomes encourage the use of demand-side incentives as a means of quality control to improve routine care (Filmer, Hammer, and Pritchett 2000). Economists consider demand-side incentives to be valuable tools for stimulating weak demand for services or for overcoming barriers to use that can artificially dampen demand. This was how at least two of the cases included in this study constructively used demand-side incentives. However, in neither case was this use an either-or proposition; that is, both demand-side and supply-side investments were relied on to generate the successful outcomes that qualified the cases for this study.

In Peru, the newly revised National Tuberculosis Control Program offered food packages, employment training, and stipends to patients to improve compliance with the drug treatment regime. Simultaneously, the program was dramatically scaled up and the number of participating health centers rose from 977 to 6,539 over the next decade. In the clinics, nurses were the medical personnel responsible for administering DOTS. In isolated rural areas, the program recruited local leaders to serve under the direction of the nursing staff to administer the treatment and follow up with patients.

Mexico's Education, Health, and Nutrition Program (originally known as PROGRESA, but now called "Oportunidades") also provides a compelling example of how a program can use demand-side incentives to stimulate demand for basic health care services. The program offers cash transfers to families in exchange for the attendance of mothers and children age five and under at nutrition monitoring clinics and to pregnant women if they agree to prenatal care visits and nutritional supplementation. The program also includes cash transfers to promote school attendance and performance. A rigorous evaluation provided evidence of the program's effect on the use of health services: after just one year of implementation, attendance at health care clinics was significantly higher in participating localities. However, the increased demand for services was also met with significant improvements in the quality of services available through public providers. Health care providers in participating localities were paid more and

received more on-the-job training, and clinics benefited from a steadier flow of pharmaceutical and other supplies.

Summary. In sum, service-intensive interventions are highly transaction intensive, especially compared with product-intensive interventions. The more standardized the intervention, the more likely that it can be delivered by means of military-like campaigns in the same manner as product-intensive interventions, although the skill level of the health workers involved will need to be higher. If complications of treatment are possible—or if the intervention cannot easily be standardized—its deployment will likely require fairly elaborate systems of outreach and referral. Although recent scholarship has strongly encouraged the use of demand-side mechanisms, particularly in an effort to address quality concerns in public sector service provision, evidence from the cases highlighted in this chapter suggests that a variety of modalities are possible and that a mix of supply- and demand-side incentives may even be desirable.

Behavioral Change Interventions

Behavioral change interventions (box 8.3) are designed to induce or encourage an individual behavior change or habit modification to achieve specific health goals. The focus is usually on prevention, but need not be exclusively so—for example, the use of oral rehydration therapy to treat childhood diarrhea. Behavioral change interventions are often linked to the uptake of a specific product, as in the case of condoms and insecticide-treated bednets. However, unlike product-intensive interventions, behavioral change interventions require active participation by the individual and cannot be passively received in the form of an injection or supplement. Also, unlike service-intensive interventions, behavioral change interventions do not depend on the involvement of a health care professional on an ongoing basis. Illustrative examples include the uptake of oral rehydration therapy for use by mothers in the home, not the clinic; face washing to prevent trachoma; and condoms to prevent HIV infection or other sexually transmitted infections.

As Jamison (2002) notes, some changes in behavioral practices associated with improved health, such as improved

hygiene and better nutrition, are linked to rising incomes, but the pathway for this link is not entirely clear, especially at the individual level, which makes it difficult to predict which mix of programs and policies can be used to change behavior at the population level. Information plays an important role, but the evidence suggests that its effect may be limited if it is not combined with other mechanisms to induce behavioral change.

The cases under review typically used a mix of strategies to induce behavioral change, including information, education, and communication (IEC) campaigns; regulatory policies; taxation or subsidies; and financial incentives or disincentives. The evidence is suggestive, but hardly conclusive, that a relative hierarchy exists among the available strategies and policy instruments and that some are more effective than others at altering how individuals perceive risk and weigh the costs and benefits of behavioral change. Chapter 11, for example, provides an in-depth discussion of how and when fiscal instruments may be used effectively to alter producers' and consumers' decisions in ways that encourage healthy behaviors.

Information, Education, and Communication. Recent studies have challenged the effectiveness of mass IEC campaigns (Kremer and Miguel 2003), and evidence from the cases appears to support a degree of healthy skepticism. However, IEC campaigns did appear to have an effect in the cases under review when they were accompanied by the promotion of a new technology or a product. Also, acceptability appeared to increase if the product was adapted to fit the local circumstances or cultural context. In Sub-Saharan Africa, educational campaigns to stop transmission of the guinea worm to humans have encouraged the construction and maintenance of safe water sources (through deep-well digging and the application of larvicide to contaminated ponds) and the use of cloth or nylon filters to purify drinking water, in addition to case identification and containment. The primary IEC tool was so-called worm weeks—that is, weeks of intensive health education and community mobilization.

In Egypt, in addition to nurses and physicians, mothers were a primary target of the campaign to promote the use of oral rehydration salts for the treatment of diarrhea in children, especially those under three years of age. Television was the primary educational medium and proved to be an effective strategy for reaching a broad population base, including rural, illiterate households. Appropriate product design and branding were essential. Oral rehydration salt packets were supplied in a 200-milliliter size, not the standard 1-liter packs, because mothers did not have appropriate containers at home and felt that a full liter was too much to give to a child to drink. By contrast, in Bangladesh, where few households had access to a radio, much less a television, health workers went door to door to teach mothers how to make the solution in their homes.

In these cases, the targeted population not only was aware of the health care problem, but also was eager to adopt solutions to address it. Clearly this situation does not always prevail, but a reasonable conclusion is that a relatively simple technology that addresses a recognizable, but as yet unmet, need will find a receptive audience. In Bangladesh, a mass media campaign to encourage families to have fewer children was backed up by a large cadre of female outreach workers, who went door to door in rural areas to provide information to young married women and to make family-planning commodities available to them. Market research indicates that almost all Bangladeshi women were in favor of family planning but were unable to go against their husbands' objections if they were opposed to the use of contraceptives. The fact that the campaign and the provision of contraceptive commodities addressed an unmet need among Bangladeshi women may provide a partial explanation for the rapid acceptance of the program when it was launched on a large scale.

Regulatory Policies. By contrast, other behavioral changes, such as using condoms to prevent HIV infection and other sexually transmitted infections and stopping smoking, have clearly been harder to induce, although the precise reasons for this difficulty remain elusive (see, in particular, chapters 18 and 46). Nevertheless, evidence from the cases suggests that governments can put the right mix of policies in place to either discourage high-risk behaviors or encourage health-promoting behaviors. For example, they may use regulatory policies to ensure compliance through nonfinancial means and may complement these by using fines and sanctions as an enforcement mechanism.

The Thai government's 100 Percent Condom Program is an excellent example of such a strategy. In 1991, the National AIDS Committee launched a national program to be implemented at the provincial level requiring all workers in brothels and other commercial sex establishments to refuse to have sex with any client not using a condom. The program had several components, including free distribution of condoms to health workers during regular health checks and a media campaign to raise awareness of the risks of HIV and the dangers associated with unprotected sex. What gave the program its unique character was its regulatory and enforcement component. Local governments, health authorities, and police officers were responsible for monitoring and enforcing condom use in the brothels. Those brothels that failed to comply with the strict policy would be fined or forced to shut down. The results were impressive. Condom use in brothels exceeded 90 percent in just the first year of the program, up from 14 percent in 1989. The number of new HIV infections fell by more than 80 percent, from 142,819 cases in 1991 to 25,790 cases in 2001. Furthermore, the program appears to have generated important spillover effects, or externalities, in unexpected places. For example, studies

indicate that indirect sex workers—a group that cannot be reached through similar enforcement strategies—have also begun to insist that their clients use condoms.

Taxation and Subsidies. Another option for discouraging high-risk behaviors is the adoption of taxation policies. A 1997 study by the World Bank in partnership with the World Health Organization found that a price increase of 10 percent on cigarettes would lower smoking rates by about 4 percent in high-income countries and about 8 percent in low-income countries (Jha and Chaloupka 2000, 358). In South Africa, a 50 percent tax on the retail price of cigarettes contributed to a 30 percent decrease in consumption. In Poland, an increase in taxes on cigarettes from 30 to 47 percent of the retail price, in conjunction with other policies—including a ban on smoking in health care establishments, schools, enclosed spaces in the workplace, and elsewhere—contributed to a dramatic decline in smoking rates. Before the fall of communism, Poland had the highest cigarette consumption in the world, but by the end of the 1990s, there were 4 million fewer smokers compared with the previous decade, and cigarette consumption had fallen by 10 percent. These successes led to a 30 percent decrease in lung cancer among men age 20 to 44 and a 19 percent decrease among men age 45 to 64 over the same period.

The section on service-intensive investments has already discussed the remarkable power of explicit subsidies to encourage health-promoting behaviors. The Mexican case of PROGRESA offers a by now familiar example of such a strategy. Although none of the cases included in this study dealt with subsidies explicitly directed at behavioral change interventions, evidence suggests that they have a significant effect. However, as Nugent and Knaul discuss in chapter 11, poorly targeted subsidies can be costly, particularly relative to the result achieved. Much more research is needed in this area to understand the specific contexts in which subsidies can achieve their desired effects and their cost-effectiveness relative to other types of interventions.

Summary. In sum, behavioral change interventions differ from both product-intensive and environmental control interventions in that they require active participation by the individual for the intervention to be fully effective. In some cases, this requirement is also true for service-intensive interventions, but it is not as exclusively true as for behavioral change interventions. The degree to which incentives (or disincentives) are needed to induce (or discourage) behavior depends on the interaction between the usage characteristics of the intervention, the perceived risk of not using the intervention, and the perceived effectiveness of the intervention. To have an effect, policy incentives (and disincentives) must either succeed in changing the individual's risk-benefit assessment or make ignoring the policy extremely costly.

Environmental Control Interventions

As with behavioral change interventions, environmental control interventions are geared toward prevention and are used in conjunction with other treatments or alone when effective vaccines or other prophylaxes are unavailable. However, rather than focus on risk factors associated with individual behavior, environmental control interventions target risks associated with the physical environment that are largely beyond the individual's control. The *physical environment* refers to media in the natural (water, air, or soil) or man-made (housing, roads) environment. Examples of environmental control interventions include many vector control strategies, such as aerial and household spraying, water and sanitation projects, and air quality control measures. (See, in particular, chapters 41 and 43.)

Few of the cases reviewed for this study involved “pure” environmental control interventions; although in several cases environmental control measures were coupled with other types of interventions. Whenever activities involved in executing the intervention fall outside the realm of typical health care services, nonhealth government agencies will be involved, and strong political and technical leadership will be required of the ministry of health to ensure that proper attention is given to health care concerns during implementation.

Successful interventions in this category also appeared to be associated with strong multicountry partnerships, particularly in relation to vector control activities. This factor raises an interesting question concerning governments' capacity to engage in these types of partnerships. Technical capacity, although essential, is just the first hurdle, because what is ultimately required is a political and financial commitment at the highest levels in participating countries.

In the case of Chagas disease control, the Southern Cone Initiative brought together the seven countries in the endemic region under a coordinated, comprehensive, Chagas disease control strategy. This multicountry approach was led by the Pan American Health Organization, following the recognition that disease transmission from neighboring countries was threatening the health gains achieved under Brazil's national eradication plan. A central aim of the Southern Cone Initiative was to eliminate the protozoan parasite, *Trypanosoma cruzi*, in the region by coordinating technical efforts to detect and eliminate it. This coordination ensured consistent use of highly effective control measures across the region and limited any possibility of reinvasion. Infested homes throughout the region were treated with long-lasting pyrethroid insecticides and structurally improved to eliminate hiding places for the blood-sucking insects that spread the parasite. These coordinated environmental control efforts, combined with blood screening, proved to be highly successful at interrupting Chagas disease transmission in the region.

Environmental control interventions also appear to be characterized by many consecutive years of sustained activity. In

some cases, this activity may take the form of ongoing maintenance of filters and distribution systems to prevent recontamination. In other cases, as in the case of vectorborne disease control in which elimination or eradication is within reach, the intervention must be sustained at least until transmission has been interrupted in humans. (The intervention may need to be sustained for much longer, or indefinitely, if the disease has an animal host.) In the case of onchocerciasis, the lifetime of the filarial load is 14 years, and vector spraying would need to be sustained for at least 14 years to cut transmission. If reinvasions or native vector population growth are allowed to take hold before the human loads die off, transmission will occur and the disease will not be effectively controlled. The OCP in West Africa has demonstrated the effectiveness of a long-term commitment to vector control in reducing the burden of onchocerciasis. Since its inception in 1974, the OCP has used aerial spraying of blackfly breeding sites to control vector populations and interrupt transmission. The original OCP area remains free of onchocerciasis transmission following the withdrawal of regular spraying after 14 years. This sustained attention proved to be highly successful in eliminating onchocerciasis transmission and infection. Even after the introduction of ivermectin drug therapy to the program, vector control has remained a key strategy for maintaining health benefits in the expansion area of the OCP.

In sum, environmental control interventions are associated with intersectoral collaboration, multicountry partnerships, sustained activity, and attentiveness to context (for example, epidemiological conditions, patterns of disease transmission, and vector behavior). These factors place special capacity requirements on governments that may differ markedly from nonenvironmental interventions. Thus, to be effective, ministries of health must be capable of advocacy and influence within the broader structures of government.

Combination or Bundled Interventions

A two-front battle involving both prevention and treatment must be waged against most diseases and conditions to achieve the desired effect on morbidity and mortality. Under such circumstances, a combination or bundling of interventions is needed, adding an additional layer of complexity to the deployment of any particular intervention. An effective malaria control strategy, for example, demands effective distribution and uptake of insecticide-treated bednets (a behavioral change intervention) and rapid treatment of malaria symptoms through strong outreach and referral systems (a service-intensive intervention). Similarly, countries have adopted a dual approach to controlling the spread of HIV/AIDS: promoting safe sex practices (a behavioral control intervention) and supporting the scale-up of antiretroviral therapy (a service-intensive intervention). In this context, global partnerships

have a critical role to play in providing technical assistance to countries in formulating policies and developing strategic plans that are tailored toward their specific needs and capabilities.

Perhaps the most successful example of bundling interventions included in our study is the Moroccan National Blindness Control Program, launched in 1991. The program was based on the development in the mid 1980s of SAFE, a comprehensive strategy to treat and prevent trachoma. The philosophy of the new strategy, which was heavily researched and promoted under the support and guidance of the Edna McConnell Clark Foundation, was to augment the traditional medical approach to the treatment of trachoma with behavioral and environmental changes. The four main interventions the strategy recommended were surgery (service-intensive intervention); antibiotics (product-intensive intervention); face washing (behavioral change intervention); and environmental activities, including water and sanitation programs (environmental control intervention).

The program consisted of a wide-ranging partnership that included five government divisions: the Ministry of Health, the Ministry of National Education, the Ministry of Employment, the Ministry of Equipment, and the National Office for Potable Water. Targets were set—Morocco's political leaders were committed to eliminating trachoma by 2005—and the institutional and policy artillery to support the initiative was quickly put in place. Mobile surgical teams were deployed to small towns and villages to perform a simple, quick, and inexpensive procedure of the eyelid to halt corneal damage in infected patients; treatment campaigns were organized to distribute the newly discovered antibiotic, azithromycin, that could be administered in a single dose; IEC campaigns were launched at the community level with the participation of the Ministry of Education to educate the population about the causes of the disease and how to prevent it; and the National Office for Potable Water has expanded water and sanitation projects in many areas of the country. By 1999, prevalence levels had dropped 75 percent, from 28 to 6.5 percent, and acute infections in children had been reduced significantly.

CONCLUSION

The accumulation of evidence presented in this study should help allay any remaining doubts about whether existing technologies and interventions, proven to be cost-effective in randomized controlled trials, can be successfully deployed to improve the lives and health of people throughout the developing world. The evidence suggests not only that it is possible, but also that it has been achieved in many parts of the world, in many different socioeconomic and political settings.

The study also found important commonalities among programs and projects that appear to have contributed to the successful deployment and rapid scale-up of cost-effective

interventions. Strong leadership, effective management, realistic financing, country ownership, and application of new research findings and technical innovation all played a role in implementation and appeared to have made major contributions to the positive achievements of the cases under review.

In some respects, the study also presents a sobering view of the difficulties inherent in moving from a cost-effective intervention to a successful program or project. No single formula is available, and identification of unique characteristics and attributes that will permit the large-scale, effective deployment of many known interventions is difficult.

In addition, evidence from the case studies suggests that the programmatic characteristics and policies associated with successful outcomes vary depending on the type of intervention. Although no single formula exists, the implementation of the programs and projects structured around various types of interventions appears to depend on certain types of organizational, managerial, and financial capacities that can be anticipated and specifically targeted for strengthening before the full-scale launch of a program or project. Thus, the findings of this study may serve as pointers for future research seeking to understand the range of government capacities that are needed to support the successful deployment and scaling up of interventions in various contexts and in different parts of the world.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the helpful comments and feedback from Gerald T. Keusch, Phil Musgrove, John Peabody, and members of the What Works Working Group. Thanks also to Carol Kolb for providing excellent research assistance. The basic idea for the What Works Working Group, and for the material in this chapter, came principally from Richard Klausner, and we owe him special acknowledgment.

NOTES

1. Unless otherwise indicated, the background information and health impact data presented about the 17 cases reviewed for this study are drawn from Levine and What Works Working Group (2004). All materials are available at www.cgdev.org/publication/millionssaved.

2. According to *World Development Report 2004* (World Bank 2004), because the relationship between provider and client differs, each of the three types of service arrangements will experience a different constellation of market, government, and accountability failures. The report proposes that if these failures are properly addressed and client power

increases, the quality of service delivery will improve, especially among poorer groups.

Chapter 9

Millennium Development Goals for Health: What Will It Take to Accelerate Progress?

Adam Wagstaff, Mariam Claeson, Robert M. Hecht, Pablo Gottret,
and Qiu Fang

The scale of the diseases and conditions that the Millennium Development Goals (MDGs) address is staggering:

- Almost 11 million children died before their fifth birthday in 2000 (UNICEF 2001). Less than 1 percent of these 11 million deaths (79,000) occurred in high-income countries, compared with 42 percent in Sub-Saharan Africa, 35 percent in South Asia, and 13 percent in East Asia.
- In 1998, an estimated 843 million people were considered undernourished on the basis of their food intake (FAO 2000). Of the estimated 140 million children under the age of five who were underweight, almost half (65 million) were in South Asia.
- Of the 3.1 million people who died from HIV/AIDS in 2003, almost all (99 percent) were in the developing world—74 percent in Sub-Saharan Africa alone (UNAIDS 2004). Tuberculosis and malaria together killed an equal number; most of these deaths were among the poor.
- In 1995, 515,000 women died during pregnancy or childbirth: 1,000 in the industrial world, contrasted with 252,000 in Sub-Saharan Africa (UNICEF 2001).

This burden of death and suffering is heavily concentrated in the world's poorest countries (Wagstaff and Claeson 2004). Death and disease matter in their own right, but they also act as a brake on poverty reduction. Nobel laureate Amartya Sen (2002) has described health as one of “the most important conditions of human life and a critically significant constituent of human capabilities which we have reason to value.” Health also matters because it influences the living standards of both households and countries. Health expenses can easily become burdensome

for households. In Vietnam, they are estimated to have pushed 3 million people into poverty in 1993 (Wagstaff and van Doorslaer 2003).

Beyond the direct impact of ill health on households' living standards through out-of-pocket expenditures, it indirectly affects labor income through productivity and the number of hours that people can work. The effects of illness on income, which may take time to appear, are often long lasting. Malnourished children are less likely to attend school and less likely to learn when they do attend, reducing their productivity in later life. The devastating economic consequences of illness and death are evident at the macroeconomic level as well. The AIDS epidemic alone has been estimated to reduce rates of economic growth by 0.3 to 1.5 percentage points annually (Bell, Devarajan, and Gersbach 2003).

In the 1990s, the international community recognized the importance of health in development. In a period when overall official development assistance declined, development assistance to health rose in real terms. World Bank lending for health increased, with a doubling of the share of International Development Association disbursements going to health (OECD Development Assistance Committee 2000). The 1990s saw an increased global concern over the debt in the developing world, fueled in part by a perception that interest payments were constraining government health expenditures in developing countries. The enhanced Highly Indebted Poor Country Initiative, spearheaded by the International Monetary Fund and World Bank in response to the unsustainable debt burden of the poorest countries, was explicitly geared to channel freed resources into the health and other social sectors. The

Poverty Reduction Strategy Papers submitted by governments of developing countries seek debt relief or concessional (low-interest) International Development Association loans to set out their plans for fighting poverty on all fronts, including health.

The 1990s also saw the development of major new global health initiatives and partnerships, including the Joint United Nations Programme on HIV/AIDS (UNAIDS); the Global Alliance for Vaccines and Immunization; the Stop TB Partnership; the Roll Back Malaria Partnership; the Global Fund to Fight AIDS, Tuberculosis, and Malaria; and the Global Alliance for Improved Nutrition. A range of new not-for-profit organizations were set up to spur the accelerated discovery and uptake in developing countries of low-cost health technologies to address the diseases of the poor; these organizations included the International AIDS Vaccine Initiative, the Medicines for Malaria Venture, the Global Alliance for Tuberculosis, and the International Trachoma Initiative. In addition, the scale of philanthropic involvement in international health increased, with the launch of the Bill & Melinda Gates Foundation and the Packard Foundation and the continued attention to global health issues by such established entities as the Rockefeller Foundation. These initiatives brought not only new resources—funds, ideas, energy, and mechanisms—but also new challenges to harmonization in the attempt to coordinate and link global goals with local actions in the fight against disease, death, and malnutrition in the developing world.

As the 1990s closed, the international community decided that even more needed to be done. At the United Nations Millennium Summit in September 2001, heads of 147 states endorsed the MDGs, nearly half of which concern different aspects of health—directly or indirectly (box 9.1). Several other

goals are indirectly related to health—for example, the goals on education and gender. Gender equality is considered important to promoting good health among children. Other health outcomes than those included in the MDGs measure progress on health—for example, targets related to noncommunicable diseases. These targets are referred to as the *MDG plus* and are included in national priority setting, especially in many middle-income countries.

THE MILLENNIUM DEVELOPMENT GOALS FOR HEALTH: PROGRESS AND PROSPECTS

Of the MDGs for which trend data are available or estimated, the fastest progress has been on malnutrition, whereas overall progress on under-five mortality and maternal mortality has been slower.

A Mixed Score at Halftime

In-depth analysis of the health-related MDGs shows a mixed score at halftime (Wagstaff and Claeson 2004):

- The number of people living in on-track countries (countries that will reach the MDGs if they maintain the rate of progress they have already achieved during the period from 1990 to the present) matters. For the malnutrition target, 77 percent of the developing world's people live in an on-track country, but in Sub-Saharan Africa only 15 percent of the people live in an on-track country.
- Different indicators show different levels of improvement. For under-five mortality, the developing world was reduced by an average of only a 2.5 percent in the 1990s, well short of the target of 4.3 percent.

Box 9.1

The Health-Related Millennium Development Goals

Goal 1—eradicating extreme poverty and hunger. This goal includes as a target the halving between 1990 and 2015 of the proportion of people who suffer from hunger, with progress to be measured in terms of the prevalence of underweight children under five years of age. The target implies an average annual rate of reduction of 2.7 percent.

Goal 4—reducing child mortality. The target is to reduce by two-thirds between 1990 and 2015 the under-five mortality rate, equivalent to an annual rate of reduction of 4.3 percent.

Goal 5—improving maternal health. The target is to reduce by three-quarters between 1990 and 2015 the maternal

mortality ratio, equivalent to an annual rate of reduction of 5.4 percent.

Goal 6—combating HIV/AIDS, malaria, and other diseases. The target is to halt and begin to reverse the spread of these diseases by 2015.

Goal 7—ensuring environmental sustainability. This goal includes as a target the halving by 2015 of the proportion of people without sustainable access to safe drinking water.

Goal 8—developing a global partnership for development. This goal includes as a target the provision of access to affordable essential drugs in developing countries.

Source: United Nations Millennium Declaration, the United Nations Millennium Summit 2000.

- Regional differences are also pronounced, with Sub-Saharan Africa faring worse than other regions. In Africa, trends in reducing under-five mortality and underweight in children were barely above zero during the 1990s, and maternal mortality fell on average by just 1.6 percent a year compared with the annual target rate of 5.4 percent.
- Evidence on how the poor are faring within countries is mixed. For malnutrition, the poorest 20 percent of the population within countries appears, on average, to have been experiencing broadly similar rates of reduction to the population as a whole. However, for under-five mortality, the rate has been falling more slowly among the poor, while better-off families are seeing faster rates of progress.

Will the Second Half Go Better?

As a comparison of the child mortality experiences in the 1980s and 1990s demonstrates, past performance is not necessarily a good predictor of future performance. The fact that a country is on track on the basis of its performance in the 1990s does not guarantee that it will maintain the required annual rate of reduction of malnutrition or mortality during the second half of the MDG “window” from 2000 to 2015. Countries currently off track may possibly get on track in the second half if they can combine good policies with expanded funding for programs that address both the direct and the underlying determinants of the health-related goals.

Stimuli External to the Health Sector. The World Bank estimates that economic growth will fall somewhat in East Asia and the Pacific in 2000–15, turn from negative to positive in Europe and Central Asia as well as Sub-Saharan Africa, and increase somewhat in Latin America and the Caribbean, the Middle East and North Africa, and South Asia (Jones and others 2003). Primary education completion rates will probably grow faster in the new millennium as a result of the global education initiatives and partnerships on Education for All and the Fast-Track Initiative. However, higher rates of educational attainment among women of childbearing age will not be achieved until 2005 or so, and even then the first full round of effects on under-five mortality will not be felt until 2010.

More relevant is the fact that gender gaps in secondary education may well narrow faster in the new millennium than in the 1990s as a result of the gender MDG (Goal 3: Eliminate gender disparity in primary and secondary education by 2005 and in all levels of education no later than 2015). To achieve parity with boys by 2015 in the proportion of the population who are age 15 and have completed secondary education, girls will have to achieve a faster growth in completion rates in the new millennium than in the 1990s in most regions, especially in South Asia and in East Asia and the Pacific. If the water MDG (ensuring that households have access to safe drinking water) is to be reached, access rates will need to grow much

faster in 2000–15, especially in Sub-Saharan Africa (Wagstaff and Claeson 2004). Gender equality in school and access to clean water will have a positive effect on progress toward the health MDGs. Even with economic growth and faster progress on these nonhealth goals, however, many regions will still miss many of the health targets. The picture is bleakest for under-five mortality—and for Sub-Saharan Africa.

The Goals Matter for All Countries. These goals need to be taken seriously for three main reasons:

- Faster progress is important even if targets are missed. A key message of this chapter is that progress can be accelerated in all countries through a judicious mix of spending and policy and institutional reform.
- The goals facilitate benchmarking and monitoring of results. Because the goals focus on a limited set of outcomes, monitoring and evaluating progress toward the MDGs can show what is achievable and where faster progress can be made.
- Focusing attention on national progress, as measured by distributional analysis of the MDGs, forces countries to consider how the benefits of progress are distributed among the rich and poor within each country—the poor risk being left behind even in countries making progress overall. One limitation of the MDGs and targets is that they are national averages. However, distributional analysis of MDG trends (Wagstaff and Claeson 2004) reminds us that progress needs to be for everyone, not just the better off. Progress has been uneven, with the poorer countries lagging behind the rest, and for under-five mortality, the poor within countries are lagging behind the rest of the population.

SCALING UP: DEFINING INTERVENTIONS AND REMOVING CONSTRAINTS

A lack of interventions is not the primary obstacle to faster progress toward the goals, although new interventions that can be delivered by weak health systems could greatly improve progress—for example, malaria or HIV vaccines and effective vaginal microbicides to block the spread of HIV and other sexually transmitted infections. The main obstacle is the low levels of use—especially among the poor—of existing effective interventions. For example, if use of all the proven effective preventive and treatment interventions for childhood illness were to rise from current levels to reach all, the number of under-five deaths worldwide could fall by as much as 63 percent (World Bank 2003b).

Array of Interventions, Programs, and Service Modalities

The available interventions constitute a powerful arsenal for preventing and treating the main causes of malnutrition and death (table 9.1).¹ The major diseases and conditions that the MDGs aim to prevent and control are discussed in several

Table 9.1 Effective Interventions to Reduce Illness, Deaths, and Malnutrition

MDG	Preventive interventions	Treatment interventions
Child mortality	Breastfeeding; hand washing; safe disposal of stool; latrine use; safe preparation of weaning foods; use of insecticide-treated bednets; complementary feeding; immunization; micronutrient supplementation (zinc and vitamin A); prenatal care, including steroids and tetanus toxoid; antimalarial intermittent preventive treatment in pregnancy; newborn temperature management; nevirapine and replacement feeding; antibiotics for premature rupture of membranes; clean delivery	Case management with oral rehydration therapy for diarrhea; antibiotics for dysentery, pneumonia, and sepsis; antimalarials for malaria; newborn resuscitation; breastfeeding; complementary feeding during illness; micronutrient supplementation (zinc and vitamin A)
Maternal mortality	Family planning (lifetime risk); intermittent malaria prophylaxis; use of insecticide-treated bednets; micronutrient supplementation (iron, folic acid, calcium for those who are deficient)	Antibiotics for preterm rupture of membranes, skilled attendants (especially active management of third stage of labor), basic and emergency obstetric care
Nutrition	Exclusive breastfeeding for 6 months, appropriate complementary child feeding for next 6–24 months, iron and folic acid supplementation for children, improved hygiene and sanitation, improved dietary intake of pregnant and lactating women, micronutrient supplementation for prevention of anemia and vitamin A deficiency for mothers and children, anthelmintic treatment in school-age children	Appropriate feeding of sick child and oral rehydration therapy, control and timely treatment of infectious and parasitic diseases, treatment and monitoring of severely malnourished children, high-dose treatment of clinical signs of vitamin A deficiency
HIV/AIDS	Safe sex, including condom use; unused needles for drug users; treatment of sexually transmitted infections; safe, screened blood supplies; antiretrovirals in pregnancy to prevent maternal to child transmission and after occupational exposure	Treatment of opportunistic infections, co-trimoxazole prophylaxis, highly active antiretroviral therapy, palliative care
Tuberculosis	Directly observed treatment of infectious cases to prevent transmission and emergence of drug-resistant strains and treatment of contacts, Bacillus Calmette-Guérin immunization	Directly observed treatment to cure, including early identification of tuberculosis symptomatic cases
Malaria	Use of insecticide-treated bednets, indoor residual spraying (in epidemic-prone areas), intermittent presumptive treatment of pregnant women	Rapid detection and early treatment of uncomplicated cases, treatment of complicated cases (such as cerebral malaria and severe anemia)

chapters (for example, see chapters 15, 19, 21–24, 28–31, 44, and 45). The most cost-effective interventions and programs are also discussed in several chapters (see chapters 59–62 and 65). The chapters dealing with health systems and service delivery issues and other constraints related to the health MDGs are found in the latter part of the book (see chapters 66–68, and 73).

In the case of child mortality, for example, diarrheal diseases, pneumonia, and malaria account for 52 percent of deaths worldwide (World Bank 2003b). For each of these major causes of childhood mortality, at least one proven effective preventive intervention and at least one proven effective treatment intervention exist, capable of being delivered in a low-income setting. In most cases, several proven effective interventions exist. For diarrhea—the second-leading cause of child deaths—no fewer than five proven preventive interventions and three proven treatment interventions are available.

Effective Interventions Reaching Too Few People

The high rates of malnutrition and death in the developing world have several causes. First, people do not receive the effec-

tive interventions that could save their lives or make them well nourished. In middle- and high-income countries, 90 percent of children are fully immunized, more than 90 percent of deliveries are assisted by a medically trained provider (that is, a doctor, nurse, or trained midwife, excluding traditional birth attendants), and more than 90 percent of pregnant women have at least one prenatal visit (UNICEF 2001). In South Asia, fewer than 50 percent of pregnant women receive a prenatal checkup, and only 20 percent of deliveries are assisted by a trained provider.

The story is similar for other childhood interventions—and for interventions for other goals. Condom use to prevent transmission of HIV is low in much of Sub-Saharan Africa and South Asia, and inexpensive one-time treatment with antiretroviral medicine to prevent transmission from mother to child covers only a small fraction of at-risk pregnant women in most of the developing world. In Asia, where more than 7 million people are living with HIV/AIDS, no country has yet exceeded 5 percent antiretroviral therapy coverage among those who could benefit from it (World Bank 2003c).

Just as shortfalls in coverage vary across countries, so do they vary within countries, with the poor and other deprived groups consistently lagging. These groups are less likely to receive full basic immunization coverage, to have their deliveries attended by a trained provider, and to have at least one prenatal care visit to a medically trained provider. On the positive side, the poor are often making fastest progress in coverage, reflecting in part that the better off already have high coverage rates for many interventions.

Underuse of Effective Interventions Costs Lives

The low use of effective interventions—in the developing world in general and among the poor in particular—translates into rates of mortality, morbidity, and malnutrition that are far higher than necessary. If use of all the proven effective childhood preventive and treatment interventions, for example, were to rise from their current levels to 99 percent—95 percent for breastfeeding—the number of under-five deaths worldwide could fall by as much as 63 percent (Jones and others 2003). Deaths from malaria and measles could be all but eliminated, and deaths from diarrhea, pneumonia, and HIV/AIDS could be reduced dramatically. If coverage rates of the key maternal mortality interventions were increased from current levels to 99 percent, an estimated 391,000 maternal deaths worldwide (74 percent of current maternal deaths) might be averted (Ramana 2003). One intervention stands out as especially important: access to essential obstetric care, which accounts for more than half the maternal deaths averted.

WHAT DO COUNTRIES NEED TO DO?

If the lack of interventions is not holding countries back from achieving the goals, what is? What do countries need to do to make progress toward the MDGs?

In countries with good governance, additional government health spending does reduce child mortality (Rajkumar and Swaroop 2002). Development assistance has a stronger effect in countries with strong policies and institutions than in countries with only average-quality policies and institutions—and an insignificant effect in countries where policies and institutions are weak. This assertion is also consistent with the findings of a study undertaken by the World Bank for the MDG report, *The Millennium Development Goals for Health: Rising to the Challenges* (Wagstaff and Claeson 2004). The study includes other outcomes with child mortality and uses the World Bank's Country Policy and Institutional Assessment index to measure the quality of policies and institutions.

In principle, well-governed countries with good policies and institutions could achieve the goals simply by scaling up their expenditures on existing programs in proportion to current

allocations. In practice, however, the amount of extra spending required would be difficult to attain on present trends and would even be prohibitively expensive. In the case of East Asia and the Pacific, for example, if economic growth proceeds as expected and the other relevant Millennium Development Targets are attained, the region would achieve the required rates of reduction of underweight and maternal mortality—assuming that economic growth is accompanied by the development of appropriate human resources for health—even if government health spending continues to grow at its current rate. However, the region would miss the under-five mortality target. To reach that target, a minimum of 5 percentage points would need to be added to the annual rate of growth of the government health share of gross domestic product (GDP). That would take the projected share of GDP spent on government health programs to 3.7 percent in 2015—more than twice what it would be if the 1990s pattern of growth continued (Wagstaff and Claeson 2004).

In Sub-Saharan Africa, the situation is even starker. Even if faster economic growth materializes and the other targets are achieved, the share of government health spending in GDP would need to grow nearly sixfold over the coming decade, taking the share to 12.2 percent of GDP in 2015. This percentage compares with a 2000 figure of 1.8 percent and a 2015 forecast of 2.2 percent based on the 1990s annual growth in government spending for health. In conclusion, African countries will not be able to reach the MDGs simply by multiplying their health spending along the lines of historical expenditure patterns, because the multiples required are beyond any realistic expectation of what these governments will be able to do during the next 10 years.

What Are the Implications?

Poorly governed countries cannot expect to make much progress toward the MDGs simply by scaling up their expenditures on existing programs in proportion to current allocations. Although well-governed countries could, in principle, simply scale up existing spending to reach the targets, this option is unlikely to be affordable for them or their donors.

This situation has two implications:

- First, targeting additional government spending to activities that will have the largest effect on the MDGs is important for both sets of countries.
- Second, building good policies and institutions is important for all countries: doing so increases the productivity not just of additional spending but also of existing spending commitments. What do better policies and institutions entail in the health sector? Health systems are very broad, and weak policies and institutions can arise at several points along the pathway, from government health spending to health

outcomes (Claeson and others 2001). Countries can do a number of things, with help from donors, to build stronger policies and institutions.

Improving Expenditure Allocations and Targeting

In most countries, government spending gets stuck in the cities and disproportionately accrues—in a financial sense—to people who are better off.

Geographic Targeting. Resource allocation formulas can be used to reduce government spending gaps across regions and ideally to favor geographic zones that are furthest behind. These formulas have been used, for example, as part of Bolivia's decentralization efforts since 1994 and have been associated with some large—and pro-poor—improvements in maternal and child health indicators. Targeting resources to poor regions and provinces may be most effectively implemented through nontraditional mechanisms for priority setting and implementation, such as social investment funds. In Bolivia, a recent impact evaluation concluded that such funds were responsible for a decline in under-five mortality from 88.5 to 65.6 per 1,000 live births over a five-year period (Newman and others 2002).

Changing the Allocation of Spending across Care Levels. Spending on health in developing countries is characterized by a high concentration of spending on secondary and tertiary infrastructure and personnel. Some governments have tried to scale back the share of hospital spending. Tanzania, for example, reduced the share of hospital spending from 60 percent in 2000 to 43 percent in 2002. Chapter 3 deals with the issue of how to couple expenditure reallocations across levels of care with measures to improve performance at each level of the health care system.

Targeting Specific Programs. Programs such as those delivering directly observed treatment short course (DOTS) for tuberculosis or integrated management of infant and childhood illness (IMCI) for child health are good examples of programs that may yield high returns to government spending at the margin. A recent World Bank study in India provides further support for the idea that the way government spending is allocated across programs makes a difference to its effect on the Millennium Development Indicators (World Bank 2003a). Successful public health programs—large-scale programs with a measurable health effect over at least a five-year period—are further discussed in chapter 8. All successful programs have several factors in common: technical innovation and stakeholder consensus, strong political leadership, coordination across agencies and management, effective use of information and financial resources, and participation of the beneficiary community.

Targeting Specific Population Groups. Many countries subsidize all government health services for everyone. These blanket subsidy schemes not only fail to target interventions that give rise to externalities but also fail to disproportionately benefit the poor—despite the stronger equity case for subsidizing their care and the fact that they tend to bear a disproportionate burden of malnutrition as well as child and maternal mortality. There are many proven ways to target the poor—for example, by delivering essential services in clinics or health posts that only poor families attend or by promoting and delivering services in a way that segments the market and appeals to those in low-income households.

Targeting Spending to Remove Bottlenecks. A planning and budgeting approach is to assess—for a country—the health sector impediments to faster progress, to identify ways of removing them, and to estimate both the costs of removing them and the likely effects of their removal on MDG outcomes (Soucat and others 2002). MDG analysis along these lines—referred to sometimes as *marginal budgeting for bottlenecks* (MBB)—has begun in several African countries and in some states of India (UNICEF and World Bank 2003). In Mali, key bottlenecks were identified for supporting home-based practices and delivering periodic and continual professional care. They included low access to affordable commodities and the need for community-based support for home-based care; low geographical access to preventive professional care (immunization, vitamin A supplementation, and prenatal care); shortages of qualified nurses and midwives; and an absence of effective third-party payment mechanisms for the poor for professional continuous care. Important health systems bottlenecks, such as human resources, drug availability, and health care management, are discussed in chapters 71–73.

Improving Policies toward Households as Producers and Demanders of Care

Households are at the center of any efforts to scale up; they not only demand and consume care, but they are also important producers of prevention and care. Policies to increase coverage of cost-effective interventions to reach the health MDGs, therefore, need to identify and influence the key constraints to both the production and the demand for those services at the household and community levels.

Lowering Financial Barriers. Low income is a barrier to the use of most health interventions, and economic growth is an important weapon in the war against malnutrition and mortality. However, social protection programs are also important. Successful schemes aimed at households and communities are discussed in chapter 56.

One part of the affordability equation is price. User charges for MDG interventions are to be discouraged. Why? Many of those interventions involve benefits that spill over to people who do not receive the intervention; high coverage of immunization is a classic example. However, an equity case also can be made for reducing prices facing the poor and near poor, even where no spillovers occur. Subsidies should be targeted to services with spillovers and to the poor. In practice, subsidies are often badly targeted in at least one respect if not both. Exceptions exist. In Ifakara, Tanzania, a voucher program for mosquito nets was launched successfully for pregnant women and children under five (Schellenberg and others 2001).

Some recent programs, especially in Latin America, have not only made health care affordable for the poor but have also made it profitable. Rather than simply reducing the cost of using specific interventions, these programs provide users with cash payments, which are linked to specific interventions and restricted to certain groups—often poor mothers and their children. The experience with these programs in targeting and achieving results is encouraging (Mesoamerica Nutrition Program Targeting Study Group 2002; Morris and others 2003; Palmer and others 2004).

Risk aversion coupled with the unpredictability of illness provides a motivation for pooling risks through an insurance scheme. The Arab Republic of Egypt, for example, introduced a school health insurance program for all children attending school. The program resulted in larger increases in coverage among the poor and achieved considerable effect on use and out-of-pocket expenditures (Yip and Berman 2001). However, insurance in the developing world is very limited, and those who are least able to smooth consumption without insurance are the least likely to have insurance coverage (Musgrove, Zeramdini, and Carrin 2002). Another problem is that many of the schemes are small scale, and evaluations of these schemes do not generally measure health effect or effect on equity, thus resulting in limited evidence (Palmer and others 2004).

Providing Information—Enhancing Knowledge. Lack of knowledge is a major factor behind poor health. It results in people not seeking care when needed, despite the absence of price barriers, and it also results in people—especially poor people—wasting limited resources on inappropriate care. Ignorance may also result in people not getting the maximum health gain out of inputs they have available to them and use. Many people do not know that hand washing confers much of the health benefit of piped water (see chapter 41). Not surprisingly, piped water has a much greater effect on the prevalence of diarrhea among the children of the better off and better educated. Better-educated women—especially those with a secondary education—achieve better health outcomes for themselves and their children not by using health-specific knowledge that they acquire at school, but by using general

numeracy and literacy skills learned at school to acquire health-specific knowledge later in life. Although better-educated girls will mean healthier women and healthier children in years to come, a shorter and more direct route to increasing health-specific knowledge and skills is through information dissemination, health promotion, and counseling in the health sector.

Several success stories exist. In Brazil, after health workers trained by IMCI provided information and counseling at health facilities and in the community, health knowledge among mothers improved, as did feeding practices (Santos and others 2001). After only 18 months, the nutritional status of children in the area improved as well. Social marketing and media campaigns—for example, malaria and social marketing of insecticide-treated nets (see chapter 21)—have also proved effective in some circumstances.

Reducing Time Costs Transportation systems, road infrastructure, and geography influence the demand for care delivered by formal providers through their effect on time costs, which can be substantial. In rural communities, where the roads are poor and the transportation unreliable, the time spent waiting for the transportation is also a major cost. Time costs tend to be a major issue for maternal mortality: health centers are unable to provide essential obstetric care for a complicated delivery, and women would have to travel to distant hospitals to get such services. Road rehabilitation and other transportation projects are important here, but so are subsidies linked to the use of health services. Malaysia and Sri Lanka provide free or subsidized transportation to hospitals in emergencies (Pathmanathan and others 2003). Other options for tackling inaccessibility include using outreach and establishing partnerships between government and nongovernmental organizations (NGOs), private providers, or community organizations.

Providing Access to Water and Sanitation The availability of adequate supplies of water and improved sanitation is associated with better maternal and child health outcomes, at least among the better educated, even after controlling for other influences. This result is not altogether surprising. Hand washing is easier if the household has piped water that provides readily available quantities of safe water. The safe disposal of feces is easier if the household has an improved form of sanitation. The developing world lags well behind the industrial world in both; the poorer people fare especially badly. They are less likely to be connected to a network, and the sources they rely on tend to be more costly per liter than the networked services used by the better off.

The challenge from a health perspective is to get maximum health benefits from investments in access to water and sanitation infrastructure. Efforts to work across sectors on water and health, in order to influence the health MDGs, are under way in Ethiopia, Peru, and Rwanda.

Improving Health Service Delivery

Health providers—in the public and private sectors, as well as in both formal and informal sectors—should deliver interventions of relevance to the MDGs. Many are efficient, deliver high quality services, and are responsive to their patients. Many, however, are not; many are not even there to deliver any services at all. As a result, resources—public and private—are often nonexistent, underused, or wasted.

Two things can make a difference. One is the quality of management. Better management means a clearer delineation of responsibilities and accountabilities inside organizations, a clearer link between performance and reward, and so on. Management means getting accountabilities right within an organization. The other thing that can make a difference is getting accountabilities right between the organization and the public (World Bank 2003d).

Improving Management—Increasing Accountability within Provider Organizations. Management styles in government-funded and government-implemented health schemes have recently begun to change, focusing on performance—that is, on outputs and outcomes—rather than on inputs and processes. Good performance is rewarded, financially or in some other way. The focus is on clients and on the belief that an organization is ultimately accountable to its clients. A client-oriented strategy emphasizes customer choice and satisfaction. Business techniques enhance performance and are a standard part of strategic planning.

This new approach is evident in several countries, and elements of the approach are visible in successful nutrition and child health programs (see chapter 56). For example, in Tamil Nadu's Integrated Nutrition Program, community nutrition workers were given clearly defined duties. Information on outputs not only enabled the community to keep the workers accountable but also enabled the nutrition workers to see how their program was working. In Ceara's Programa de Agentes de Saude, which is credited with a substantial reduction in child mortality (Victora and others 2000), health agents and nurse-supervisors were assigned clear tasks and given clear responsibilities. The intended outcomes of the program were emphasized to health workers and members of the public, and the health agents were held accountable through community-based monitoring and rewarded for good performance.

Governance. The accountability of provider organizations to the public can be improved through enhanced governance or contracting. Having community representatives participate in the governance and oversight of providers can improve the productivity and quality of public sector providers. In Burkina Faso, participation of community representatives in public primary health care clinics increased immunization coverage, the availability of essential drugs, and the percentage of

women with two or more prenatal visits. In Peru, comparisons of primary health care clinics with and without community participation in governance suggested decreases in staff absenteeism and waiting times and suggested increases in perceived quality by patients (Cotlear 1999). The approach probably works best for primary care and in situations in which strong technical and advisory support is provided to community representatives who are close to the service being delivered.

Contracting. Evidence on the effect of contracting within the public sector is mixed, and the experiences are mainly based on lessons learned from middle-income countries. In several countries in Europe and Central Asia, evidence shows a positive effect from performance-based payment, but that is not necessarily the same as contracting, which can occur without performance-related pay. The best evidence relates to the use of target payments for the attainment of a given level of coverage—for example, for immunization or cervical cytology at the primary care level (Langenbrunner 2003). In Argentina and Nicaragua, social security institutes have increased productivity by establishing capitation-based payments for an integrated package of inpatient and ambulatory services (Bitran 2001). Key influences on the success of contracts within the public sector include whether the provider has the ability to respond, whether service commitments are congruent with funding levels, whether output and key components of performance expectations are easily measurable, and how far capacity strengthening of the payer or funder is addressed.

Contracting with nonprofit organizations is most common in low-income countries (see chapter 12, which contains a longer discussion of contracting with NGOs). Most cases have had positive effects on target outcome or output variables. In Bangladesh, contracts with nonprofit organizations for planning and implementing an expanded program on immunization project were credited with a dramatic increase in immunization. In Haiti, contracting for a primary health care package also significantly increased immunization coverage (Eichler, Auxilia, and Pollock 2001). In Bangladesh, Madagascar, and Senegal, significant reductions in nutrition rates were attributed to contracting initiatives (Marek and others 1999). Only a few cases assess efficiency. Contracting with nonprofits works best when the contractors have well-functioning accountability arrangements and strong intrinsic motivation and when the government makes timely payments to the NGOs. The government needs to be capable of assessing, selecting, and managing the ongoing relationship with contractors. The methodological quality of evaluating contracting is often poor and needs to be improved. An exception is the Cambodian contracting trial that used a rigorous cluster randomized design, but the intervention groups had greater input of resources than the control communities, which may have been partly responsible for the difference in performance.

Results on contracting with for-profit private service providers are also mixed. Experience from the hospital sector warns that weak government contracting capacity often allows the provider to capture efficiency gains or to expand volume—not necessarily of cost-effective services—to generate more income. In Zimbabwe, the cost per service decreased, but the lack of volume control led to an increase in total cost (McPake and Hongoro 1995). Other adverse outcomes are possible. In Brazil, contracting with for-profit hospitals led to increases in access, but also increases in fraud (false billing) and cream-skimming to avoid costly patients (Slack and Savedoff 2001). These problems seem less pronounced in primary health care. In Peru and El Salvador, contracting with private primary health care providers increased access, choice, and consumer satisfaction (Fiedler 1996). Contracting with for-profit providers seems to work best when the government invests in the development of capacity to manage the contracting process (Mills, Bennett, and Russell 2001); when quality is at least as high in the private sector as in the public sector; and when the services involve primary care or other relatively observable services, such as diagnostic services.

Strengthening Core Public Health Functions

Vulnerable populations need to be protected from risks and damages, informed, and educated. Public health regulations need to be established and enforced. Infrastructure needs to be in place to reduce the impact of emergencies and disasters on health. All this action needs to be implemented through a public health system that is transparent and accountable. Governments in developing countries generally recognize that these public health functions are important, but they often lack the capacity and financial resources to implement them. Indeed, few low-income countries invest in these public health functions.

By employing public health professionals with core public health competencies, the government can develop and enforce standards; can monitor the health of communities and populations; and can emphasize health education, public information, health promotion, and disease prevention. Public action can help improve consumer knowledge and change attitudes so that private markets can operate effectively to meet the needs of the poor, for example, through social marketing of insecticide-treated bednets to reduce malaria transmission or of condoms for protection against HIV/AIDS.

Government-Led Monitoring and Evaluation. Integrated disease surveillance, program assessment, and collection and analysis of demographic and vital registration data are essential if governments and donors are to ascertain whether policies and programs are positively affecting health goals. Governments can use a list of intermediate indicators and

proxies for the goals that can help monitor progress, test the impact of policies, and adjust programs going forward (World Bank 2001). Such indicators should be simple, easily measurable, representative, easy to understand, scientifically robust, and ethical. They need to be assessed regularly because the MDGs themselves are difficult to collect, thus entail delays, and are therefore not useful for regular monitoring of progress. Greater investments are needed in systems to monitor these intermediate indicators and to track expenditures on public health.

Although some good practices in surveillance are being developed—for example, in Brazil, China, and India—few low-income developing countries can afford to invest in the infrastructure required for strong surveillance systems. Most rely on alternative short- to medium-term solutions for data gathering, such as intermittent household surveys, health facility surveys, and simplified facility-based routine reporting. A few countries have made special efforts to improve the surveillance of a specific intervention, such as AIDS and tuberculosis treatment or childhood immunization, whereas others have attempted to monitor progress toward a specific MDG. INDEPTH (International Network of Field Sites with Continuous Demographic Evaluation of Populations and Their Health in Developing Countries), which is supported by the Rockefeller Foundation with help from other donors, coordinates a range of surveillance sites, many of them in Africa, and the Health Metrics network aims at improving the quality of surveillance data. Some governments are explicitly developing or modifying their monitoring and evaluation framework to focus on the MDGs.

Intersectoral Actions—Going Beyond the Ministry of Health. A review of the evidence base for the key determinants of the health and nutrition MDGs identifies significant potential for intersectoral synergies (Wagstaff and Claeson 2004).

Transportation Although roads and transport are vital for health services, especially for reducing maternal mortality, it is not just the physical infrastructure that matters. Also important are the availability of transportation and the affordability of its use, as shown in a study in Nigeria (Eissen, Effenne, and Sabitu 1997). Transportation and roads complement health services. A 10-year study in Rajasthan, India, found that better roads and transportation helped women reach referral facilities, but many women still died because no corresponding improvements took place at household and facility levels. Working with the transportation sector is also important for reducing HIV transmission in many settings and making progress on the HIV/AIDS-related MDG.

Hygiene Improved hygiene (use of hand washing) and sanitation (use of latrines and safe disposal of children's stools) are at least as important as drinking water quality in shaping health

outcomes, specifically in reducing diarrhea and associated child mortality (Esrey and others 1991). Constructing water supply and sanitation facilities is not enough to improve health outcomes; sustained human behavior change must accompany the infrastructure investment. By collaborating with other sectors, the health sector can develop public health promotion and education strategies and implement them in partnership with agencies that plan, develop, and manage water resources. The health sector can also work with the private sector to manufacture, distribute, and promote affordable in-home water purification solutions and safe storage vessels—and advocate for water, sanitation, and hygiene interventions in strategies to reduce poverty.

Indoor Air Quality Indoor air pollution is caused by use of low-cost, traditional energy sources, such as coal and biomass for cooking and heating, the main source of energy for 3.5 billion people. Indoor air pollution is a major risk factor for pneumonia and associated deaths in children and for lung cancer in women who risk exposure during cooking (see chapter 42). Studies in China, Guatemala, and India are under way to improve access to efficient and affordable energy sources through local design, manufacturing, and dissemination of low-cost technologies, modern fuel alternatives, and renewable energy solutions. The community-based project in China was initiated by the Ministry of Health, which was troubled by the leveling off of child mortality reductions among the rural poor and was seeking ways to influence major environmental determinants of child mortality. The program combines appropriately improved stoves and ventilation with behavior-change modification; it is in an early stage of implementation, and results on outcomes are not yet available. Agricultural policies and practices influence food prices, farm incomes, diet diversity and quality, and household food security. Policies that focus on women's access to land, training, and agricultural inputs; on their roles in production; and on their income from agriculture are more likely to have a positive effect on nutrition than interventions without a focus on women, particularly if combined with other strategies, such as women's education and behavior change (Johnson-Welch 1999; Quisumbing 1995). The MDG agenda highlights the need not only to prioritize within health to achieve better health outcomes, but also to better inform priority setting in resource allocations between sectors, identifying intersectoral synergies and finding ways to maximize benefits for health.

COSTING AND FINANCING ADDITIONAL SPENDING FOR THE MDGS

Additional health spending will be required in many countries to accelerate progress toward the health goals (see chapter 12). What will it cost, and how will extra spending be financed?

Cost of Achieving the MDGs Globally

The global estimates of what it would cost to achieve the MDGs range from an additional US\$20 billion to US\$70 billion a year. A World Bank study (<http://www.worldbank.org/html/extdr/mdgassessment.pdf>) estimates that the additional official development assistance required to meet the health goals is in the range of US\$20 billion to US\$25 billion per year, which is roughly four times the current amount of official development assistance spending for health in 2002 (US\$6.5 billion) and three times all external financing, including that of foundations and loans from multilateral sources (see chapter 13). The dramatic shortfalls in resources required to achieve the MDGs were emphasized during the 2002 Monterrey Conference on Financing for Development, which brought significant attention to issues concerning the estimation of the cost of achieving the health MDGs.

Another analysis conducted by the Commission on Macroeconomics and Health (2001) of the World Health Organization estimated that an additional US\$40 billion to US\$52 billion annually would be required until 2015 to scale up the coverage for malaria, tuberculosis, HIV/AIDS, childhood mortality, and maternal mortality (Kumaranayake, Kurowski, and Conteh 2001). A third study using the production frontiers approach estimated that between US\$25 billion and US\$70 billion of additional spending was needed to bring poorly performing countries up to the level of high performers (Preker and others 2003). A fourth study prepared by the World Bank for the Development Committee estimated at least US\$30 billion annually in additional aid was needed to accelerate all the MDGs, including health (Development Committee 2003). Whatever the method of analysis, all global estimates show that reaching the MDGs will require significant additional resources compared with the current levels of funding for health.

Cost of Achieving the MDGs in Countries

Global estimates of what it costs to achieve the health MDGs are not very useful for countries wanting to plan and budget in order to reach the MDGs. The substantial range of estimates between US\$20 billion and US\$75 billion per year to achieve the MDGs at a global level has led to debates over the most appropriate costing method for country-specific analysis and to the development of new costing methodologies for obtaining consistent and reliable estimates to use for policy dialogue and decision making at the country levels. Some of the methods are summarized in box 9.2.

Preliminary Country Cost Estimates. Table 9.2 provides a set of preliminary country-level estimates for the cost of removing bottlenecks and accelerating progress toward the health MDGs (MBB method) and for the cost of achieving the health MDGs (Millennium Project tools) in selected

countries. The estimates are presented for illustration of orders of magnitude and should not be used for intercountry comparison.

Financing Extra Health Spending

The additional resources needed to reach the MDGs are large at both country and global levels, as discussed in the previous section. The key question is how to finance the extra spending that is needed.

Encouraging Risk Pooling Rather Than Out-of-Pocket Spending. Health spending can be broken down into three categories:

- private (out-of-pocket expenditures and private insurance)
- public (financing from general revenues and social insurance contributions)
- external sources (development assistance).

Box 9.2

Estimating the Cost of Scaling Up to Achieve the MDGs

The following are the country-specific models for MDG cost analysis:

- The *MDG Needs Assessments Model* developed by the United Nations Millennium Project, (Millennium Project 2004). The Millennium Project model yields total cost estimates for full coverage of the needs of a defined population with a comprehensive set of health interventions in a given year. It uses unit cost of covering one person multiplied by the total population in need in a given year to yield the direct health cost. Additional resource requirements are added (on the basis of assumptions rather than actual inputs) for, among other items, health system improvement, salary increases for human resources, administration and management, promotion of community demand, and research and development.
- The *Marginal Budgeting for Bottlenecks Model* developed by the United Nations Children's Fund, the World Bank, and the World Health Organization (Soucat and others 2002, 2004; UNICEF and World Bank 2003). The MBB model yields additional resources required for removing a set of health system bottlenecks that are considered to hinder the delivery of health services to the population through three delivery modes: family-community, outreach, and clinical levels. The MBB method also estimates the effect on outcomes (for instance, child and maternal mortality) of increased coverage and use of the health services provided. First, a set of high-impact services are selected on the basis of a country's epidemiological needs. These services are the same as those cost-effective priority interventions identified in the relevant disease control priorities chapters. Second, health system bottlenecks hindering delivery of these services are identified. Then, strategies for removal of bottlenecks are discussed, and the inputs are identified for improving coverage, for example, in a village. Cost estimates are based on these inputs by scaling up the cost to cover the district, province, or nation.
- Elasticity estimates through *econometric modeling* developed by the World Bank staff (Wagstaff and Claeson 2004). A few studies have used econometric techniques to analyze the effect on MDG outcomes of certain cross-sector determinants (such as economic growth, water and sanitation, education, and road infrastructure) as well as government expenditures on health. Econometric analysis has been used mostly to analyze the effect of changes in government health expenditures on outcomes using cross-sectional or panel data at a global scale. But in one particular study in India, the methodology was used to estimate the marginal costs of averting a child's death at the state level. The estimates could vary from as low as US\$2.40 per child death in a low-income state to US\$160 in a middle-income state in India.
- The *Maquette for Multisectoral Analysis* of MDGs is under development by the World Bank (Bourguignon and others 2004). The thesis for this new approach is that development aid is a key ingredient of a country's development process, but its effectiveness has to be assessed at the country level within each country's local implementation and macroeconomic constraints. The objective of the model is to calculate the financial needs to attain a targeted path to 2015 and determine an optimal allocation of additional funding toward different social sectors for the MDGs. This modeling framework is still at an early stage of development and will be applied later to countries. This model is anticipated to draw extensively from results of other models, such as the elasticity analysis and MBB models.

Private spending absorbs a larger share of income in poorer countries. In low-income countries, it absorbs a larger share of GDP, on average, than domestically financed public spending. In low-income and lower-middle-income countries, it invariably means out-of-pocket expenditures rather than private insurance (Musgrove, Zeramini, and Carrin 2002). This situation leaves many near-poor households heavily exposed to the risk of impoverishing health expenses. The risk is clearly greater the poorer the country, because poorer countries tend, on average, to have larger shares of poor people (World Bank 2000). Governments thus have a major role to play in helping shape effective risk-pooling mechanisms, in addition to increasing their own spending and targeting it to services for the poor that will have a large positive effect on the MDGs.

Getting Governments to Spend What They Can Afford

Government spending is an important part of the picture, and the issue is how much they can afford. Unlike private spending, government spending as a share of GDP is higher in richer countries. However, at any given per capita income, a surprising amount of variation occurs across countries in the share of GDP allocated to government health programs. Countries that appear able to spend similar shares of GDP on government health programs end up spending quite different amounts.

How can extra domestic resources be mobilized if countries are spending less than they can afford? Domestically financed government health spending comes from general revenues, social insurance contributions, or both. The amount of general revenues flowing into the health sector is the product of the amount of general (tax and nontax) revenues collected by the government (the *general revenue share*) and the share of general revenues allocated to the health sector (the *health share of government spending*) (Hay 2003). Low government health spending could be attributable to either share or both shares being low. In poorer countries, both shares are typically lower

than they are in richer countries. However, differences exist across countries that cannot be explained by per capita income alone.

Countries need to ascertain whether their low spending is caused by unduly low general revenues or by unduly low allocations to health and explore ways of making appropriate adjustments. Bolivia managed to raise its general revenue share consistently in the 1990s as the result of a sustained reform process begun in 1983. The health sector there has been one of the beneficiaries of this growth of tax revenues: government health spending as a share of GDP grew at an annual rate of nearly 10 percent in the 1990s.

Although raising domestic resources takes time, countries that can apparently afford to spend more out of their own resources should be encouraged to start the process. Development agencies have a role here—in providing technical support of tax reform, in helping develop government commitment to health in public expenditure allocations, and in giving financial assistance, both to ease the adjustment costs and to provide support while the gap is being closed between current and affordable spending.

Recognizing the Limits of Development Assistance. Official development assistance tends to account for a larger share of government health spending in poorer countries. Development assistance for health is especially important in Sub-Saharan Africa. Twelve countries in Sub-Saharan Africa had external funding exceeding 35 percent of total health expenditures in 2000 (World Bank 1998).

Increased development assistance is needed to achieve the MDGs. Development assistance, however, is not without its drawbacks. Many donors require that assistance be kept in parallel budgets outside the ministry of finance, which risks undermining government efforts to appropriately plan and target expenditures. Such off-budget expenditures make it difficult in some countries to properly target resources to

particular interventions, geographic locations, or population groups, even though such targeting may be essential for improving the effect of expenditures on outcomes and the probability of reaching the health goals. Donors often require recipient governments to maintain separate accounts and to provide separate progress reports, thereby increasing the administrative burden on weak health ministries. Most important, donor commitments of expenditures in health are short term, whereas the needs are permanent. Thus, any external financing must at some point be substituted with additional domestic revenues or expenditure reallocations. This substitution or transition to domestic sources of funding has typically been difficult to achieve, leading to a dropoff in effort in important health programs, such as immunizations and reproductive health services.

Consensus on how to improve aid effectiveness is growing among development partners, and partners at the High Level Forum on Health MDGs (<http://www.hlfhealthmdgs.org>). This agenda includes supporting countries in developing more MDG-responsive Poverty Reduction Strategy Papers, tracking resource flows, strengthening monitoring and evaluation, and more effectively dealing with the human resources crisis in health. Effective monitoring can help ensure that increased external funds do not simply lead to reduced domestic financing (the *fungibility problem*) but actually boost overall spending for health. In concert with moves affecting all development assistance, donors and governments are trying to see that in the health area external funds are pooled and that ministries can use a common management and reporting format. In addition, a research agenda to support acceleration toward the health MDGs is being proposed; it needs to focus on how to translate knowledge into action and on how to remove health systems constraints to scaling up coverage of cost-effective interventions that are available but do not reach those who need them (Claeson and others 2004; Task Force on Health Systems Research 2004).

NOTE

1. *Intervention* in this chapter refers to the direct action that leads to prevention or cure.

Chapter 10

Gender Differentials in Health

Mayra Buvinić, André Médiçi, Elisa Fernández,
and Ana Cristina Torres

In health, more than in other social sectors, sex (biological) and gender (behavioral and social) variables are acknowledged useful parameters for research and action because biological differences between the sexes determine male-specific and female-specific diseases and because behavioral differences between the genders assign a critical role to women in relation to family health. Until recently, however, the importance of sex and gender informed work on female-specific diseases but did not carry over to diseases shared by men and women. As a result, the literature contained comparatively little about which diseases affect men and women differently, why that difference might be the case, and how to structure prevention and treatment in response to these differences. This situation has changed, however, and interest in measuring, understanding, and responding to sex and gender differentials in disease has surged, nurtured by breakthroughs in science and advances in advocacy.¹

In line with this interest and using global burden-of-disease data for 2001, this chapter reviews worldwide gender differentials in mortality and morbidity that result in excess disease burdens for women and examines cost-effective interventions drawn from chapters 17 (on sexually transmitted infections), 26 (on maternal and perinatal conditions), 29 (on health service interventions for cancer control in developing countries), 31 (on mental disorders), 32 (on neurological disorders), 51 (on musculoskeletal disability and rehabilitation), and 57 (on contraception) to address them.

The focus on women's excess disease burden is justified to fill gaps in knowledge regarding women's health that are in part a product of male bias and male norms in clinical studies. In the past, medical research often wrongly assumed that women were biologically weaker (male bias) and extrapolated findings

from trials with male subjects only (male norm) to both sexes, whereas female biology can affect the onset and progression of disease, and women's lower position in society can affect their health-seeking behaviors (Pinn 2003; Sen, George, and Ostlin 2002).

As A. K. Sen (1990) and others have indicated, gender bias results in the neglect of female children and in selective abortion and excess female mortality in China, India, and other South Asian countries, explaining the "missing" women in population counts. In addition, such bias can have intergenerational health effects, starting with maternal undernutrition and leading to fetal growth retardation, low birthweight, child undernutrition, and ailments in adult children of disadvantaged mothers (Osmania and Sen 2003).

This chapter only partially addresses women's health needs. It omits important disease conditions for women, such as lung cancer and HIV/AIDS, where men and women currently have similar disease burdens. (In the case of HIV/AIDS this balance is changing, and women's disease burden is rising over men's, especially for the 18–25 age group and for specific world regions.) It also does not cover important sources of the disease burden for women that are not measured in disability-adjusted life years (DALYs), such as burden from female genital mutilation (FGM). Last, the emphasis on disease underplays women's reproductive and other health needs.

ANTECEDENTS

The chapter's emphasis on gender differentials and inequalities in health rather than on women's absolute health conditions reflects the evolution of thinking on women and health issues.

(Annex 10.A charts these advances in the past two decades, highlighting milestones and influential publications.) In the 1960s and 1970s, the field of international women's health issues emerged from and was influenced by an interest in women's fertility behavior as a means of curbing population growth and by an interest in maternal and child health to improve child welfare, with little or no attention paid to mothers (McNamara 1981; Rosenfield and Maine 1985). Much of the work in the 1980s sought to bring a woman-centered perspective into population and maternal and child health programs. This focus included awareness of how women's lower status in society affected health delivery and health-seeking behaviors and how women's time burdens in poor households affected child health. The issues raised included the quality of care in health and family-planning programs and the nature of women's work and its impact on child survival and health (Bruce 1990; Leslie 1988). Reducing maternal mortality became a major development objective (Herz and Measham 1987).

The 1994 United Nations International Conference on Population and Development in Cairo placed women's reproductive health and rights at the center of the population and development debate, and the United Nations Women's Conference in Beijing the following year reinforced the importance of women's empowerment and of a gender perspective in health. Along with the global burden-of-disease effort, researchers estimated the loss of women's healthy years of life caused by gender violence (Heise, Pitanguy, and Germain 1994), and gender was identified as central to women's risk of and treatment for HIV/AIDS (Gupta 2000; Mann 1993). The World Health Organization analyzed how differences between women and men in access to and control over resources determine differential exposure to risk and access to the benefits of health technology and care (WHO 1998). After more than two decades almost solely devoted to maternal and reproductive health issues, attention expanded to cover a range of women's health issues unrelated to reproduction and to identify and correct gender differentials and inequities in health (Sen, George, and Ostlin 2002). These new emphases complemented renewed interest in health inequities and their reduction in the field of international health (see, for instance, Evans and others 2001).

Framework

Both sex and gender matter in health. We use the term *sex* to describe differences between men and women that are primarily biological in origin and that may be genetic or phenotypic. By contrast, we use the term *gender* to describe differences that are primarily caused by social conditions or cultural and religious beliefs and norms regarding the sexes. Structural gender inequalities that place women in a subordinate position to men underlie and contribute to gender differentials in disease (Sen, George, and Ostlin 2002). A gender perspective addresses dif-

ferences between men's health and women's health that arise from this lower position and the consequent unequal power relationship between the sexes. Sex and gender can act alone, independently, or interactively in determining differentials in the burden of disease (Krieger 2003). Some women's excess health burdens, such as uterine cancer, are based almost solely on biology. At the other end of the continuum, some women's excess health burdens, such as injuries from domestic fires or domestic abuse, are solely gender based.

However, in most cases sex and gender interact to determine women's disease burdens. Two salient examples are depressive disorders and HIV/AIDS. Women are twice as likely as men to become depressed, and genetics and hormones influence the risk of depression. However, genes and sex hormones cannot entirely explain women's excess burdens, and gender factors play an important role (WHO 2000). HIV infection rates among teenage girls are 5 to 16 times higher than among teenage boys in Sub-Saharan Africa. This earlier age of HIV exposure for girls is partly explained by the greater biological efficiency of male-to-female transmission and partly by girls' lack of knowledge, opportunities, and bargaining power in sexual relations that make them prime victims of the rapid spread of the disease.

Existing knowledge about the interplay between sex and gender in determining disease is imperfect and evolving (Krieger 2003; Pinn 2003). This chapter groups women's excess health burdens from diseases into the following four broad categories:

- diseases specific to women (that is, where biology plays a major role in the disease)
- diseases related to women's average greater longevity (where both sex and gender tend to play important roles)
- diseases that result from the interaction of sex and gender
- diseases that are predominantly gender based (that is, that result from specific behavioral, social, and cultural factors associated with women's condition).

Sex and gender have a much wider influence on disease than is usually acknowledged. They influence the etiology, diagnosis, progression, prevention, treatment, and health outcomes of disease as well as health-seeking behaviors and exposure to risk. Whereas sex plays a bigger role in the etiology, onset, and progression of disease, gender and its consequences influence differential risks, symptom recognition, severity of disease, access to and quality of care, and compliance with care. In addition, poverty and social exclusion because of race and ethnicity interact with sex and gender and contribute to women's excess disease burdens in ways that are largely unexplored to date (Breen 2002).

Factors that influence gender differentials in relation to the risk of disease include (a) biological (genetic, physiological, and

hormonal) differences between the sexes; (b) women's longer life expectancy; (c) nature and rate of change of women's labor force participation compared with men's participation; (d) women's differential access to social protection mechanisms (health and social insurance); (e) cultural norms, religious beliefs, and family arrangements and behaviors determining gender roles and gender hierarchy in society; (f) gender differences in educational attainment; (g) income differences between the genders resulting from the interaction of all the previous factors; and (h) interactions between race, ethnicity, income, and gender.

Women's overall underutilization of health services has been well documented. For instance, even though women in India report more illness than men, hospital records show that men receive more treatment (World Bank 1996); in Thailand, men are six times more likely than women to seek clinical treatment for malaria, a disease that affects women and men similarly (Hanson 2002); and in Brazil, the Dominican Republic, Jamaica, Paraguay, and Peru, low-income women underuse health services (Levine, Glassman, and Schneidman 2001).

Three groups of factors influence this underuse of health services. The first group is service factors, such as accessibility; affordability (money and time costs); and appropriateness or adequacy, including friendliness, of the health and social infrastructure for meeting women's needs. The second group is user factors, which include social constraints, such as restrictions on women's mobility and women's average lower incomes and greater time burdens than men's; asymmetric information about health needs and rights and the availability of services, which disproportionately affects poor women; and marital status, family roles, and work conditions affecting access and use. The third group is institutional factors, including men's decision-making power and control over health budgets and facilities, which affect local perceptions of illness and norms concerning treatment, and stigmatization and discrimination in health settings, which affect women among the poor and women of minority ethnic and racial groups.

Context

The global demographic dynamic, a product of the interplay of nature and nurture, biology and society, helps determine gender differentials in health. In 2001, the world's population, an estimated 6.2 billion, was 50.3 percent male and 49.7 percent female. The surplus male population was concentrated in the developing countries, whereas the developed countries had a higher proportion of women, primarily in the older age groups (WHO 2001).

In the developed countries, the number of women age 80 and older was more than double the number of men in the same age group. This female advantage in longevity helps shape a gender paradox in health outcomes worldwide: on average,

males live shorter but healthier lives than females. Even though more boys are born than girls, gender differences in mortality eventually change the sex balance in populations so that by age 30 or so women start outliving men, and the absolute female advantage in survivability increases with age (Kinsella and Gist 1998). Therefore, differences in life expectancy at birth by gender, using 2000 data, vary in favor of females, ranging from one year in the low-income countries of South Asia and Sub-Saharan Africa to seven years in Europe and Central Asia and nine years in the middle-income countries of Latin America and the Caribbean.

Overall, however, women have higher morbidity than men. Murray and Evans (2003) find that in relation to expected lost healthy years at birth, whereas men lose 7.8 years over their lifetimes as a result of poor health, women lose 10.2 years. In other words, women spend about 15 percent of their lives in unhealthy conditions and men spend just 12 percent. Therefore, living longer lives should not be taken to indicate better health for women. Women live less healthy lives and are saddled with higher morbidity in part because they outlive men (Verbrugge 1989). Supporting the less healthy lives assertion, women up to age 65 reported worse health status in virtually all 64 household surveys from 46 countries (Sadana and others 2000). Because of these differences in morbidity, the concept of healthy adjusted life expectancy at birth describes differences in health conditions between males and females better than the concept of life expectancy at birth.

GENDER DIFFERENTIALS IN DISEASE BURDENS

The global burden of disease for 2001 proportionally affects males slightly more than females. About 52 percent of DALY losses are attributed to males, but this proportion varies between 54.8 percent in Europe and Central Asia and 49.9 percent in South Asia. The only region where the global burden of disease affects females more than males is South Asia.

Table 10.1 shows the burden of disease by region, gender, and age group. The burden of disease during early childhood (age 0 through 4) is somewhat smaller for girls than boys; however, from age 5 through 29, females lose more DALYs than males, but only in developing countries. Larger differences favoring women appear starting at age 30 and continue until after the age of 70, when women, because of their greater longevity, lose more DALYs than men. However, when DALYs are estimated per 1,000 males and females as in table 10.1, women in the older age groups lose fewer DALYs than men both in low- and middle-income countries (LMICs) and in high-income countries (HICs).

Communicable diseases and maternal conditions contribute significantly to females' burden of disease in developing countries and add little to their burden in HICs, where

noncommunicable diseases prevail in both women's and men's disease burden. Injuries weigh more heavily in males' than in females' burden of disease across regions. In summary, in both developed and developing countries, the overall burden of disease is higher for males than for females; however, this situation reverses in developing countries for young girls and women in their prime childbearing years. In addition, in LMICs, females are more affected than males by highly preventable communicable diseases.

WOMEN'S EXCESS DISEASE BURDENS

The 2001 global burden-of-disease data underestimate both women's and men's disease burdens because of the incompleteness of health statistics, especially in the developing world. This underestimation is probably more pronounced for women because they experience more disability—which is less well recorded than mortality—than men. This underestimation is aggravated by underreporting resulting from the stigma associated with certain diseases in women, such as sexual infections;

the prevalence of asymptomatic illness, such as sexually transmitted infections among women; the differences in health-seeking behaviors that favor males accessing formal health care, which is the main source for health statistics; and the exclusion of some conditions that affect only women, such as FGM, from global burden-of-disease estimations (Hanson 2002). Thus, the findings in the preceding section may be affected by a quality problem, and the estimates in this section are probably conservative.

Table 10.2 breaks down 11 conditions specific to women by region. In 2001, conditions specific to women accounted for 5.3 percent of women's total DALY losses, compared with 0.7 percent for two conditions (prostate cancer and benign prostate hypertrophy) specific to men.² Most causes of mortality or morbidity specific to women are related to maternal conditions and malignant neoplasms. The DALY losses associated with conditions specific to women are around 6 percent in both HICs and LMICs, but maternal conditions are more prevalent in LMICs, whereas neoplasms cause more DALY losses in HICs.

a. Related to maternal conditions only.

b. Even though these conditions are not specific to women, women account for more than 90 percent of the DALY losses associated with these conditions.

Table 10.3 shows the gender ratio and burden of disease of eight conditions, by region, that are more prevalent among women than among men. The selection of diseases was done using as the threshold the mean plus one standard deviation (SD) of the distribution of gender ratio scores for each disease. The diseases selected were then screened for their importance in women's disease burden, using the same criterion of the mean plus one SD in the distribution of DALY scores for women. Although some diseases, such as unipolar depressive disorders and osteoarthritis, are priorities for both HICs and LMICs, others, such as Alzheimer's disease, are more relevant in HICs, reflecting women's longer life expectancy. Conditions such as age-related vision disorders, migraine, fires, and cerebrovascular diseases have particular relevance in specific regions.

Combining gender-specific conditions and shared conditions that disproportionately affect women gives a total of 19 priority conditions for women. Taken together, these conditions represent about one-fifth of women's total DALY losses and indicate priorities for research and the search for cost-effective methods of promotion, prevention, and treatment. Note that some important contributors to females' health burdens, such as malaria and HIV/AIDS, have been omitted because females do not currently suffer disproportionately from these diseases. However, the growing feminization of the HIV/AIDS epidemic in developing countries should result in excess disease burdens for women in the near future.

We determined priority conditions affecting females in different age groups using a method that took into account both the gender ratio and the weight of specific conditions in females' total DALYs lost. The results indicate that women are affected by communicable diseases and maternal conditions until age 29 and by noncommunicable diseases after age 30, with chronic diseases having a heavy weight during the last stages of the life cycle. Conditions for which females' burden of disease is more or less double that of males at a specific stage in the life cycle are migraine at age 5 to 14, fires and panic disorder at age 15 to 29, and unipolar depressive disorders at age 60 to 69.

PRIORITY DISEASE GROUPS FOR WOMEN

Table 10.4 presents conditions with excess burdens for women divided into the four groups defined earlier.

Conditions Specific to Women

In developed countries, advances in medical technology have almost eliminated the burden of disease resulting from maternal conditions. Three types of cost-effective intervention packages for maternal conditions are the prevention of pregnancy by means of effective family-planning methods; the prevention of complications (for example, hemorrhage); and the prevention

n.a. = not applicable; BOD = burden of disease; GR = gender ratio.

Note: The gender ratio is the ratio of female to male DALYs.

For each world region or classification, data are shown only for those diseases that are classified as "priority" given that they meet the selection criteria according to the methodology used in this study (that is, the gender ratio was equal to or higher than the mean plus one SD of the distribution of gender ratio scores, and in a second screening, the BOD was equal to or higher than the mean plus one SD of the distribution of female DALY scores).

of death or disability resulting from complications through emergency obstetric care. Proven technologies also exist for screening and early detection of some neoplasms, although their implementation has been uneven. Problems pertaining to conditions in this category are not simply related to the availability of medical technologies, but also to the behavioral and social factors that influence women's exposure to risks and underuse of services as well as the economic and institutional factors that influence the availability and quality of services, especially in developing countries.

Even though the international women's health movement has promoted significant advances in the quality of care for reproductive health and maternal conditions in the past 25 years, the main challenges in relation to conditions specific

to women include reaching poor and socially excluded women with basic maternal and reproductive health services; strengthening the adoption of preventive health behaviors in developing countries; extending the quality of care to other conditions specific to women, including neoplasms; and educating and empowering women to promote their own healthy behaviors.

Conditions Associated with Women's Greater Longevity

The main group of diseases with excess burdens for women associated with women's greater longevity are Alzheimer's disease; musculoskeletal disorders, such as osteoarthritis, rheumatoid arthritis, and osteoporosis; and cardiovascular diseases,³ which together account for 12 percent of total DALY losses for women worldwide. LMICs account for about 80 percent of the DALYs resulting from these conditions, likely because of the lack of medical care during the early stages of these diseases.

Alzheimer's disease and other dementias account for 1.5 percent of total female DALYs, and this burden is almost twice as high as that for men. About 46 percent of this burden is concentrated in HICs and 54 percent in LMICs, but DALYs lost per capita are much greater in the HICs than in more densely populated LMICs. Because of population aging, during the next 50 years the number of people with Alzheimer's disease is expected to more than double, with more women affected than men (McCann and others 1997). Studies of the effects of estrogen therapy on Alzheimer's disease have been inconsistent: estrogen may increase the risk of both dementia and other diseases such as stroke in postmenopausal women (Shumaker and others 2003).

As concerns musculoskeletal disorders, osteoarthritis affects 9.6 percent of men and 18.0 percent of women age 60 or older worldwide and accounts for 1.5 percent of total female DALYs. Osteoarthritis is related to aging and is most common in overweight women over the age of 45. Demographic changes in developing countries, especially middle-income countries, indicate that osteoarthritis prevention and treatment needs will increase during the next decade. Most prevention and treatment are linked to regular exercise, healthy weight management, physical and occupational therapy, and pain management with over-the-counter medications.

Because cardiovascular diseases are generally thought of by society as "men's diseases," women tend to delay seeking treatment for cardiac-related events (Seils, Friedman, and Schulman 2001). However, cardiovascular and cerebrovascular diseases account for about 8.2 percent of total female DALYs, more than half of which is caused by cerebrovascular diseases.

In addition to age, smoking, and obesity, another risk factor that exposes women to a greater burden of cardiovascular

diseases is depression, which is associated with increased morbidity and mortality from heart diseases and is highly prevalent in women (Linfañte and others 2003). Also, women's symptoms of heart disease tend to be different from men's, increasing the difficulties of diagnosis (Seils, Friedman, and Schulman 2001). Finally, evidence suggests that physical activity significantly reduces the risk of cardiovascular events; however, women tend to exercise less than men (Manson and others 2002). Whether this observation can be generalized to all age groups and whether it occurs because of biological factors or social norms deserve further attention.

Conditions Arising from the Interaction of Sex and Gender

In the group of conditions resulting from the interaction of biological and social factors, unipolar depressive disorders have the most significant gender ratio and most unequal burden of disease in every region except East Asia and the Pacific. Unipolar depressive disorders account for 4.2 percent of women's global burden of disease. Even though the DALYs lost per capita are similar in LMICs and HICs, these disorders represent a higher share of women's total burden of disease in HICs (7.3 percent) than in LMICs (3.9 percent). Another important consideration is the high comorbidity between depression and other psychiatric disorders (for example, anxiety disorders). Neuropsychiatric disorders account for 11.8 percent of women's total global burden of disease and 23.5 percent in HICs.

The exact contributions of biology and society in the etiology of depression are unknown. Some believe that genetic causes account for about half of the risk for mood disorders (Zubenko and others 2002), whereas others suggest that gender roles, stressors, social relationships, and personality traits may play a larger role than hormones and neurotransmitters (Bromberger 2004). As concerns biology, aside from genetic predisposition, the fluctuation of sex hormones, especially estrogen, during women's reproductive life is believed to be an important risk factor for depression (Bromberger 2004). As concerns social factors, poverty; lack of proper nutrition and education; stressful and insecure life circumstances; and domestic and sexual violence and the concomitant feelings of loss, entrapment, and lack of control are likely at the root of depression (Bromberger 2004; WHO 2000).

Treatment for depression includes medication and psychotherapy or counseling, and instruments are available to assess the severity of depression, including prenatal and postpartum depression. In developing countries, severe depression and anxiety disorders go mostly untreated (76 to 85 percent of serious cases receive no treatment), partly because of ignorance, social barriers, and stigmatization, which may affect women's access to treatment (WHO 2004). A main challenge, therefore, is increasing women's access to treatment for

depression in developing countries by creating systems that help them overcome social stigma and economic and social barriers.

In addition to treatment, prevention of depression and other mental illness needs to address women's role in society and the control they have over their lives and circumstances. According to the World Health Organization, pertinent factors are related to having sufficient autonomy to exercise some control in response to severe events, access to adequate resources to be able to make choices, and social supports (WHO 2000). The promotion of healthy behaviors, including exercise, is also crucial for prevention.

Gender-Based Conditions

The main characteristic of gender-based conditions is that they have no biological referent and can, therefore, be prevented by means of behavioral change. The role of social components in this category explains excessive health burdens for women in particular world regions. For example, women are disproportionately affected by fires in South Asia, an outcome of the violence caused by dowries. Too often women die in what are called "cooking fire accidents," whereas in reality they are murdered so that their husbands may remarry and obtain another dowry.

Another characteristic of the diseases and injuries in this category is that they are often underreported because of stigma and social pressures. As a result, the data probably underreport the true extent of the problem. FGM and domestic violence are two examples. In 2000, estimates indicated that 100 million to 140 million girls and women had undergone FGM and that more than 2 million girls were at risk. At least 28 African and Middle Eastern countries practice FGM for social, cultural, or religious reasons (WHO 2000). Unfortunately, global burden-of-disease data do not report the resulting DALYs lost. Regarding violence against women, 10 to 50 percent of women report having been physically abused by an intimate partner, and 12 to 25 percent report attempted or completed forced sex. Although men experience more absolute DALY losses from violence, women are also seriously affected. In 1998, interpersonal violence was the 10th-leading cause of death for women age 15 to 44 worldwide.

Given the complexity of these health problems, comprehensive interventions are necessary. Changes are needed in the following areas:

- legislation and law enforcement
- public policies and programs in areas such as health, education, and police and legal services
- training of service providers and creation of gender-sensitive services, especially at the community level

- education of the general public to create awareness, behavioral change, and promotion of advocacy groups
- better data collection, research, and understanding of the individual and social mechanisms sustaining these problems.

COST-EFFECTIVENESS OF INTERVENTIONS

This section summarizes the costs and health benefits of strategies to address conditions that are specific to women and conditions that affect women disproportionately. Table 10.5 presents cost-effectiveness estimates for recognized effective interventions.

Conditions Specific to Women

Conditions specific to women include the cluster of diseases related to women's maternal function plus chlamydia (which is predominantly but not exclusively a female disease) and female-specific cancers.

Maternal Conditions. The analysis developed in chapter 26 uses a model for maternal and perinatal conditions that generates 128 potential scenarios. According to the findings of this theoretical exercise, the cost per DALY averted of mother and baby packages could vary from US\$77 to US\$151 in Sub-Saharan Africa and from US\$143 to US\$278 in South Asia, depending on the complexity of the intervention.

Prenatal care prevents almost a quarter of maternal deaths, especially when backed by essential and emergency obstetric care to deal with conditions detected during the course of pregnancy care. Good prenatal care includes information, education, and communication activities and behavior-change communication to increase women's skills in relation to the identification of danger signs and potential complications and where to seek care in these cases (Dayaratna and others 2000). In Uganda, for example, integral prenatal care ranged from US\$2.26 (public services) to US\$6.43 (religious mission services) per pregnant woman per year (Levin and others 1999).

Another important service is supplementation with iron and folic acid. Iron deficiency accounts for 1.8 percent of women's deaths and 2.6 percent of female DALY losses. Iron and folic acid supplements administered to highly anemic pregnant women can save lives at a cost of US\$13 per DALY averted (Berman and others 1991), demonstrating that this intervention is very cost-effective.

Good maternal health services can strengthen the entire health system. A health facility that is equipped to provide essential obstetric care can also treat accidents, trauma, and other medical emergencies. The costs of emergency obstetric care vary depending on the country. In Uganda, costs per

episode vary from US\$73 (public hospital) to US\$86 (mission hospital) (Levin and others 1999). In Bolivia, the cost of a cesarean section ranges from US\$56 to US\$104 (Rosenthal and Percy 1991), and the cost of a normal delivery varies from US\$11 to US\$16 (Dmytraczenko and others 1998).

In developing countries, 61 percent of maternal deaths occur 23 to 48 hours after delivery because of such problems as postpartum hemorrhage and hypertensive disorders or after 48 hours because of sepsis. Complications from unsafe abortions account for 13 percent of maternal deaths, though this figure is probably an underestimate because of the scarcity of data. Little information is available on costs related to postnatal care given the different kind of interventions and the severity of cases, but the literature generally agrees that emergency obstetric care can reduce costs. As concerns postabortion care, costs per case in LMICs could vary from US\$4.40 to US\$17.19 (Dayaratna and others 2000).

Millions of premature deaths, illnesses, and injuries could be avoided by helping women prevent unwanted pregnancies and obtain prompt treatment for reproductive health problems. The contraception costs per couple-year of protection could vary, depending on the method used, from US\$6 (intrauterine device) to US\$20 (condoms or injections) (Dayaratna and others 2000). A 1999 experiment by the Planned Parenthood Association of South Africa considered total health planning costs per couple-year of protection, including travel expenses to health clinics. Comparing these costs with total health planning costs in services provided by community-based doctors, the study found that the former cost US\$44 per couple-year of protection and the latter cost US\$42.

Chlamydia. Although not specific to women, chlamydia is nine times more prevalent among women than among men, and its consequences and treatment are much more complicated and severe for women, affecting women's and infants' health during pregnancy and the postnatal period. Chlamydia is widespread in low-income countries. Chlamydia, as well as other sexually transmitted diseases, could be prevented by using condoms, with an average cost per DALY averted in developing countries estimated at US\$3.40 in noncore target groups and US\$12.60 in core target groups (Mumford and others 1998). Detecting chlamydia in pregnant women could cost \$4.38 per case, with treatment, at \$3.82 per case, being less expensive than detection (Shultz, Schulte and Berman 1992). Chlamydia's adverse effects are trachoma (chronic conjunctivitis, endemic in Africa and Asia), reproductive tract infections, genital ulcer disease in tropical countries, and infertility. The cost of each adverse outcome averted varies from about US\$85 to US\$308 (Shultz, Schulte, and Berman 1992).

Neoplasms. Cancers specific to women are responsible for high levels of female morbidity and mortality, with cervical

Source: Authors.

QALY = quality-adjusted life year.

Note: Costs are based in current U.S. dollars as presented in each study. Many studies do not present well-documented data regarding reference period of costs. To avoid mistakes on interpretation, we kept the costs in the currency informed by the authors. n.a. indicates that information is not available.

cancer being one of the most important. Recommended strategies involve early detection and treatment. The following are the main strategies to prevent cervical cancer:

- screening and treatment performed during the same visit
- screening and treatment performed at two separate visits
- traditional three-visit intervention, in which a cytology sample is obtained during the first visit, a diagnostic colposcopy is performed for those who screened positive during the second visit, and treatment is provided at the third visit.

The data on costs associated with cervical cancer detection and treatment in developing countries are limited. In Honduras in 1991, costs per visit for cervical cancer detection varied from US\$5.60 (small clinics) to US\$12.90 (larger clinics) (Mumford and others 1998). Lower detection costs were found in Ecuador in 1996 (US\$2.95 to US\$3.51 per visit) and in Zimbabwe in 1995 (US\$3.00 to US\$3.90 per visit). Recent studies on cervical cancer screening in South Africa show that the two-visit method is more cost-effective than the traditional three-visit method, US\$39 per DALY averted compared with US\$81 (Goldie and others 2001). Studies in Vietnam found costs equivalent to US\$725 per DALY averted with cytology screening (Suba and others 2001).

Regarding treatment of cervical cancer, Rose and Lappas's (2000) studies in developed countries find costs varying from US\$2,384 to US\$28,770 per DALY averted. Costs are lower in developing countries, ranging from US\$52.51 to US\$432.42 per visit in Mexico and from US\$12.35 to US\$95.82 per visit

in Zimbabwe. Differences in treatment costs are associated with the kinds of procedures used. How the results of cost-effectiveness studies for cervical cancer prevention and screening interventions in developed countries might translate to health care delivery settings in developing countries is not clear, but prevention could clearly play an important role.

Many studies of breast cancer prevention view diet as an important condition explaining the predisposition for breast cancer. Ministries of health in many developing countries invest in promotion and prevention, issuing communications and guidelines for early detection using self-testing as a cost-effective way to provide information. Few studies of the cost-effectiveness of different breast cancer treatments are available, especially in developing countries. One on the management of breast cancer in Brazil in 1995 showed extremely high costs of US\$1,678 per death averted (Arredondo, Lockett, and Icaza 1995).

Conditions That Affect Women Disproportionately

Few studies on shared diseases that affect women disproportionately include gender-related considerations, especially in developing countries. Most literature on Alzheimer's disease, unipolar depressive disorders, and osteoarthritis presented in this section is based on studies in developed countries with no specific analysis of gender differences in relation to cost-effectiveness.

Alzheimer's Disease and Other Dementias. Alzheimer's disease is linked to genetic and other risk factors, including

increasing age, positive family history of dementia, and lower levels of education. Treatment is based mostly on drugs, and the practical benefits of treatment translate mainly into reduced caregiver hours.

Some studies have found that interventions aimed at reducing caregiver stress, even providing low-dose antipsychotic medication, can be effective. However, the costs of undertaking such interventions have not been quantified; thus, their cost-effectiveness cannot be calculated. Institutional care for patients with any form of dementia is extremely limited in LMICs. The costs of setting up institutions for those with Alzheimer's disease and the costs of care are prohibitive. In this context, inexpensive, home-based care appears to be the only viable option for Alzheimer's disease patients in developing countries. These countries will therefore have to face the challenges of addressing families' needs in relation to financial and social support and caregiver training. Another issue is the tradeoff between women's income-earning opportunities and their traditional primary role as family caregivers.

Unipolar Depressive Disorders. Depression is among the most disabling and costly illnesses in the world, especially for women. Despite good short-term treatment outcomes, long-term outcomes remain disappointing. Costs associated with depression affect not just the sufferers themselves, but also their families and friends (time dedicated to caregiving); employers (payment for treatment and care, as well as for reduced productivity); and society (provision of mental health care financed by taxpayers). Most of these costs are difficult to obtain, but the consensus is that the indirect costs of depression are larger than the direct costs.

The treatment setting for depression is usually primary health care, with many kinds of episodic treatments combining old and new generations of antidepressants and psychosocial procedures. Averting depressive episodes results in average gains of up to 50 disability days per treated case per year. Studies of the factors influencing women's access to screening, prevention, and treatment for depression and the cost-effectiveness of treatment options should be a priority in developing countries.

Osteoarthritis. Despite clear evidence of a reduction in symptoms and delayed progression of osteoarthritis with weight reduction, no formal studies of cost-effectiveness are available. Education and exercise programs for osteoarthritis are available in developed countries, but such programs are unknown in developing countries. Studies of the effect of diet and physical exercise in preventing osteoarthritis in women are a priority not just in developed countries, but especially in developing countries with fiscally strapped health systems and growing elderly populations.

Acetaminophen is thought to be the most cost-effective initial treatment with drugs. In addition, some cost-effectiveness

measures of using several kinds of medicines (acetaminophen, naproxen, misoprostol, celecoxib, and rofecoxib) under different conditions are available. Sigal (2002) shows that by using different combinations of medicines, treatment costs can vary from US\$2,001 to US\$2,140 per quality-adjusted life year, but these costs are prohibitive for developing countries.

Another treatment for osteoarthritis is synovial fluid replacement, but given the costs of this intervention, it is not currently recommended for developing regions. Surgical interventions for osteoarthritis, such as joint replacement, are most commonly performed in developed countries. Sigal and others (2004) review a number of interventions for osteoarthritis and suggest a cost per quality-adjusted life year of US\$6,000 for knee replacements. In developing countries, however, the availability of surgical interventions is constrained by its costs and by the availability of surgeons qualified to perform the operation.

RESEARCH AGENDA

Health research and practice should give priority attention to the 19 conditions with excess burdens for women that this chapter has identified and clustered into four main groups, according to the interplay of sex and gender in their etiology, to improve women's health status worldwide. A number of cost-effective health technologies are available, but women are dying because these technologies are not available and accessible to all. Thus, a priority need is to deploy them more widely in developing countries. The research challenge is also urgent, given the unacceptably high disease burdens for women in developing countries and the rising numbers of older women worldwide. Research on sex and gender factors affecting women's disease burdens should give physicians new information that will increase their options in relation to diagnostic practices and drug approaches, not only for women, but also for men, thereby improving the provision of gender-appropriate health care for all.

Key general items in a research agenda to reduce women's excess disease burdens include the following:

- Expand and sharpen analyses of sex and gender and their interaction in the etiology, onset, progression, prevention, and treatment of diseases that women and men share, but where women face an excess health burden, and in the assessment of cost-effective interventions.
- Increase research to identify the determinants of women's underuse of health services, paying special attention to the accessibility, affordability, and appropriateness of services. Identify and analyze best practices in health service delivery that incorporate gender variables to inform training and human resource development programs for health sector providers in developing countries for both services specific to women and general services.

- Investigate how interactions between sex and gender, race, ethnicity, and poverty affect the etiology, onset, and progression of disease as well as access to and compliance with prevention and treatment. Investigate the effects of stigmatization and discrimination on service quality and use.
- Use demographic accounting methods to project and plan for the demands that women's overall greater longevity imposes on health systems and investigate cost-effective treatment options, effect of gender variables on prevention and treatment, and viable options for increasing older women's access to health and to social insurance and protection mechanisms. Investigate affordable options for family care of elderly patients that take into account the time and the physical and emotional burdens on women, the traditional family caretakers.
- Improve the methodology used for disease classification, and expand data collection efforts to address the largely unreported causes of women's disease burdens, emphasizing conditions specific to women, including FGM and other domestic-, social-, and religious-based violence against women.
- Promote research, health promotion activities, health services, and advocacy efforts that will help women adopt desirable nutrition and physical exercise practices for optimal health. Exercise is a preventive measure that can help reduce women's excess disease burdens throughout the life cycle and has numerous indirect psychological and social benefits, but it will often require changing deeply rooted cultural mores.
- Support research on the costs and effectiveness of treatments for diseases that affect both men and women but affect women disproportionately, especially in developing countries.

Research needs pertaining to specific conditions include the following:

- Carry out further testing of innovative technologies for diagnosing neoplasms specific to women and explore new options for preventing their growth and proliferation. Regarding treatment, the literature describes few best practices and cost-effective measures, especially for breast and ovarian cancer.
- Evaluate the viability of applying the results of cost-effectiveness analysis carried out in developed countries on the prevention and treatment of cancers specific to women in developing countries to help adapt viable procedures.
- Promote and study the cost-effectiveness of approaches to preventing Alzheimer's disease, osteoarthritis, and other chronic conditions related to aging.
- Compare the prevalence of Alzheimer's disease in different populations, including carrying out genetic epi-

demology studies to assess the importance of different genetic risks.

- Expand research on the biological and behavioral determinants of depression in women, on screening alternatives, and on cost-effective prevention and treatment options adapted to specific contexts in developing countries. Explore ways to reduce the stigmatization and discrimination associated with depression in developing countries.
- Continue research to document the risks and benefits of common, but unproven, approaches of preventing and treating diseases specific to women, such as the finding that long-term hormone replacement therapy does not reduce cardiovascular disease in postmenopausal women as had long been thought but instead increases risks for cardiovascular disease and breast cancer.
- Establish a research program to document the prevalence and disease burdens associated with FGM, and seek prevention and treatment alternatives.

CONCLUSIONS

The purpose of this chapter has been to move beyond the traditional international health focus on women's diseases related to their reproductive and maternal functions and to highlight those conditions for which sex and gender considerations, if adequately incorporated into prevention and treatment, could reduce women's excess health burdens and, as a result, increase health equity. Because of the approach taken, the chapter has excluded a set of important conditions for which the gender ratio is similar or is unfavorable for men, including HIV/AIDS, injuries resulting from domestic violence, and malaria. Therefore, this chapter should not be viewed as covering all diseases and conditions important to women or all conditions that result from the interaction of sex and gender.

The chapter has two other main limitations. First, the dataset (the global burden of disease) understates certain disease burdens, especially for women, because it does not estimate disability weights for some gender-based conditions, such as FGM. Second, the information available for cost-effectiveness analysis is inadequate. Following this chapter's emphasis on the importance of sex and gender in explaining women's excess disease burdens, assuming that sex and gender considerations in prevention and treatment would affect the analysis of cost-effectiveness seemed reasonable; however, general information for assessing cost-effectiveness was deficient, and gender-related information was entirely lacking. This limitation was additional to the common limitation of cost-effectiveness analysis in terms of underestimating the value of prevention for conditions specific to women and non-health sector interventions important to women.

NOTES

1. See, for instance, the documentation of efforts to understand gender differentials in infectious diseases (Altman 2004) and in unipolar depressive disorders (Gilbert 2004).

2. Males suffer the weight of some external causes in the burden of diseases more than females. For example, in 2001, mortality and morbidity caused by war and violence worldwide accounted for about 2.7 percent of males' total DALY losses and 0.6 percent of females' losses.

3. Cardiovascular diseases include cerebrovascular diseases but do not include ischemic heart disease, which affects men more than women, or coronary artery disease.

Fiscal Policies for Health Promotion and Disease Prevention

Rachel Nugent and Felicia Knaul

Governments use fiscal policy to encourage healthy behavior. The instruments of government for this purpose are taxes and subsidies, and direct provision of certain health services for free or at subsidized rates. Examples of fiscal policies for health are taxes on tobacco and alcohol, subsidies on certain foods, and tax incentives for health care purchases.

Government intervention through fiscal policy works best when public institutions and credibility are strong, the design and application of the fiscal instruments are appropriate, and consumers' and producers' responsiveness to a price signal is high. When these conditions are not present, direct provision, information and education campaigns, or legislation may be preferable in conjunction with fiscal policy.

The purpose of this chapter is to review country experiences with promoting health through fiscal policies and to examine the usefulness and success of these policies. The chapter considers both the role of fiscal policies in the production of health and the effect of these policies on the well-being of the economy—fiscal policy for health and healthy fiscal policy.¹ Little exists in the literature linking fiscal policy and health promotion except in relation to tobacco. This work contributes to filling that gap.

The chapter deals specifically with experiences at the country level with tax policies affecting some goods related to health, such as food, tobacco, alcohol, and condoms; subsidized provision of workplace promotion of healthy behavior and caregiving; and direct subsidies affecting food provision and fortification, cooking fuels, water purification and soap, condoms, bednets, vaccines, and medical research. The chapter only touches on health care provision and does not discuss its financing, either directly by governments or through insurance, because other chapters deal with those topics.

The chapter is divided into five sections:

- The first section provides a general framework through which fiscal policy options can be considered in terms of their impact on health and the health sector.
- The next section examines the experiences in developing countries of using subsidies to achieve health-related objectives (columns 1 and 2 in table 11.1).
- The third section presents examples of how taxes are used in a number of countries to promote health (column 3 in table 11.1).
- The next section discusses nonhealth goods where fiscal policies are often used and have important indirect health benefits (lower part of column 2 in table 11.1).
- The final section presents conclusions and suggestions for further research and policy development.

USE OF FISCAL POLICY FOR HEALTH IN DEVELOPING COUNTRIES

Fiscal policies come in a wide range of designs, but the main effect is either to alter the price of health-related goods or to alter the quantity available. Table 11.2 summarizes the health interventions subject to fiscal policies. The behaviors that require these interventions are divided into the following categories:

- unhealthy consumption (foods, tobacco, and alcohol), for which the most salient fiscal policies are taxes on consumers and producers, and fines

Table 11.1 Fiscal Policies for Health Promotion Covered in Chapter 11

Subsidy for or tax imposed on	Health-related products receiving direct subsidies	Subsidized provision of health	Health-related products directly taxed	Government financing of health care
Consumer	Medicine Food Cooking fuel Water purification Soap Condoms Bednets	Caregiving (partially covered)	Tobacco Alcohol Food Imported medicine and supplies	Not covered
Producer	Vaccinations Food additives Medical research	Workplace promotion of healthy behavior (partially covered)	Fuel usage (partially covered)

- health promotion and disease and accident prevention (hygiene, pollution, safety, public health, maternal and child and reproductive health, infectious disease, and healthy lifestyles), for which the most important fiscal instruments are subsidies, but which may also be affected by tax policy
- health care goods and inputs, including insurance and human resources, that may be exempted from taxation, subsidized, or guaranteed as a constitutional right
- other goods that indirectly promote health (education, housing, agriculture, energy, charitable giving, charities that provide targeted subsidies, and so on), which are often subject to their own particular tax regime or sets of subsidies that affect their production or consumption and, therefore, also affect health behavior
- research and development initiatives that can be applied to health and health care goods and are sensitive to tax exemptions and subsidies.

Fiscal interventions can have various rationales, such as macroeconomic benefits, equity, or efficiency—and promoting health may or may not be the primary goal. A fiscal policy may be designed to affect some other sphere of behavior or a good other than health—for instance, education—and the effects on health or the use of health care may be indirect. The shaded boxes in table 11.3 indicate the possible rationale behind each type of fiscal policy.

A fiscal policy should be effective, efficient, and cost-effective and should promote or maintain equity goals. An effective tax or subsidy reaches the intended target and alters health-related behavior in the desired manner. An efficient policy minimizes resource distortions and involves minimal administrative costs. A cost-effective policy has the lowest cost relative to the desired health goal.

SUBSIDIES FOR HEALTH AND HEALTH-RELATED PRODUCTS

Using examples primarily from developing countries, this section of the chapter analyzes the range of subsidies that are available to promote healthy behavior and the consumption of health-related goods. The first sections deal with consumer subsidies both to promote the consumption of health-producing goods and of health care. The second section discusses producer subsidies.

Consumer Subsidies

Governments use consumer subsidies to encourage the use of a beneficial product by lowering the price consumers pay—usually in situations where the consumers are too poor, the market prices of the good are too high, or both situations apply—to otherwise achieve a socially optimal consumption level. Examples include subsidies for staple foods, condoms, soap, insecticide-treated bednets, cooking fuels, and medicines.

Staple Foods. Ample evidence indicates that food subsidies are effective in improving nutrition; however, appropriate targeting is often a problem (Alderman 2002). Subsidies may be targeted to specific foods, specific delivery locales or geographic areas, or specific populations. Often targeting includes all three.

Food-specific subsidies, whether in the form of general subsidies, ration cards, quotas, or food stamps, increase food consumption. They will have a positive effect on health if this consumption occurs in undernourished populations that require increased caloric or nutrient intake. In some cases, food subsidy programs have had unintended macroeconomic and

Table 11.2 Use of Taxes and Subsidies to Promote Health by Type of Intervention

Intervention	Taxes					Tax preferences				Subsidies

microeconomic consequences (Adams 2000; del Ninno and Dorosh 2002; Pinstrip-Anderson 1988; Siamwalla 1988). They become expensive if they are too widely available, can create incentives for black market activities, and can affect prices and volumes in agricultural and trade markets.

Indonesia switched from a general rice support system to a limited subsidy during the 1997 macroeconomic crisis. The earlier system had successfully reduced food insecurity to low levels, but higher prices increased the cost of maintaining the subsidy and led to food being smuggled out of the country (Tabor and Sawit 2001). The government targeted the new rice subsidy to the poor and issued ration cards. Within roughly a year of implementation, the subsidy was reaching an estimated 85 percent of the poor. Only about 10 percent of the subsidy appeared to be reaching nontarget population groups.

India has subsidized essential consumer goods for decades, including health-related goods such as food grains, edible oils, sugar, and fuels (S. Jha 1992). The government rationed certain goods in the belief that only the truly needy would endure waiting in lines and purchasing the poorer quality products that were involved in the subsidy schemes. This is called *self-targeting*. However, Jha shows that 40 percent of the population purchased subsidized rice in 1990, only half of whom were poor. The government recently modified the program to better target the subsidy to the poor and removed such barriers as bulk purchasing (Rao 2000).

The Arab Republic of Egypt's generalized program also illustrates the problems that beset broad food subsidy programs. The program reached its zenith in 1980, when it subsidized 20 food products and accounted for 15 percent of government expenditures (Adams 2000). The program has been scaled back to cover four staple foods and now accounts for 6 percent of government expenditures. Nevertheless, about 75 percent of the population holds ration cards entitling them to purchase the subsidized foods. The program is intended to achieve self-targeting, but the nonpoor purchase many of the subsidized foods. The program accounts for 44 percent of the total calorie supply of the poorest quintile group, but in rural areas, the rich obtain more calories from subsidized food than the poor do.

Musgrove (1993) reviews 104 supplementary feeding programs in 19 countries in Latin America and the Caribbean. The review covers a range of program sizes, from those serving 1,000 individuals to those supplying 28 million people; of types of subsidies (namely, food distribution, direct feeding, and direct payments); of levels of coverage of the targeted population, ranging from 1.9 to 100.0 percent; and of extent of coverage of the poor, varying from 5.8 to 88.0 percent. The per capita costs of reaching beneficiaries differed widely. The most common reasons for program ineffectiveness were spreading resources too thinly across beneficiaries, targeting foods with minor health benefits, choosing inappropriate beneficiaries, and encountering excessive costs in distributing resources.

These kinds of issues underscore the importance of design considerations and country conditions in creating effective and efficient food subsidy programs.

In sum, many food subsidy programs avoid the political and administrative challenges of explicit targeting by allowing universal access to the subsidies on the assumption that the needy will self-select into the programs. However, Adams (2000) shows that countries with targeted food programs—for example, Chile, Jamaica, and Peru—provide much higher income transfers to the poor than do self-targeted programs of the kind used in Egypt, Morocco, and Tunisia.

Condoms. Preliminary investigation indicates that subsidies on condoms can be effective in increasing their use in both general and high-risk populations, but whether price reduction, increased access, or education leads to greater use is not clear (Price 2001) because information campaigns about the health benefits of condoms usually accompany price subsidies. Recent surges in social-marketing schemes to distribute condoms as part of the fight against HIV/AIDS, especially in Africa, have increased condom use.²

Few researchers have compared HIV infection rates—or even condom use rates—before and after the introduction of a subsidy on condoms. Cohen and others (1999) conclude that in a particular jurisdiction in Louisiana, free distribution through public clinics and 1,000 small businesses in areas with high levels of HIV and other sexually transmitted diseases achieved significantly higher condom distribution than a fee-based system (77 percent use during the last sexual encounter compared with 64 percent) and that the revenues from cost recovery were insufficient to justify imposition of the fee. The dropoff in condom use during the cost-recovery period persuaded the jurisdiction to reinstate the free distribution program.

Another example suggests that promotion and information are also effective. A social-marketing effort in Turkey in the early 1990s offered condoms at a commercial price but included intensive advertising and other promotional efforts. It achieved sales well beyond original expectations and gained 41 percent of the market share (Yaser 1993).

Water Purification. The U.S. Centers for Disease Control and Prevention and the Pan American Health Organization designed the Safe Water System Initiative to improve the quality of drinking water for households that draw their water from sources outside the home. The principle underlying the initiative is to subsidize storage containers, disinfectant, and education on proper handling to avoid contamination (Quick and others 1999). Numerous countries have implemented similar initiatives, including Bangladesh, Bolivia, Burkina Faso, Kenya, and Zambia. The government provides containers and chemicals at subsidized prices, but the costs are still higher than the cost of boiling water (Quick and others 2002).

Soap. Another proven method for reducing the incidence of diarrhea and other hygiene-related diseases is hand washing, with or without soap. Whether the key factor is education or the subsidized provision of soap is unclear. Some investigators claim that small-scale programs that subsidize soap and educate households about the benefits of hand washing are self-financing because of the consequent reduction in disease (Borghi and others 2002).

Luby and others' (2001) results from Pakistan suggest that education alone may be just as effective as education accompanied by soap provision in reducing diarrheal disease. By contrast, Hoque (2003) and other researchers suggest that the cost of soap is a barrier to its widespread use among extremely poor populations and that behavioral change may be difficult to achieve without a subsidy.

Insecticide-Treated Bednets. The degree of subsidization of bednets has become a controversial issue, with some arguing for full subsidization and others for partial subsidization. Most long-term studies indicate that consumers resist purchasing bednets even at subsidized prices after they have had access to free bednets (Snow and others 1999).

A number of researchers have undertaken studies in various locations in Africa to assess the effect of selling bednets rather than providing them free to vulnerable populations (Armstrong-Schellenberg and others 2001; Kolaczinski and others 2004; Snow and others 1999). The key issue is consumers' responsiveness to changes in the prices of bednets, through either subsidies or a reduction in taxes and tariffs. Many households do not own a bednet because they cannot afford it, while other reasons are lack of information, poor access to markets, and cultural preferences (Hanson and Worrall 2002; Simon and others 2002). The evidence suggests that responsiveness to price changes alone may be modest, but in combination with removing some of the other barriers, demand for bednets could increase substantially in malaria-affected regions (Simon and others 2002).

Nigeria removed tariffs and taxes on bednet insecticide in 2001, and the 18 percent price drop resulted in an estimated 9 to 27 percent increase in purchases (Simon and others 2002). Another study that reviewed a public sector subsidy for bednets combined with private sector marketing and distribution by means of a social-marketing scheme concluded that the program was successful because 18 percent of children slept under bednets as a result; however, the low insecticide retreatment rate led the authors to conclude that subsidies were needed on both bednets and insecticide (Armstrong-Schellenberg and others 2001).

Clean Cooking Fuels. High rates of respiratory illness occur as a result of exposure to smoke and particle emissions from biomass burning in many developing countries. Fuel subsidy pro-

grams have been designed to promote the use of liquid petroleum gas, natural gas, or kerosene, which burn more cleanly and emit a low amount of smoke and particulates, but none has been efficacious or efficient (UNDP 2003).

Liquid petroleum gas subsidies have been shown to benefit middle- and higher-income families in urban areas rather than the poor (UNDP 2003). In attempting to target the poor more accurately, Côte d'Ivoire and Senegal focused subsidies on smaller liquid petroleum gas cylinders but found that poor consumers still preferred charcoal (UNDP 2003). Electricity subsidies in low-income countries are also often skewed toward the well off, who are more likely than the poor to be connected to the electricity grid (Alderman 2002).

Medicines and Medical Supplies. In relation to the direct provision of health-related goods, including drugs, supplies, and services of medical personnel, governments may subsidize and regulate drug prices, make bulk purchases from manufacturers for distribution at reduced prices, and distribute certain drugs with complete or partial subsidies to target populations. Specific interventions—for instance, antiretrovirals, vaccines, or reproductive health care—are often more heavily subsidized or may be targeted by population group or disease—for example, child and maternal health, tuberculosis, and malaria. With the exception of antiretroviral drugs, the health benefits and low costs of these medicinal interventions make them good targets for subsidization.

General Health Care. In developing countries, where informal sectors tend to be large, providing subsidized health care is an important tool for health promotion. Some countries have chosen direct provision of health goods, whereas others combine the public provision of services with subsidized health insurance for families below a certain income cutoff. Both models require identifying the families that are unable to afford health care and the types of services that are considered public goods.

One example of subsidizing the production and provision of health care is the Mexican program originally called PROGRESA and now known as Oportunidades. This program is also an example of how income transfers for other goods can affect health and how cross-subsidies can be used to strengthen the incentive effects of a fiscal policy to promote healthy behavior. The government launched the program in 1997 to provide subsidized health, nutrition, and education to poor families. By mid 2004, it was serving the majority of those living below the poverty line. Oportunidades combines a cash transfer equivalent to 20 to 30 percent of families' incomes that includes incentives for positive behaviors in relation to health, nutrition, and schooling with subsidized basic health interventions. The program is largely financed from federal budgets.

Oportunidades is successful both in terms of targeting the poorest households and in terms of achieving measurable gains in health, health care use, nutritional status and growth, school attendance, and school achievement. Gertler (2004), for example, finds significant and cumulative reduction in illness rates among children, lower prevalence of anemia, and an additional centimeter of growth in the first year of the program.

The program's success is attributable to many factors, including a rigorous longitudinal evaluation process; an integrated package of services; and the presence of financial stimuli tied to school attendance, visits to health clinics, and participation in health education initiatives. Furthermore, the program incorporates several targeting methods.

Producer Subsidies

Governments use producer subsidies to encourage production that improves health by lowering manufacturers' costs in situations in which the private market supply is inadequate to meet social needs. Examples include medical supplies, vaccines, food additives, and medical research.

Food Fortification. Governments sometimes subsidize the fortification of staple foods through the addition of selected micronutrients as a way of achieving broadly based nutrition improvements. Challenges involve maintaining a relationship between the public sector, which initiates and funds the program, and the private sector, which implements the fortification. Incentives for private providers are often needed in the form of tax exemptions, import preferences, subsidies for start-up costs, quality control, and training. Illegal markets selling nonfortified products at a lower price often arise in response (Alderman 2002; Dorosh, del Ninno, and Sahn 1996; Rao 2000).

Health Research. Government support for health research consists of the provision of direct subsidies for private sector investment, the granting of tax benefits for private research and development (R&D) investment, the establishment of property rights and a system to protect them, and the promotion of private goods by other means (OECD 2003). Despite the strong evidence from developed countries that the private sector will underinvest in R&D and that tax incentives increase R&D investment, developing countries should be cautious in applying those results to their own situations. Empirical investigations tend to conclude that producer subsidies for R&D in developing countries are not effective (Shah 1995; Zee, Stotsky, and Ley 2002). Many conditions need to be in place to realize high social returns and to minimize rent seeking and profiteering, including a strong private sector research effort that is stimulated by the public investment, the presence of appropriate targeting, a transparent and fair set of public laws and insti-

tutions to grant and monitor the tax benefits, and the ability to forgo alternative public investments.

TAXES AND TAX EXPENDITURES: DESIGN AND OUTCOMES

The following section describes various examples of the use of taxation directed at both consumers and producers. This section of the chapter also analyzes the design issues that are important in order to guarantee that these instruments contribute to achieving healthy fiscal policy.

Taxes on Consumers

Sales taxes—including excise taxes and value added taxes—and exemptions from those taxes are the most common fiscal policy tools used to influence consumers' health purchases. Examples are exempting medicines and foods from sales tax and imposing an excise tax on cigarettes and alcohol. Developed countries often use income tax incentives to provide deductions and credits for specific health care purchases. Box 11.1 discusses issues surrounding use of taxes for health.

“Sin” Taxes on Tobacco and Alcohol. A wide range of countries and local jurisdictions have taxed tobacco, with acknowledged success in reducing consumption (P. Jha 1999). The health benefits of curbing the demand for cigarettes may go beyond eliminating the health consequences of smoking and secondhand smoke if consumer expenditures are diverted from cigarettes to healthier alternatives (for example, food).

Taxes on alcohol are widespread and are used primarily to raise revenue. Governments typically impose taxes at the producer, wholesale, and retail levels that are levied as a percentage of the sale price or are based on a flat amount per unit. Harmful alcohol consumption is controlled through prohibition, government monopolization of sales, “dry” days, restrictions on hours when sales are legal, restrictions on age and locations for sales and consumption, laws against drinking and driving, limits to alcohol content, laws against the sale of certain types of alcohol, and licensing.

Alcohol taxes do contribute revenue to government coffers in developing countries, generally in higher proportions than in developed countries (WHO 2002a), but smuggling and tax evasion are common. For example, Zimbabwe raised taxes on certain beers in 1995 but repealed the increase within months when tax revenues dropped significantly (WHO 2002a). Some developing countries have lowered alcohol taxes with consequent negative results. Mauritius experienced a dramatic increase in drunk-driving arrests, alcohol-related fatalities, and hospital admissions after it reduced taxes on alcohol (WHO 2002a). In sum, alcohol taxes do reduce drinking, but the evidence that such taxes are well targeted to those most at risk of problem drinking is not strong.

Box 11.1

Using Taxes to Influence Consumption and Production Behavior

Taxes as a tool for health policy face significant implementation obstacles. First, targeting can be difficult. A close link must exist between the consumption of the product or behavior to be taxed and a specific population with a health risk. For instance, all consumers would pay a tax on “junk” food, even though it would only present a health threat to a small percentage of them. The taxed good must also be appropriately defined in relation to close substitutes; for example, taxing only certain forms of tobacco such as cigarettes, but not chewing tobacco, may increase consumption of the latter. Governments may also distinguish between locally produced goods and imported goods, often because of lobby groups. If governments place a higher tax on the good that is less harmful, this action will encourage greater consumption of the more harmful good.

Key weaknesses in using taxes for health policy include the feasibility of smuggling and the existence of large

informal or illegal markets. Smuggled or contraband products that cannot be regulated or certified for quality and safety, such as alcohol or tobacco in particular, may be more harmful to health than goods that are legally produced and sold.

Any tax should be efficient in terms of both its administration and its effect on resource allocation. Tax authorities need a well-functioning system for imposing, collecting, and monitoring taxes and taxed products, and the public should perceive the system as fair and credible in order to achieve a high degree of compliance.

Finally, a tax should be cost-effective in achieving its stated goal of improving health outcomes. The net costs of imposing the tax should compare favorably with the net costs of using another policy instrument, such as regulation or direct government provision. Depending on the characteristics of the tax base, the health goal and the revenue goal may even be at odds.

Food Taxes. The issue of taxing unhealthy foods has received increasing attention in the wake of the Global Strategy on Diet, Physical Activity, and Health, which was approved by member countries of the World Health Organization (WHO 2004). The global strategy points to the rising prevalence of obesity and overweight in developing countries, along with that of nutrition-related noncommunicable diseases, and recommends that countries consider fiscal policies and other measures to reduce those problems.

Governments can use excise taxes to reduce the consumption of unhealthy foods only if tax rates are sufficient to change consumption in a way that improves health outcomes, if they tax enough harmful foods or food ingredients, and if they levy the taxes in an effective manner. Guo and others' (1999) study in China demonstrates significant potential for price changes to affect consumption. The researchers studied dietary intake in a sample of urban and rural Chinese households and show that a 10 percent increase in the price of pork potentially reduces fat consumption by 8 percent. Energy and protein intake would both drop by 2 percent. The overall effect may be different for the poor and the rich. The potentially harmful effects on the poor of increasing the price of pork would be buffered by substitutions from other food groups, such as oil, wheat flour, and coarse grains, but concerns remain that overall nutrition would worsen. These results suggest that using price changes to alter dietary intake

in a setting where overnutrition and undernutrition coexist may have mixed outcomes.

A natural experiment in Poland during the economic downturn of the 1990s suggests a beneficial role for price policy in a consumer switch from animal fats to vegetable fats with lower amounts of trans fatty acids (Zatonski, McMichael, and Powles 1998). A dramatic decline in ischemic heart disease and related circulatory system diseases during the first half of the 1990s is most easily explained by the removal of consumer subsidies from foods of animal origin, the aggressive marketing of margarines, and a general decline in food purchasing power. The major change in the food supply appeared to be a reduction in foods containing animal fats; however, no direct relationship can be conclusively attributed without further study of the Polish experience and the experiences of other countries undergoing similar transitions.

Governments may choose to address food-related health problems by taxing imports of high-fat or high-sugar food; however, such efforts conflict with rules governing international trade. Fiji, for example, tried to ban the import of mutton flaps, an extremely fatty food that was contributing to the country's obesity problem. To comply with its World Trade Organization obligations, Fiji had to ban the sale of all mutton flaps, not just imports (Evans and others 2001). One analysis suggests that the same kind of broad treatment would be necessary to grant subsidies to healthy foods, but taxing unhealthy

domestic foods alone would probably not pose a problem under World Trade Organization rules (WHO 2003). Furthermore, avenues for using other regulatory and economic policies to improve the consumption of healthy foods may be acceptable under the World Trade Organization Agreement on Technical Barriers to Trade and the Agreement on Agriculture if countries can justify them as contributing to legitimate national health objectives.

Agricultural policies affect food prices, food choices, and farm incomes in addition to the food security of both rural and urban populations. Each country must assess the potential for reorienting its agricultural policies so as to produce a healthier food supply. Developing countries are generally more likely to directly subsidize food consumption than food production; however, they frequently make indirect subsidies available through the provision of cheap fuel, chemical inputs, water, and loans to the agriculture sector. These policies may be environmentally and fiscally costly and rarely contribute to improved population health.

Research is needed on individual countries' agricultural policies and food supply needs to make them more compatible (Nugent 2004). At the same time, the dynamics of food choice and the effects of price manipulation need to be better understood before tax and subsidy systems can be designed to effectively promote healthy food choices.

Sales Tax Exemptions on Healthy and Staple Foods and Medicines and Other Health Care Goods. Governments may set tax policies to ensure that certain expenditures on health-related behaviors and health goods are tax deductible or tax exempt for firms, employers, or individuals. Exemptions should apply to a limited number of goods that are easily differentiated from goods that are not exempted. Note that in countries with large informal sectors, income tax systems are weak, and fiscal policies for the deductibility of credits are unlikely to be effective.

South Africa provided value added tax exemptions for a short list of essential foods and found a varied consumption pattern by commodity, with the poor receiving most of the benefits of the maize exemption, but few of the benefits of the milk exemption (Alderman and del Ninno 1999).

Mexico imposes a 15 percent value added tax on almost all goods. Exemptions include medicines, physician's services, and some foods. Recently, a government proposal to make drug and food purchases eligible for value added tax and to channel the resulting revenues into financing programs targeted to the poor has given rise to extensive debate. Those in favor have argued that the existing subsidy is regressive because most drug and food purchases are by the wealthy (Fundación Mexicana para la Salud 2001).

Many developing countries concerned about the spread of HIV/AIDS have dropped import taxes on condoms, but others

continue to impose tariffs on imports. For example, Malaysia is a major producer and imposes a 25 percent tax on imports. Brazil used to impose both an import tax and a distribution tax that amounted to a total of 45 percent of the original condom price, but it granted a permanent sales tax exemption when condom sales increased following a temporary tax holiday.

Taxes on Producers

Producer taxes are usually aimed at discouraging socially harmful products or processes. They can be imposed either on the use of certain inputs, such as more heavily polluting fuels, or on their outputs, such as emissions of air pollutants.

Theoretical and simulation models have examined the use of taxes on fuels and emissions taxes to control air pollution (World Bank 1994a, 1994b), but empirical data are lacking. Models of taxes suggest potential to induce substitution by cleaner fuels and reductions in overall energy use, but actual results will depend on the availability of fuel substitutes within countries. Data on Chilean manufacturing support the possibility of clean fuels substitution but indicate the likelihood of uneven sectoral incidence of the emissions tax. For example, bakeries were responsive to changes in relative prices, whereas metal products plants were unresponsive, and meat packers were unable to adjust their electricity demand but could reduce energy from other sources (World Bank 1994b). If this potential were realized on a global or regional basis—for example, through agreements to the Kyoto Protocol—a double benefit of reducing harmful externalities and raising significant revenues might be achieved.

FISCAL POLICY TO PROMOTE HEALTH

The fiscal policies discussed in this chapter in relation to health and health care goods can be applied to other goods and markets, such as housing and education, some of which may have important effects on health. This chapter does not provide an exhaustive discussion of the goods that indirectly promote health, but it does briefly consider some of these policies in relation to workplaces, employment leave policies, and day care. Note that policies focused on formal labor markets will not be effective in reaching large segments of the population in many countries. Policies that provide health-related services, such as day care, that are not based on formal labor market participation may have a broader effect.

Workplace Health

Governments can use tax relief and financial support to producers to encourage firm-specific actions to promote health. Many countries mandate safeguards in the workplace and levy penalties against occupational health violations. Most

government actions are mandates rather than fiscal policies, but a combination of approaches may also be used.

A growing area for workplace health promotion is HIV/AIDS. Bloom and others (2004) suggest that the failure on the part of most firms to act—even if they correctly perceive the business, human, and social challenges HIV/AIDS poses—is attributable to a lack of incentives. Significant externalities (benefits to society and firms) are likely to result from promoting greater action by firms. Some private firms have begun providing HIV/AIDS prevention and treatment services to employees, families, and their communities (“Face Value: AIDS and Business” 2004). Sometimes government support is involved, but little information is available to evaluate the potential of fiscal policy.

Maternity Leave, Sick Leave, and Family Care Leave

Government policy can alter choices regarding different types of worker leave. Many countries have financial or legislative support for caregiving, although most focus on children. Rhum (1998) cites evidence that more than 100 countries—and almost all the industrial countries—have some legislation about parental leave, although in several countries it is unpaid.

Caregiving policies that allow people to take time off work to care for aged and chronically ill family members are less common than policies for child care, particularly in developing countries, but tax benefits and allowances for these types of caregiving are becoming increasingly available in the industrial countries (Brodsky, Habib, and Mizrahi 2000; Pijl 2003; Wiener 2003). Although the provision of services in kind by the government is still an important mechanism, the trend is toward empowering consumers by offering subsidies or tax deductions that allow them to choose among caregiving options. Countries tend to use a combined approach to financing that relies on payroll taxes imposed on employees and employers, general taxation, and copayments. Important issues that developing countries need to address in this respect include targeting compared with universal provision, the mechanisms to pay for or to insure care, and the extent to which long-term care should be integrated into the health care and social service systems (Brodsky, Habib, and Mizrahi 2000; WHO 2003).

Day Care and Early Childhood Education

Some countries use targeted fiscal policies, such as income tax deductions or direct provision, to increase the use and quality of early childhood education and child care services. Important health, labor market efficiency, growth, and equity arguments support subsidizing these services, particularly for low-income families, because without subsidies women may be forced to limit their work or to leave the labor market, and families

may have to use low-quality care or leave children unattended. Van der Gaag and Tan (1997) argue for public subsidies based on cost-benefit analysis of early childhood development programs. They conclude that the greatest payoff comes from targeting the most deprived families and that the private benefits are sufficient to expect better-off parents to pay.

Two large-scale, home-based day care programs targeted to poor families are Community Well-Being Homes (Hogares Comunitarios de Bienestar) run by the Colombian Institute for Family Well-Being (Instituto Colombiano de Bienestar Familiar) in Colombia (Myers 1995) and the Integrated Child Development Program in Bolivia. The former is an interesting case of a targeted cross-subsidy because the financing comes from the wealthier formal sector by means of a payroll tax, whereas the services are targeted to the poorest families. The program was 85 percent subsidized in the early 1990s. Parents paid a proportion of the caregivers’ wages on a sliding-scale user fee (Young 1996). The Bolivian program includes nutrition, health, and cognitive development interventions and is one of the few early childhood programs in developing countries that has been formally evaluated (Behrman, Cheng, and Todd 2000). The evaluation shows that the program significantly increases cognitive achievement, although the results depend on age and the duration of exposure to the program.

CONCLUSIONS

A broad range of experiences cited in this chapter demonstrates that fiscal and health policies interact in a number of areas. Although substantial research has focused on tobacco and alcohol, other links—for example the promotion of health in the workplace—have been much less recognized or studied, particularly in developing countries.

The research presented in this chapter suggests that fiscal policy can be a useful tool for influencing health in developing countries. Nevertheless, budgetary limitations to withstand pressure for program expansion, leakages to unintended beneficiaries, public compliance with the tax system, and corruption among both government officials and the public are important factors to take into account in design and implementation. Table 11.4 summarizes some lessons learned on the use of fiscal policy to promote health.

Governments may find it worthwhile to examine their use of fiscal policies to identify the entire range of effects and have health ministries participate in this exercise. More generally, the chapter indicates an area for increased interaction between ministries of health and finance. Healthy fiscal policy and fiscal policy for health should be topics that are debated, agreed on, and formalized between the two areas of policy making to guarantee that those developing fiscal policy take both its economic and its health implications into account.

Table 11.4 Lessons in Using Fiscal Policy for Health Promotion

Intervention choice	Program design	Instrument design	Policy regime
<ul style="list-style-type: none"> • Select interventions that directly address the health objective. • Ensure that interventions are sufficient to effect the health change, but not excessive. • Choose interventions with high health returns and low costs relative to alternatives. 	<ul style="list-style-type: none"> • Ensure that the health benefits of the desired change are apparent and significant. • Make sure that the tax base is adequate and stable and that no untaxed close substitutes are available. • Be aware that a large informal labor sector will limit the effectiveness and equity of benefit delivery. • Avoid programs whose expenses may become unsustainable because of uncontrollable factors. 	<ul style="list-style-type: none"> • Choose the appropriate recipients for a subsidy or tax preference. • Do not spread the benefits across too large a group. • Note that targeting by demographic, geographic, or need categories is more efficient than no targeting or self-targeting. • Be aware of the price elasticities of a taxed good so that its incidence is clear. 	<ul style="list-style-type: none"> • Ensure that policy is consistent and predictable. • Ensure that institutions carrying out a policy are open, accountable, and uncorrupted. • Consider tradeoffs between efficiency and distributional goals. • Seek non-health sector opportunities to effect health goals.

Source: Authors.

Rigorous evaluation studies are needed of most of the fiscal policy interventions discussed in this chapter. Such studies should address the health, fiscal, macroeconomic, and distributional effects of using fiscal policy to achieve health goals and should be performed in a range of countries with mixed public and private sector capacity to deliver health services. The studies should also examine the differing effects of policies in urban and rural settings and across income quintiles. Of particularly high priority are further studies of the results of subsidizing drugs, medical supplies, and hygiene interventions with or without education campaigns. Those areas may reveal new fiscal approaches for addressing the disease burden in developing countries.

DISCLAIMER AND ACKNOWLEDGMENT

The results and conclusions in this chapter are those of the authors and do not necessarily reflect the opinions of the institutions for which they work. The authors are grateful to Ana Mylena Aguilar, Hector Arreola, Ania Burczynska, Esperanza Calleja, Marissa Courey, Monica Hurtado, Vanesa Leyva, Eugenia Rocha, Swathi Sista, and Sinaia Urrusti for excellent research assistance and to the Mexican Health Foundation's Council on Health and Competitiveness and the National Council for Science and Technology of Mexico for support for this research.

NOTES

1. The idea of healthy fiscal policy is discussed in Cook and Vlaisavljevich (1994), Joffe and Mindell (2004), and Secretaria de Salud (2001).

2. *Social marketing* is defined as the use of marketing principles to influence behavior for a socially desirable outcome. It provides a desirable product at an affordable price with adequate promotion and placement (that is, access).

Chapter 12

Financing Health Systems in the 21st Century

George Schieber, Cristian Baeza, Daniel Kress, and Margaret Maier

This chapter assesses health financing policy in low- and middle-income countries (LMICs). It discusses the basic functions of health financing systems and the various mechanisms for effective revenue collection, pooling of resources, and purchase of interventions (WHO 2000). It analyzes the basic financing challenges facing LMICs as a result of revenue generation and collection constraints, increasing flows of development assistance for health (DAH) coupled with donors' concerns about aid effectiveness, and the difficult economic situation facing many LMICs as a result of globalization and poor economic management.

In 2001, about US\$3.059 trillion—approximately 9 percent of global gross domestic product (GDP)—was spent on health care worldwide (WHO 2004b; World Bank 2004e); however, only 12 percent of this amount was spent in LMICs, which account for 84 percent of the global population and 92 percent of the global disease burden (Mathers and others 2002). Ongoing epidemiological, demographic, and nutrition transitions will pose significant challenges for health financing systems in LMICs in the near future as the communicable disease burden lessens and the noncommunicable disease and injury burdens expand. At the same time, the current communicable disease burden in low-income countries (LICs) and in many middle-income countries (MICs), especially that caused by malaria, tuberculosis, and HIV/AIDS, poses a serious threat to public health, health systems, and economic growth.

As a result of the international focus on poverty reduction, the HIV/AIDS pandemic, and the Millennium Development Goals (MDGs), international health financing policy has evolved over the past decade from defining a basic package of

cost-effective health services to figuring out how to finance and deliver those services equitably and efficiently, to recognizing the need to scale up health systems to meet basic service needs and achieve the MDGs, which will require large amounts of DAH for poor countries (see, for example, WHO 2000, 2001; World Bank 1993, 2004b).

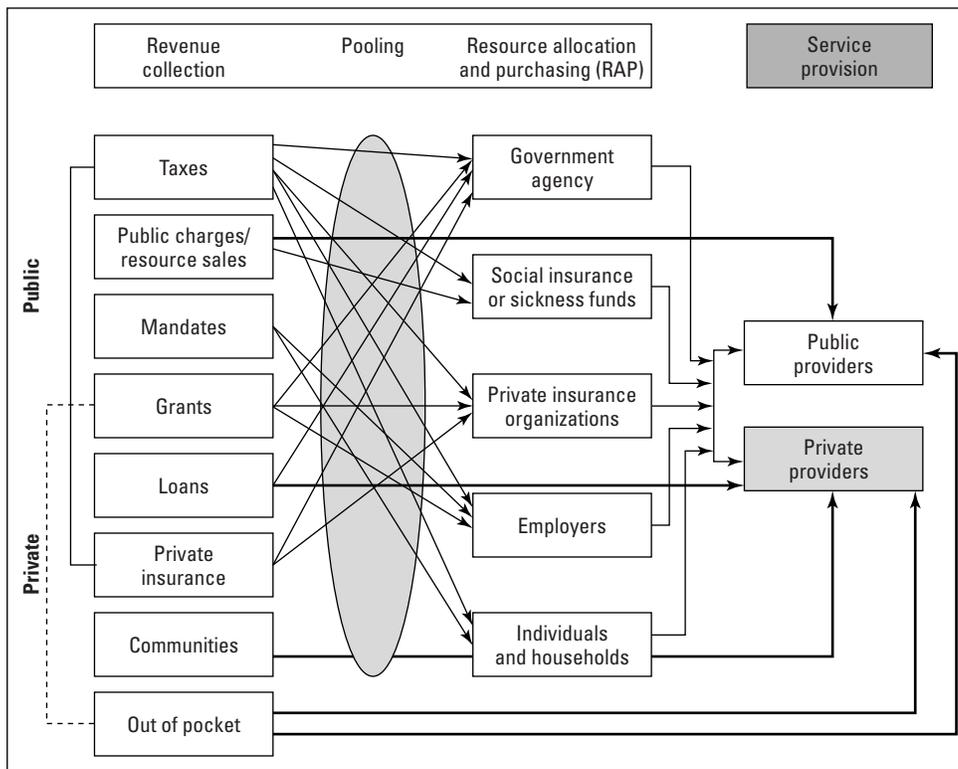

This chapter updates and reviews the global evidence on health spending, health needs, revenue-raising capacity, organization of health financing, and trends in DAH. It discusses the key challenges that country policy makers face in ensuring access to services and financial protection while dealing with a new health policy world defined by new instruments such as sectorwide approaches (SWAs) and Poverty Reduction Strategy Papers (PRSPs). The chapter also discusses the scope and potential effects of new and relatively large global funding sources, such as the Bill & Melinda Gates Foundation; the Global Fund to Fight AIDS, Tuberculosis, and Malaria; and the Global Alliance for Vaccines and Immunization (GAVI) Vaccine Fund.

HEALTH FINANCING SYSTEMS

Health financing provides the resources and economic incentives for the operation of health systems and is a key determinant of health system performance in terms of equity, efficiency, and health outcomes.

Health Financing Functions

Health financing involves the basic functions of revenue collection, pooling of resources, and purchase of interventions.

Source: Authors.

Figure 12.1 Interactions among Revenue Raising, Risk Pooling, Resource Allocation, and Service Provision

- *Revenue collection* is how health systems raise money from households, businesses, and external sources.
- *Pooling* deals with the accumulation and management of revenues so that members of the pool share collective health risks, thereby protecting individual pool members from large, unpredictable health expenditures. Prepayment allows pool members to pay for average expected costs in advance, relieves them of uncertainty, and ensures compensation should a loss occur. Pooling coupled with prepayment enables the establishment of insurance and the redistribution of health spending between high- and low-risk individuals and high- and low-income individuals.
- *Purchasing* refers to the mechanisms used to purchase services from public and private providers. Figure 12.1 illustrates these functions and their interactions.

In terms of health policy at the country level, these three financing functions translate into the following:

- raising sufficient and sustainable revenues in an efficient and equitable manner to provide individuals with both a basic package of essential services and financial protection against unpredictable catastrophic financial losses caused by illness or injury.

- managing these revenues to equitably and efficiently pool health risks; and,
- ensuring the purchase of health services in an allocatively and technically efficient manner.

These financing functions are generally embodied in the following three stylized health financing models:

- *national health service (NHS)*: compulsory universal coverage, national general revenue financing, and national ownership of health sector inputs
- *social insurance*: compulsory universal coverage under a social security (publicly mandated) system financed by employee and employer contributions to nonprofit insurance funds with public and private ownership of sector inputs
- *private insurance*: employer-based or individual purchase of private health insurance and private ownership of health sector inputs.

Although these models provide a general framework for classifying health systems and financing functions, they are not useful from a micropolicy perspective because all health systems embody features of the different models. The key health policy issues are not whether a government uses general

revenues or payroll taxes, but the amounts of revenues raised and the extent to which they are raised in an efficient, equitable, and sustainable manner. Similarly, nothing is intrinsically good or bad about public versus private ownership and provision. The important issue is whether the systems in place ensure access, equity, and efficiency.

Revenue Collection

Governments use a variety of financial and nonfinancial mechanisms to carry out their functions, including directly providing services; financing, regulating, and mandating service provision; and providing information (Musgrove 1996). A substantial literature is devoted to the various sources for financing health services and the economic and institutional effects of using these sources in terms of efficiency, equity, revenue-raising potential, revenue administration, and sustainability (Schieber 1997; Tait 2001; Tanzi and Zee 2000; WHO 2004b; World Bank 1993). An additional source of revenue receiving increasing attention is efficiency gains (Hensher 2001). LICs rarely use tax credits as a financing source (Tanzi and Zee 2000).

The key fiscal issue for LMICs is for their financing systems, both public and private, to mobilize enough resources to finance expenditures for basic public and personal health services without resorting to excessive public sector borrowing (and creation of excessive external debt); to raise revenues equitably and efficiently; and to conform with international standards (Tanzi and Zee 2000). Institutional constraints are particularly important, including a country's economic structure—for example, large rural populations and limited formal sector employment; ineffective tax administration; and lack of data, all of which tend to preclude LMICs from using the most efficient and equitable revenue-raising instruments (Schieber and Maeda 1997; Tait 2001). The high level of inequality in most LMICs means that governments face the difficult situation of needing to tax the politically powerful and wealthy elites to raise significant revenues in an equitable manner but of being unable to do so easily. As Tanzi and Zee (2000, 4) point out, “tax policy is often the art of the possible rather than the pursuit of the optimal.”

Another area of health financing that continues to generate heated debate is user fees (that is, charges to individuals for publicly provided services). The need to significantly scale up resources to meet the MDGs in LICs has pushed the user fee issue to the forefront of this debate. Arhin-Tenkorang (2000) and Palmer and others (2004) suggest that the overall effect is negative: use decreases, particularly among the poor, and frequently, administrative costs of collecting the fees are higher than the revenue generated. Further, Kivumbi and Kintu (2002) suggest that granting waivers and exemptions for the poor is difficult, if not impossible. Given those findings, many have called for the abolition of user fees, including the United

Nations Millennium Project (2005) and the Commission for Africa (2005).

Others have argued, however, that absent resources to fund drug purchases, provide facilities with some discretionary funding, and motivate providers, use of primary health care by the poor will remain low because of both poor quality and lack of drugs, and the poor will purchase these essential services on the private market. The Bamako Initiative shows that user fees may be an important revenue source where institutions are weak, resources are limited, and the choice is between having drugs or not having them (World Bank 2003, 76–77). Furthermore, studies indicate that user fees can improve benefit incidence if user fee and waiver policies have been well designed and implemented and if providers are compensated for forgone revenues. Indeed, proponents of user fees argue that as long as the fees are set below private market levels, this “savings” may result in a net reduction in overall out-of-pocket spending for the poor (Bitrán and Giedion 2003). These diverse experiences demonstrate the difficulty involved in making blanket statements regarding user fees. As the World Bank (2003, 71) points out, “user fees, as with other public policy decisions, must balance protection of the poor, efficiency in allocation, and the ability to guarantee that services can be implemented and sustained.”

Risk Pooling and Financial Protection

Preventing individuals from falling into poverty because of catastrophic medical expenses and protecting and improving the health status of individuals and populations by ensuring financial access to essential public and personal health services provide a strong basis for public intervention in financing health systems. Public intervention may be needed because of market failures in private financing and provision (for instance, information asymmetries) and instabilities in insurance markets (such as favorable risk selection by insurers and moral hazard). Indeed, in virtually all Organisation for Economic Co-operation and Development (OECD) countries except the United States, governments have decided to publicly finance or require private financing of the bulk of health services. However, given both low income levels and limits on possibilities for domestic resource mobilization in LICs and some MICs, these countries face severe challenges in publicly financing essential public and personal health services. They also often confront difficult tradeoffs with respect to financing these basic essential services and providing financial protection against the costs of catastrophic illness.

Ensuring Financial Protection. Ensuring financial protection means that no household spends so much on health that it falls into and cannot overcome poverty (ILO and STEP 2002b). Achieving adequate levels of financial protection requires maximizing prepayment for insurable health risks; achieving the

largest possible pooling of health risks within a population, thereby facilitating redistribution among high- and low-risk individuals; ensuring equity through prepayment mechanisms that redistribute costs from low- to high-income individuals; and developing purchasing arrangements that promote efficient delivery of good-quality services.

Meeting those requirements depends on how health systems arrange the three key health financing functions of revenue collection, risk pooling, and purchasing. Although all health financing functions play an important role in ensuring financial protection, risk pooling and prepayment—whether through taxes or individual premiums—play the central and often the most poorly understood roles.

Risk pooling refers to the collection and management of financial resources so that large individual and unpredictable financial risks become predictable and are distributed among all members of the pool. The pooling of financial risks is at the core of traditional insurance mechanisms. Whereas pooling ensures predictability and the potential for redistribution across individual health risk categories, *prepayment* provides various options for financing those risks equitably and efficiently across high- and low-income pool members. The health financing models described earlier embody different means for creating risk pools and financing such pools through prepaid contributions.

In most LMICs, multiple public and limited private arrangements coexist, making system fragmentation the norm rather than the exception. This situation increases administrative costs; creates potential equity and risk selection problems, for example, when the wealthy are all in one pool; and limits pool sizes. Moreover, health care risks change over the life cycle of an individual or household, but because generally little correlation exists between life cycle needs and capacity to pay, subsidies are often necessary and are facilitated by risk pooling.

Risk pooling and prepayment functions are central to the creation of cross-subsidies between high-risk and low-risk (that is, a *risk subsidy*) and rich and poor (that is, an *equity subsidy*) individuals. The larger the pool, the greater the potential for spreading risks and the greater the accuracy in predicting average and total pool costs. Placing all participants in a single pool and requiring contributions according to capacity to pay rather than individual or average pool risk facilitates cross-subsidization and, depending on the level of pooled resources, can significantly increase financial protection.

However, spreading risks through insurance schemes is not enough to ensure financial protection, because it can result in low-risk, low-income individuals subsidizing high-income, high-risk individuals. Furthermore, significant portions of the population may not be able to afford insurance. For this reason, most health care systems aim not only at spreading risk, but also at ensuring equity in financing of health care services through subsidies from high- to low-income individuals. Equity subsidies are the result of such redistribution policies.

At least four alternative organizational arrangements exist for risk pooling and prepayment: ministries of health (MOHs) or NHSs, social security organizations (SSOs), voluntary private health insurance, and community-based health insurance (CBHI). Each of these is linked to distinctive instruments for revenue collection (for example, general revenues, payroll taxes, risk-rated premiums, and voluntary contributions) and for purchase of health services.

Within these organizational structures, three alternatives often coexist for generating revenues and financing equity subsidies: subsidies within a risk pool, subsidies across different risk pools, and direct public subsidies through transfers from the government. Although medical savings accounts (with or without public subsidization) are also sometimes referred to as a risk pooling mechanism, they do not pool risks over groups and, therefore, are far more limited in terms of predictability and equity subsidization. They are simply intertemporal mechanisms for smoothing health risks over an individual's or household's life cycle.

Subsidies within a risk pool, whether financed through general revenues or payroll taxes, are prerequisites for pooling risks in traditional NHSs and SSOs. The goal of collecting revenues through an income-related or general revenue-based contribution (in contrast to a risk-related contribution, as is generally the case with private insurance) is to generate subsidies from high- to low-income individuals. These systems are effective when payroll contributions are feasible, when the general revenue base is sufficient and a large proportion of the population participates in the same risk pool, or when both conditions exist. Moreover, in a system with multiple, competing, public and private insurers and a fragmented risk pool, payroll contributions may increase incentives for risk selection. In the case of a NHS or SSO, financial resources might be insufficient or inappropriate for spreading the financial risks or for creating an equity subsidy, particularly if the general revenue or payroll contribution base is regressive.

Subsidies across different risk pools involve the creation of funds, often called *solidarity* or *equalization funds*, financed by a portion of contributions to each risk pool. This mechanism is found in systems with multiple insurers in, for example, Argentina, Colombia, Germany, and the Netherlands. A key element of this mechanism's success is the implementation of adequate systems of compensation among different risk and income groups.

Finally, in many OECD countries, direct public transfers funded through general taxation are made to insurers for subsidizing health care for certain groups or for the entire population. They are also used in some LMICs, although at a limited level because of low revenue collection capacity.

In most LMICs, risk pool fragmentation significantly impedes effective risk pooling, while limited revenue-raising capacity precludes the use of broad public subsidies as the main

source of finance. Therefore, targeting scarce public subsidies across different risk pooling schemes is probably the most feasible way to finance equity subsidies for the poor and those outside formal pooling arrangements. However, this method has important transaction costs. Because a significant portion of the population is excluded from the formal sector, using this mechanism for ensuring universal financial protection is limited, particularly in LICs. Even if significant subsidies are available from general taxation, the lack of insurance portability restricts its usefulness as a subsidization mechanism among risk pools because individuals may lose their coverage when they change jobs. LICs and certain MICs will be challenged both to publicly finance essential public and personal health services and to ensure financial protection through equity subsidies. Thus, LMICs should strive to achieve the best value for publicly financed health services in terms of health outcomes and equity and should try to facilitate effective risk pooling for privately financed services. Providing public financing for cost-effective interventions is one critical aspect of determining which services to finance publicly.

Distributing and Sourcing Health Expenditures. As table 12.1 shows, health spending is derived from three broad sources: public sector (expenditures financed out of general revenues and social insurance contributions), private sector (expenditures financed out of pocket and by private insurance), and external sources (grants or loans from international funding agencies). In 2001, high-income countries spent an average of 7.7 percent of their GDP on health (country weighted), MICs spent 5.8 percent, and LICs spent 4.7 percent.

Even though a clear upward trend between a country's income level and the level of public and total health spending is apparent in terms of both absolute spending and share of GDP, spending for any given income level varies a great deal, particularly at lower income levels (Musgrove, Zeramini, and Carrin 2002). The composition of health spending also exhibits major differences. As incomes increase, both private and out-of-pocket shares of total health spending decrease. In LICs, private and out-of-pocket spending and external assistance account for the bulk of all health spending. As countries move up the income scale, public spending predominates and both out-of-pocket spending and external assistance decrease drastically.

LMICs with high levels of out-of-pocket spending have limited opportunities for risk pooling, which hinders allocative efficiency and financial protection efforts.¹ Moreover, low overall spending levels in many LICs and some MICs result in limited access to essential services and limited financial protection, particularly for the poor. As Musgrove (personal communication with G. Schieber, April 2004) indicates, if GDP is adjusted for basic subsistence needs, poor households in LICs appear to be spending a substantial share of their postsubsistence income on health, reinforcing much of the discussion

that follows on the need for additional funds from external financing sources.

As also discussed by Hecht and Shah in this book (chapter 13), external funds—development assistance for health—have become an increasingly important source of health financing in LICs, supporting some 20 percent of LIC spending. Specifically, DAH from governments, multilateral and bilateral agencies, and private foundations increased from an average of US\$6.7 billion between 1997 and 1999 to US\$9.3 billion in 2002. Sub-Saharan Africa received 36 percent of DAH funds in 2002, and in 13 extremely poor countries, DAH accounted for more than 30 percent of health spending (WHO 2004b).

The relationship between health expenditures and health outcomes is not always clear. Higher spending does not necessarily translate to better health outcomes. Although the evidence tenuously demonstrates a positive relationship between public spending on health and selected health indicators, it falls far short of a definitive statement (Bidani and Ravallion 1997; Filmer and Pritchett 1999; Gupta, Verhoeven, and Tiongson 2001; World Bank 1993, 2003). Health outcomes also vary across income groups, with the poor generally receiving fewer services and having worse health outcomes. As in the case of health services and health outcomes, health spending is often not pro-poor (Gwatkin and others 2003). The quality of a country's institutions also plays a key role in determining the effectiveness of health spending (Devarajan, Swaroop, and Heng-Fu 1996; Rajkumar and Swaroop 2002; Wagstaff and Claeson 2004; World Bank 1993).

Mobilizing Government Revenues. Governments of LICs have recognized the need for greater domestic investments in health. In the 2001 Abuja Declaration on HIV/AIDS, Tuberculosis, and Other Related Infectious Diseases, African leaders pledged to increase health spending to 15 percent of their government's budgets (Haines and Cassels 2004; UNECA 2001). Yet LICs' ability to raise enough revenue to meet needs and demands for publicly financed health services is highly constrained (Gupta and others 2004; Schieber and Maeda 1997). Even though revenue mobilization is directly correlated with income, wide cross-country variation in revenue mobilization within income groups is apparent. For example, Myanmar's tax revenues amounted to only 4 percent of its GDP, whereas Lesotho's were 36 percent (WHO 2002).

As table 12.2 shows, during the early 2000s, LICs collected the equivalent of about 18 percent of their GDP as revenues, whereas high-income countries collected almost 32 percent. Given projected future economic growth on the order of 4 percent for LMICs during 2006–15, they will face difficulties in mobilizing additional domestic revenues (World Bank 2004b). In other words, even though economic growth is a necessary condition for progress, it is unlikely to provide the financing

base needed to deal with the HIV/AIDS pandemic or to achieve the health MDGs.

Trends in Health System Financing

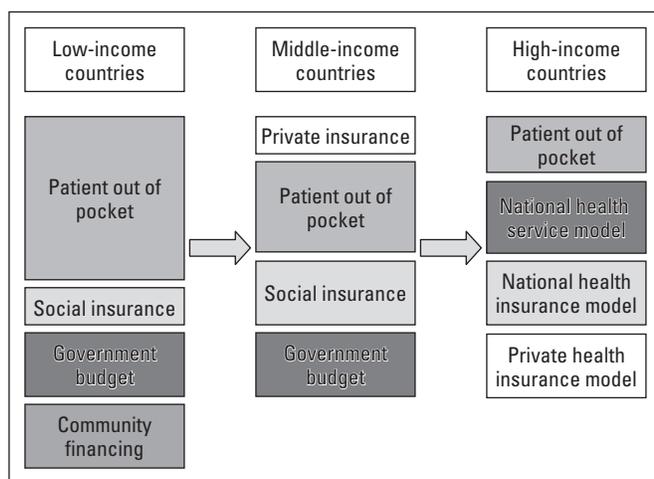

As countries move to different stages of the income spectrum, their health financing profiles transition as well. The following discussion compares countries at different stages of the income spectrum. Given health systems' variability across time periods, countries, and income levels, the analysis provides only a snapshot. Figure 12.2 illustrates transitions in general health systems as countries move from low- to middle- to high-income status.

In LICs, almost half of health spending is private, virtually all out of pocket, and usually in the form of payments for

privately provided health services and pharmaceuticals. The government, through the MOH, generally operates like a NHS. It provides basic public health and other services, including some tertiary-level hospital care, generally in major urban areas, to the entire population within an extremely limited budget. In general, because of the small size of formal sector employment, social insurance is limited, except perhaps for government employees. Community-based health insurance may be available to varying degrees but is unlikely to play a major role. Private health insurance, if any, is extremely limited because of people's inability to pay and institutional constraints to the industry's development, including the lack of well-developed financial markets and regulatory environments.

As countries' economies improve, government revenues tend to increase because of the expansion of the more readily taxable formal sector. Other institutions, such as financial markets, legal systems, and regulatory capabilities, are able to develop. Although private spending still accounts for some 40 percent of all health spending in MICs, the out-of-pocket share declines as private health insurance markets develop. The MOH generally continues to provide basic public health services and to serve as the insurer of last resort for the poor or for the entire population for specific chronic conditions as social health insurance mechanisms develop.

Countries move into the high-income group with improved institutions, more efficient governments, and greater revenue-raising capacity and spend a relatively small share on basic public health. With few exceptions, publicly financed universal coverage—or, in some cases, publicly mandated private coverage—becomes the goal. MOHs maintain responsibility for public health and surveillance and for the general regulatory environment but generally do not directly provide services. Risks are pooled either through a NHS, as in Italy and the

Figure 12.2 Health Care Financing System Trends by Country Income Level

United Kingdom, or through single or multiple insurance mechanisms, as in France and Germany. The Netherlands requires wealthier individuals to be insured through a private system. Private spending declines to 30 percent, and out-of-pocket spending represents about 20 percent of total health spending. Although health financing systems are highly country specific, available information on sources of health spending and government revenues supports these stylized models.

ABSORPTION, EFFECTIVENESS, AND SUSTAINABILITY OF DONOR FUNDS

In recent years, several new dimensions have emerged in the debate on international health financing, namely the effectiveness of large increases in DAH and the enormous costs of scaling up health and other social systems to meet the MDGs. Both the donor community and recipient countries have raised concerns pertaining to countries' absorptive capacity, aid effectiveness, and sustainability.

Countries' Absorptive Capacity

Large increases in DAH channeled to LICs have raised questions about whether countries can make effective use of these new aid flows. As table 12.3 shows, absorptive capacity has macroeconomic, budgetary management, and service delivery dimensions.

Increased aid has important macroeconomic implications given its potential effect on exchange rates, inflation, balance of trade, overall competitiveness, aid dependency, domestic

revenue mobilization efforts, and future recurrent costs. Most studies indicate that the macroeconomic saturation point for aid lies somewhere between 15 and 45 percent of GDP, depending on the country's policy environment (Clemens, Radelet, and Bhavnani 2004; Collier and Dollar 1999; Collier and Hoeffler 2002; Foster 2003).

Aid can have a number of negative effects. If aid flows are not included in the recipient country's budget, they can result in corruption. Aid may substitute donors' priorities for countries' priorities. A country may have insufficient human resources, physical infrastructure, or managerial capacity to use funds effectively. Resources that may already be in short supply and that are critical for effective service delivery may be diverted from other important activities. New resources may overwhelm the system, and the donors' reporting and administrative requirements may impose additional burdens on countries.

Absorptive capacity problems may also result from demand-side constraints at the individual, household, or community levels, including lack of education, limited information, travel costs, and income loss (Ensor and Cooper 2004). Conditional cash transfers are among the demand-side innovations developed to improve the use of essential public health services by the poor that have been receiving increased attention. Such programs were initially developed in Latin America as part of social safety-net programs and provide direct cash payments to poor households contingent on certain behavior, such as completing a full set of prenatal visits or attending health education classes (Rawlings 2004). Conditional cash transfers are in effect negative user fees. Even though investigators have found that such programs are quite successful in

MICs and have the potential to improve human capital and health outcomes and reduce poverty with relatively modest administrative costs, their applicability in LICs is still unresolved.

Health sector supply and demand constraints can also hinder countries' effective employment of large increases in health resources. As Mills, Rasheed, and Tollman point out in this book (chapter 3) and elsewhere, these constraints can occur at all levels of service delivery and governance (Oliviera-Cruz, Hanson, and Mills 2003). Additional funding alone does not create sufficient conditions for overcoming structural weaknesses, particularly in the short run. If aid is targeted to specific diseases or interventions, effective use of such aid may "consume" different amounts of a country's administrative capacity. Increased public funds may supplant private spending not only by the poor, but also by the nonpoor, resulting in limited marginal effects on the poor (Filmer and Pritchett 1999).

Aid Effectiveness

Given calls for increases in aid of anywhere between US\$25 billion and US\$75 billion a year, the question of aid effectiveness has taken on increased importance.² A protracted debate has generated the following findings concerning aid (Burnside and Dollar 1997; Clemens and Radelet 2003; Clemens, Radelet, and Bhavnani 2004; Collier and Dollar 1999; Collier and Hoeffler 2002; Foster 2003; United Nations Millennium Project 2005; WHO 2001; World Bank 2004a):

- Aid has diminishing returns.
- Countries' absorptive capacity is limited.
- Aid is fungible overall and among sectors.
- Aid achieves better results in good policy environments.³
- Aid requires ownership by countries; for example, donor-imposed conditions rarely work.
- Aid is related to increased investment and growth.
- Debt repayments have a negative effect on economic growth.
- Aid has high transaction costs for countries.
- Aid makes governments accountable to donors as opposed to their citizens.

Serious overall and health sector-specific questions pertain to the levels, predictability, variability, fungibility, and sustainability of aid flows, and debate continues between those arguing for vertical disease-specific program assistance and those supporting broader health system reform changes (WHO 2001). As Mills, Rasheed, and Tollman show in this book (chapter 3), evidence on the effectiveness of both approaches is mixed. Aid unpredictability and uncertainty need to be addressed by aligning donors' disbursement and commitment cycles with those of recipient countries, strengthening

countries' budgetary and financial management capacity, and fostering a more transparent and predictable implementation structure (World Bank 2004a).

The effect of the composition of aid on countries' efforts to mobilize domestic resources is also critical given the strong push by heavily indebted countries, several Group of Seven (G-7) countries, and the United Nations Millennium Project for grant assistance. Gupta and others (2004) find that increases in overall aid (net loans plus grants) result in a decline in total domestic revenues; however, the effects of loans were quite different from those of grants. Each 10.0 percent increase in loans was associated with a 2.3 percent increase in domestic revenues, whereas a 10.0 percent increase in grants was associated with a 2.8 percent decrease in domestic revenues. The same study also finds higher levels of corruption result in reduced domestic revenue-raising efforts.

Fiscal Sustainability

Fiscal sustainability is an often used but rarely defined term, though it has generally been defined in terms of self-sufficiency. In its broadest context, achieving sustainability means that, over a specific period, the managing entity will generate sufficient resources to fund the full costs of a particular program, sector, or economy, including the incremental service costs associated with new investments and the servicing and repayment of external debt.

Knowles, Leighton, and Stinson (1997, 39) define *health system sustainability* as the "capacity of the health system to replace withdrawn donor funds with funds from other, usually domestic, sources" and *sustainability of an individual program* as the "capacity of the grantee to mobilize the resources to fund the recurrent costs of a project once it has terminated." However, given the enormous unmet needs in the poorest countries, coupled with stagnant economic performance, some donors are now defining sustainability on the basis of the managing entity's commitment of a stable and fixed share of program costs (Brenzel and Rajkotia 2004; Kaddar, Lydon, and Levine 2003).

In light of criticisms leveled at the International Monetary Fund (IMF) regarding its structural adjustment programs and fiscal ceilings, IMF has recently paid increased attention to fiscal sustainability. However, evaluating a country's fiscal situation and defining sustainability are not easy matters (Croce and Juan-Ramon 2003; Dunaway and N'Diaye 2004; Hemming, Kell, and Schimmelpfennig 2003; Tanzi and Zee 2000). Work is under way to develop operational indicators of debt and fiscal sustainability and to define the concept of fiscal space (Dunaway and N'Diaye 2004; Heller 2005). Understanding the details of IMF fiscal programs and ensuring stable and predictable long-term DAH are important conditions for avoiding the macroeconomic distortions discussed earlier.

HEALTH FINANCING ISSUES IN LICs

This section discusses the severe challenges LICs face in mobilizing sufficient revenues, both domestically and externally, to meet even the basic health needs of their populations.

The Needs Gap

Since the release of the 1993 World Bank *World Development Report: Investing in Health*, researchers have undertaken numerous efforts to estimate the costs of a basic package of essential health services. The Commission on Macroeconomics and Health (WHO 2001) estimated that, in 1997, the 48 poorest developing countries were spending on average US\$11 per capita (US\$6 per year in public funds) and that the level of spending would have to rise to US\$34 per capita to ensure delivery of an essential package.⁴ On the basis of these data, the Commission on Macroeconomics and Health estimated that total DAH should rise to US\$27 billion in 2007 and to US\$38 billion by 2015 to scale up coverage (WHO 2001).

Within the framework of the MDGs, a number of other studies have been undertaken to determine the financial resources needed to meet the goals. In this book, Wagstaff and others (chapter 9) review the estimates and methodologies from these various studies, finding that the annual cost of scaling up to meet the MDGs is between US\$25 billion and US\$75 billion. The United Nations Millennium Project (2005) estimates that the additional overall development assistance needed for scaling up to meet all the MDGs will be US\$74 billion by 2015. All the studies indicate that most LICs will face enormous constraints in raising additional resources through domestic resource-mobilization efforts and that the international community must essentially finance most of the gap.

New Global Alliances and Funds

Recent years have witnessed a marked increase in the number of global alliances and institutions aimed at alleviating specific health sector deficiencies, a number of which owe their existence to resources made available by philanthropic organizations.⁵ The GAVI Vaccine Fund and the Global Fund to Fight AIDS, Tuberculosis, and Malaria are perhaps the largest and most well known. While the GAVI Vaccine Fund is both a funder and an implementer, Roll Back Malaria is an example of an alliance that is a global partnership without a funding mechanism. Some entities like the Global Fund are purely financial vehicles with little alliance structure. The effect of these new alliances and funds is significant. Since its inception in 2000, the GAVI Vaccine Fund has raised and spent more than US\$1 billion for immunization, and the Global Fund has commitments of more than US\$5 billion and has signed grant agreements with more than 70 countries worth in excess of US\$3 billion.

Although assessments of global initiatives and alliances are generally positive, some observers have concerns about their effects on health systems and prioritization (Travis and others 2004). Increasing concerns are being expressed about the “verticalization” of DAH and the development of separate health system “silos,” each dedicated to specific diseases and activities. This strategy is especially problematic in light of the scarce human resources available for health in many LICs (Global Health Trust 2004; Joint Learning Initiative 2004).

As a result of these concerns, the G-7 countries are currently discussing a number of new, broad-based, global financing mechanisms to mobilize and facilitate the transfer of resources from developed countries to LICs, and significant progress has been made in relation to the International Finance Facility (IFF), a proposal advanced by the U.K. government. The IFF will frontload development assistance by issuing bonds on international markets that would be secured based on legally binding, long-term donor commitments. The IFF would repay bondholders using future donor payments. Depending on the number of donors involved, the IFF could raise an additional US\$50 billion a year in development assistance between now and 2015. One of the many advantages of this kind of mechanism is that a portion of funding for international development is effectively taken out of the annual budgetary process in participating countries. In this way, the hope is that the revenue streams available to fund development can be rationalized, both in terms of the total volume of assistance and in terms of the stability of annual flows.

These global funds have added a major new dynamic to global health policy and a new level of influence over LICs. Large grants are approaching the World Bank's financing levels for the health sector. Moreover, such funding is often targeted to specific diseases or interventions, frequently outside the basic broadly based financing instruments required by the World Bank and the IMF. This factor raises important issues of donor coordination and harmonization of procedures and has implications for IMF fiscal ceilings.

Financing Instruments

During the past decade, a new reform instrument known as the SWAp has heavily influenced health financing, particularly for LICs. Concomitantly, the World Bank and the IMF have imposed a series of requirements and instruments to ensure that external assistance is targeted to the poor through PRSPs. These new policy blueprints and requirements are radically different from previous DAH mechanisms, which were largely funded on a bilateral basis through projects.

SWAps. Starting in the mid-1990s, donors and recipient countries established the SWAp to address the limitations of project-based forms of donor assistance, to ensure that overall health

reform goals were met, to reduce large transaction costs for countries, and to establish genuine partnerships between donors and countries in which both had rights and responsibilities. The core elements of a SWAp follow (McLaughlin 2003, 2004):

- The government is “in the driver’s seat.”
- The partnership results in a shared vision and agreed-upon priorities for the sector.
- A comprehensive sector development strategy that reflects all development activities to identify gaps, overlaps, or inconsistencies.
- An expenditure framework that clarifies sectoral priorities and guides all sectoral financing and investment.
- A partnership across development assistance agencies that reduces governments’ transaction costs.

SWAps explicitly recognize the need to tie health sector changes to new aid instruments, to macroeconomic and public sector management, to poverty reduction, and to achievement of the MDGs (Cassels 1997). A key aspect of this approach is to improve countries’ policy-making processes, including budget and public expenditure management, by capturing all funding sources and expenditures and by putting resource allocation decisions into a medium-term budget and expenditure framework that is based on national priorities (Foster 1999). To date, SWAps are in various stages of development and implementation, and few conform fully to the specifications listed above (Institute for Health Sector Development 2003). At this point in their evolution, SWAps should be viewed as a way of coordinating development assistance and creating country ownership. They should be judged on how well they do these things compared with the previous environment characterized by multiple, stand-alone projects.

PRSPs. Starting in the mid 1990s, the World Bank and the IMF began to radically change both the focus and the tools for providing development assistance to poor countries. In response to criticisms about the ineffectiveness of previous development assistance efforts and the high level of indebtedness in some of the world’s poorest countries, the two organizations focused on debt forgiveness for heavily indebted poor countries, poverty reduction, and improved economic growth. Debt forgiveness required countries to reprogram the bulk of the savings from forgiven debt into social sectors such as health and education.

In 1999, the World Bank and the IMF stipulated that all of their concessionary assistance to 81 eligible poor countries would need to be based on a Poverty Reduction Strategy Paper (IMF and World Bank 2002, 2003). This new approach was intended to the following:

- strengthen country ownership
- enhance the poverty focus of country programs

- provide a comprehensive coordination framework for the World Bank, the IMF, and other development partners
- improve public governance and accountability
- improve priority setting.

The PRSP process is country driven, involves broadly based participation, is results oriented and focused on outcomes that benefit the poor, is comprehensive in recognizing the multidimensional nature of poverty, is partnership oriented, and is based on a long-term perspective (IMF 2004a; World Bank 2004d).

The PRSP process has made poverty reduction the priority issue for development (SHC Development Consulting 2001). Because macroeconomic and sectoral strategies need to be formulated around the PRSP, health reform strategies must be included and focus on the poor. As of September 2004, about 42 LICs had developed PRSPs that are serving as the basis for World Bank and IMF financing in those countries. Extensive evaluations of PRSPs by the World Bank and the IMF, by bilateral donors, and by other development partners have painted the following mixed picture of their success (IMF 2004a; IMF and World Bank 2002, 2003; World Bank 2004d):

- PRSPs have the potential to encourage the development of country-owned, long-term strategies for poverty reduction and growth, but tensions concerning ownership among countries, the World Bank and the IMF, and other donors remain. External partners have not adapted their assistance programs to PRSP processes in a coordinated manner, and better frameworks for accountability of both countries and partners are needed.
- Country participation has improved; however, greater inclusiveness is still needed. Moreover, the process has not strengthened domestic institutional policy-making processes or accountability.
- PRSPs are an improvement over previous processes in terms of results orientation, poverty reduction focus, and long-term perspective. They have fallen short in terms of being a strategic reform road map, especially in relation to undertaking structural reforms, boosting economic growth, linking with medium-term expenditure frameworks and budgets, integrating sectoral strategies into the macroeconomic framework, assessing the social effects of macroeconomic strategies, understanding links between macroeconomics and microeconomics, integrating strategy components, and linking medium- and long-term operational targets.
- Capacity constraints have been serious impediments to effective implementation, but little attention has focused on capacity building.
- Monitoring and evaluation is still a significant weakness.

Evaluations of the health sector components of PRSPs raise many of these issues (DFID Health Systems Resource Centre 2003; WHO 2004a). As more and more partners buy into this

process and as increased amounts of development assistance are funneled through PRSPs, their effectiveness will ultimately depend on country commitment, capacity, and processes; partner flexibility; and funding availability. At this stage, PRSPs still seem to be a work in progress.

Community-Based Health Insurance

As noted earlier, private and out-of-pocket spending accounts for almost half of total health spending in LICs. Given LIC governments' limited abilities to mobilize revenues, country and donor attention has turned to informal sector insurance mechanisms as a way to improve financial protection, mobilize revenues, and improve the efficiency of out-of-pocket spending. *Community-based health insurance* is an umbrella term for the various types of community financing arrangements that have emerged because of high out-of-pocket spending, uncertainty surrounding anticipated financial flows from donors, and large and unregulated private sectors. Here, CBHI refers to prepayment plans that attempt to pool risks to reduce the financial risk an individual faces because of illness (Atim and others 1998; Bennett, Creese, and Monash 1998; Bennett, Kelley, and Silvers 2004).

CBHI is found throughout the world but is particularly prevalent in Sub-Saharan Africa (Bennett, Kelley, and Silvers 2004). CBHI plans are relatively heterogeneous in terms of populations covered, services offered, regulation, management function, and objectives. The Commission on Macroeconomics and Health found that CBHI plans provided significant financial protection and extended access to a large number of rural and low-income populations (WHO 2001), but that affordability impeded access for the very poor. As a result, the commission called for increased support for CBHI and for the establishment of a cofinancing scheme that would match dollar for dollar the premiums individuals paid toward their health insurance with a government or donor dollar (WHO 2001).

One recent review of the CBHI experience found less positive results, noting "no evidence from the documents reviewed that [CBHI schemes] positively impact health status or at least the utilization of services and financial protection for their members and/or for society at large, particularly the poor" (ILO and STEP 2002a, 54). The review finds that most CBHI schemes "tend to be small organizations (70 percent covering less than 200 members) with community participation in key decisions at one point or another in their history but with limited legal or de facto ownership by the community and with significant dependence from other health subsystems or subsidies as reflected by their low market exposure" (ILO and STEP 2002a, 54).

In his assessment of CBHI, Ekman (2004, 249) notes the following:

Overall, the evidence base is limited in scope and questionable in quality. There is strong evidence that

community-based health insurance provides some financial protection by reducing out-of-pocket spending. There is evidence of moderate strength that such schemes improve cost-recovery. There is weak or no evidence that schemes have an effect on the quality of care or the efficiency with which care is produced. In absolute terms, the effects are small and schemes serve only a limited section of the population. The main policy implication of this review is that these types of community financing arrangements are, at best, complementary to other more effective systems of health financing.

The evidence from these reviews suggests that, even though CBHI provides financial protection for those enrolled and some degree of resource mobilization, the overall effect is relatively small and schemes are less effective in reaching the very poor. Thus, CBHI is unlikely to be a panacea for substantially improving risk pooling and mobilizing resources in LICs, and for MICs, CBHI is less relevant given higher incomes and levels of formal sector employment. This finding does not suggest that CBHI should not be part of an overall solution to financing health care, but it indicates that CBHI is unlikely to play a major role.

The most critical challenge facing LICs is raising sufficient revenues to meet their basic health needs and the health MDGs. Although increased grant funding is badly needed, the large amounts of funds often targeted to a few countries and for specific diseases and interventions raise questions of country absorptive capacity, potential distortions of health systems' priorities, and interactions with IMF fiscal ceilings. Concomitantly, LICs must improve their institutions in order to increase absorptive capacity and increase the effectiveness of all official development assistance. It is also critical for the international community to reassess the entire official development assistance and DAH structure; to develop country-compatible mechanisms to reinforce promised international redistribution; and to improve the targeting, levels, predictability, and timeliness of external assistance.

HEALTH FINANCING ISSUES IN MICs

MICs benefit from higher levels of domestic funding, higher initial levels of risk pooling and prepayment, and stronger health systems than LICs. Many MICs are now focused on ensuring access and financial protection through universal health coverage. Chile, Colombia, the Republic of Korea, Mexico, Poland, and Thailand are implementing universal coverage reforms or have already done so. However, they and many other MICs still face challenges similar to those facing LICs.

Alternative Risk Pooling Arrangements

Country experience shows that the critical factors for increasing coverage—that is, the number of individuals covered and

Table 12.4 MIC Reforms and Innovations for Achieving Universal Coverage

Organizational arrangement	Reforms or innovations
Social security	Opening affiliation to self-employed and informal sector workers Mandating universal participation Providing direct public subsidies to the organization for including the poor Subsidizing premiums for the poor, self-employed, and workers in the informal sector
MOHs and NHSs	Separating the purchase and provision of care Using public and private purchasing Reforming provider payments
Private health insurance	Regulating voluntary health insurance Making private insurers eligible for mandatory social security for health Providing demand-side subsidies for health insurance
Integration reforms (reforms that allow synergic interaction of multiple organizational arrangements)	Using public and private purchasing Providing demand-side subsidies for health insurance for the poor and for high-risk groups Setting up risk equalization and solidarity funds Providing health education to stimulate demand Having a virtual single pool

Source: Authors.

the extensiveness of the benefit package—are increased risk pooling and prepayment and better access to equity subsidies. As discussed earlier, most MICs face fragmented risk pools (ILO and STEP 2002b). Table 12.4 presents MIC approaches to reforming risk pooling arrangements for achieving universal coverage.

Most MICs face an additional strategic decision: whether to pursue aggregation of all pools in a single organization (a single pool) or whether to allow for the existence of multiple risk pooling organizations, which would explicitly or implicitly compete for members and would be subject to the same rules regarding benefit packages, revenue collection mechanisms, and portability of benefits (that is, a virtual single pool). Colombia and Turkey have opted for the virtual single pool reform, whereas Costa Rica has chosen a single risk pool. In the OECD context, Germany and the Netherlands have virtual single pool arrangements, whereas New Zealand and the United Kingdom have single pool arrangements.

Reforms of Social Security. Because SSOs traditionally cover salaried formal sector workers from whom payroll contributions can be collected, requiring informal sector workers or self-employed workers to join is difficult. The reforms for confronting this issue range from voluntary enrollment to various types of subsidization, as detailed in table 12.4.

Country experiences are also illuminating. For instance, Chile and Mexico have opened SSOs to the informal sector and the self-employed through voluntary affiliation, yet they still

face risks of adverse selection because of the voluntary nature of enrollment and the exclusion of the poorest (Bitrán and others 2000; Instituto Mexicano de Seguro Social 2003). Chile, Colombia, Costa Rica, and the Philippines have addressed exclusion either by subsidizing the SSO directly or by subsidizing premiums for the poor and informal and self-employed workers who join. The Republic of Korea and Taiwan, China, have implemented mandatory universal participation, including gradual expansion to the whole population, whereas Panama has expanded coverage to dependents of contributing members.

Some of the most important advantages underlying SSO innovations include the existence of organizational capacity and of pools of funds (or sometimes a single large fund) that allow newly enrolled individuals and groups to take advantage of the risk and income cross-subsidization mechanisms and purchasing arrangements that are already in place. This approach results in an immediate enlargement of the risk pool in contrast to creating other pooling organizations as intermediate steps for the future merging of schemes. However, SSOs usually cover only a relatively small portion of the total population, and their focus on formal sector workers and use of payroll contributions as their main revenue collection mechanisms might be an insurmountable obstacle for reaching the informal sector and the poor, particularly those in rural areas.

In countries where a SSO is well established and covers a large population, it might face problems in including informal sector workers in the absence or even the presence of public

subsidies if the incentive structure is not well designed. For instance, in the case of Mexico, the SSO operates a scheme that is partially subsidized by the central government, yet the scheme still has experienced severe adverse selection and has few participants, which has also discouraged actively promoting enrollment (World Bank 2004c).

Reforms of MOHs and NHSs. MIC reform approaches for MOHs and NHSs include introducing internal markets, including separating the purchasing function from the provision of health services; using public-private purchasing; reforming provider payment systems; and decentralizing. In theory, efficiency gains in the system could be used to provide access to new enrollees, to increase the number and quality of services to all participants in the system, or to do both. Success in these areas has been limited (Baeza and Packard 2005). Effective modernization of public sector management and civil services statutes has to date been missing from most provider payment and health sector reform efforts.

Private Health Insurance Reforms in MICs. Since the 1980s, MICs have seen two main reforms related to private insurance: (a) the facilitation and promotion of voluntary health insurance, including formal recognition of competing private health insurance, and (b) the integration of regulated private insurance as one component of mandatory social security schemes for formal workers. Many MICs, such as Indonesia, Mexico, and the Philippines, now recognize and regulate voluntary private health insurance. In Chile and Colombia, private insurers participate in the provision of mandatory risk pooling for social security.

The literature provides some evidence of the potential benefits and problems resulting from the introduction of private health insurance and competition in the insurance market (Londoño and Frenk Mora 1997; Sheshinski and López-Calva 1998). However, an ample literature also deals with the equity and efficiency problems of private health insurance competition, including risk selection (insurers seeking to enroll low-risk individuals) and underservice (insurers setting barriers to the use of services, for instance, by not contracting with providers of expensive interventions or in low-income areas) (Arrow 1963; Hsiao 1994, 1995; Laffont 1990; Milgrom and Roberts 1992).

As to whether harnessing private health insurance contributes to or damages MICs' chances for achieving universal coverage, the question is whether MICs can take advantage of the benefits of introducing health insurance competition and avoid the related efficiency and equity problems. MICs must confront the feasibility of introducing specific financial, regulatory, and organizational reforms at a level of transaction costs that would not offset the benefits of competition and privatization (Baeza and Cabezas 1998; Coase 1937; Newhouse 1998; Williamson 1985).

Single Pool versus Virtual Single Pool. Most MICs must also decide whether to aggregate all pools into a single organization or to aim for a virtual single pool (Baeza and Packard 2005). The implementation of more effective and efficient cross-subsidies between groups with different income and health risks is facilitated by merging smaller pools into large pools—in some cases, national pools. Indeed, the main preliminary lessons emerging from Costa Rica, the Republic of Korea, and Taiwan (China), all of which have achieved universal coverage, suggest that the combination of a clearly defined benefit package and reforms for enlarging risk pools plays a paramount role in achieving greater inclusion through solidarity in financing and increasing access.

Yet for most MICs, the reality is that multiple pooling arrangements exist, leading to a fragmented, inefficient, and inequitable health financing situation overall. Given that developing proper regulations and incentive systems for counterbalancing such problems is complicated, both institutionally and cost-wise, fostering a virtual single pool is likely the most feasible option for these countries.

Sources of Health System Financing in MICs

As discussed earlier in this chapter, health systems use different sources of financing and revenue collection, including general taxation, payroll contributions, risk-rated premiums, and user fees. However, concern is increasing about the use of payroll contributions as a mechanism for collecting revenue. In a recent study on financial protection in Latin America, Baeza and Packard (2005) argue that to extend effective risk pooling to the informal and nonsalaried sectors and to achieve universal participation in risk pooling arrangements, policy makers need to delink health insurance financing and eligibility from labor market status or employment sector, by gradually reducing and eventually eliminating payroll contribution financing. In addition to extending protection against health shocks, this delinking might also have a positive effect on labor market mobility and formalization. This delinking can be achieved through shifting health financing toward general taxation, which is likely preferred on equity and efficiency grounds, or through risk-rating premiums as a transition if fiscal constraints do not permit full fiscal financing.

Donor Disengagement from MICs

As demonstrated both by the composition and recipients of DAH and by new health financing and policy agendas, global health financing policy is currently focused on LICs, leaving most MICs under the radar. The MDG agenda is predominantly a LIC agenda, or at least most MICs perceive it as such. Thus, the question is what to do with the MIC policy dialogue. Is the status quo tantamount to disengagement? If so, the

international community is in danger of losing important financing lessons that would most likely be of great use for LICs. In addition, a more concerted effort is needed to analyze what the MDGs mean for MICs—particularly in light of their increased noncommunicable disease and injury burdens, areas that the MDGs do not address—and to invest more in the evidence base for MIC-relevant reforms. It is important to maintain broad goals, but also important to develop new MIC-specific indicators, especially for financial protection, which is at the core of poverty alleviation in MICs as well as LICs but is not explicitly reflected in the MDGs.

The PRSP process also sends a clear signal to the international community to focus on the LICs. Unfortunately, few PRSPs consider the role of the health system in ensuring financial protection and reforms of risk pooling arrangements, which are at the core of most LIC and MIC health sector financing strategies. A new approach is needed to support MICs' efforts to improve public subsidy management and health system performance to ensure financial protection. Such approaches are also critical in assisting LICs with their poverty reduction and health financing reform efforts in the future.

CONCLUSIONS

Global health financing policy is in transition. Infusions of large amounts of grant money from new financing entities have changed the players involved in shaping global health policy. Decisions made by the World Bank and the IMF in 1999 requiring PRSPs as the basis for concessionary financing have pushed LICs to develop their health policies in the context of an overall strategy framework for poverty reduction that considers intra-sectoral, intersectoral, and macroeconomic tradeoffs.

Clearly, neither increased domestic resource mobilization nor future economic growth will provide the resources necessary for LICs to finance their health needs, whether defined in terms of a basic package of essential health services or whether identified within the framework of the MDGs. Increasing official development assistance is thus critical for LICs to make progress in either respect. However, the projected magnitude and speed of scaling up raises serious questions about countries' absorptive capacity, aid effectiveness, predictability, and stability and about new investments' financial sustainability at the country and donor levels. Even though empirical evidence is still lacking, concerns have arisen that new sources and increased levels of funding for disease-specific programs will lead to verticalization and could distort health systems. The donor community and countries urgently need to reform the current system of DAH, to improve institutions in developing countries, and to develop mechanisms to ensure that donors meet their DAH commitments. Finally, MIC issues need to receive greater attention.

Global health financing policy makers face the following challenges:

- The architecture for formulating, coordinating, and implementing global health financing policy at the international and country levels needs to be improved.
- The donor community needs to harmonize procedures, ensure aid predictability, and guarantee longer-term assistance.
- Donors need to meet their development assistance obligations as well as provide more assistance to help countries improve their domestic resource mobilization efforts.
- The IMF needs to improve understanding of its fiscal programs and be more flexible in reconciling fiscal constraints with increased official development assistance and DAH.
- The global community needs to improve the knowledge base in terms of good (and bad) international practice with respect to health financing. In this context, absorptive capacity constraints on both the demand and the supply sides must be removed. Better use of existing tools, including cost-effectiveness analysis, and development of new tools are needed to help poor countries realistically prioritize their financing and spending options and deal with the tradeoffs between financing essential services and providing financial protection.
- The potential for verticalization as a result of increased levels of DAH needs to be assessed rigorously and empirically, taking into account the benefits of such assistance as well as its potential distortionary effects on other programs and on health systems as a whole. By focusing limited resources on a few targeted areas, countries can achieve impressive results in terms of disease control efforts; however, many disease eradication efforts have succeeded because such efforts enhanced overall system capacity.
- The existing assistance instruments need to be objectively and fully analyzed. Examples of potential inconsistencies, such as disease-specific program grants versus PRSPs, need to be highlighted and addressed.
- The issue of financial sustainability needs to be assessed objectively and apolitically. The international donor community needs to face up to the realities of those poor countries whose economies are not sustainable in the medium term and to consider redistributive policies to assist them.
- The donor community needs to put MICs on the agenda both in terms of their economic and social development and in terms of their use as good practice examples for LICs as they transition to MIC status.

Because of the different accountabilities of the various multilateral and bilateral organizations, global funds and alliances, and private foundations, coordinating global health financing

policy has become increasingly complex. Given that international redistribution of wealth is central to meeting basic needs in poor countries, the lack of an effective international mechanism to enforce agreed-on transfers of wealth is problematic. Under these circumstances, the global community must help countries prioritize on the basis of realistic expectations of promised donor assistance and harmonization.

Providing countries with advice on good practice and assisting both LICs and MICs to develop equitable and efficient institutional structures, revenue-raising mechanisms, and spending prioritizations are important areas worthy of more international focus and collaboration. Assessments of the costs and constraints in reaching the health MDGs, taking into account the large increases in marginal costs to cover the most difficult-to-reach 5 or 10 percent of the population, are important knowledge products in a resource-constrained world. Making better use of cost-effectiveness information and developing better-costing tools are necessary for assisting countries, and donors could help by providing better information on where to focus policies to remove bottlenecks to the absorption of additional resources, particularly in terms of achieving the MDGs. A needed step for assisting LIC and MIC governments is developing and disseminating evidence about effective health financing policies, both in severely resource-constrained LICs that have achieved good health outcomes and in MICs that have achieved universal coverage with good health outcomes at reasonable spending levels. Last, the donor community must harmonize its procedures, simplify aid instruments, ensure the predictability of assistance, and create a more effective global policy environment.

DISCLAIMER

The findings, interpretations, and conclusions expressed in this paper are entirely those of the authors and should not be attributed in any manner to the Bill & Melinda Gates Foundation, the RAND corporation, or to the World Bank, its affiliated organizations, the members of its Board of Directors, or the countries it represents.

NOTES

1. For a detailed analysis of country-specific and global health expenditure trends, see Musgrove, Zeramini, and Carrin (2002).
2. In addition to aid, countries receive significant financial inflows through foreign direct investment, expatriate workers' remittances, special targeted assistance, South-South support, and so on, and these inflows must also be taken into account (World Bank 2004b).
3. Clemens, Radelet, and Bhavani's (2004) study shows that aid can be somewhat effective in countries with weaker policy environments.
4. More recent data for all LICs indicate per capita spending of US\$19 if the data are population weighted and US\$25 if they are country weighted. The public share is 52 percent (country weighted).

5. One of the main funding organizations is the Bill & Melinda Gates Foundation, which is investing approximately US\$1.35 billion per year, with a considerable portion of that allocated to global health issues.

Recent Trends and Innovations in Development Assistance for Health

Robert Hecht and Raj Shah

After nearly a decade during which levels of external development assistance for health (DAH) stagnated, an encouraging rise has occurred in the volume of such assistance. Donors and developing countries are testing and implementing innovative approaches to the use of DAH, while simultaneously seeking ways to raise the effectiveness of existing streams of aid and more traditional financing mechanisms. In short, DAH has entered a dynamic phase that holds considerable promise.

Nevertheless, it continues to suffer from a broad range of disappointments: misuse and inefficiency in the deployment of funds, gaps in essential areas that require financing support, and weaknesses in institutional and management arrangements. Substantial room for improvement exists.

This chapter documents those recent trends, analyzes the effects and assesses the performance of DAH, and points to areas that require priority attention. In the first part, we present statistics on DAH, updating the *World Development Report 1993* (World Bank 1993) and the report of the Commission on Macroeconomics and Health (CMH 2001). In the second part, we assess the performance of DAH. In the third part, we present recent innovations to underscore the current dynamic nature of such assistance. The chapter concludes with some suggestions on future directions.

TRENDS AND GAPS IN DEVELOPMENT ASSISTANCE FOR HEALTH

Despite a decline in overall official development assistance in the 1990s, DAH rose in real terms and as a proportion of official development assistance (table 13.1). New funding sources became available in 2000–2, including the Global Fund to

Fight AIDS, Tuberculosis, and Malaria and special U.S. financing for HIV/AIDS, plus rapid growth in grant awards from the Bill & Melinda Gates Foundation and in World Bank International Development Association (IDA) grants. Commitments from all external sources, including foundations, rose from an annual average of US\$6.7 billion in 1997–99 to about US\$9.3 billion in 2002.

Total DAH is the sum of external financing for health from several different sources: bilateral agencies as reported through the creditor reporting system of the Organisation for Economic Co-operation and Development (OECD); multilateral agencies, including the United Nations (UN) system—especially the World Health Organization (WHO), the United Nations Children’s Fund, the United Nations Population Fund, and the global and regional development banks; the European Union; philanthropic organizations; and the Global Fund to Fight AIDS, Tuberculosis, and Malaria. Because no central repository of data on all the sources of DAH is currently available and comprehensive information is not published on any regular basis, painstaking and time-consuming efforts are required to assemble accurate, comparable data about all these sources.

After a long period of decline in official development assistance (grants from bilateral government channels and UN agencies plus net flows from development banks) during the 1990s, the OECD reported a real increase of 7 percent from 2001 to 2002 and a further increase of 4 percent from 2002 to 2003. Those increases took official development assistance to an all-time high, in both nominal and real terms, of US\$68.5 billion. As a percentage of gross national income, this represents an increase from the all-time low of 0.22 percent recorded during most years from 1997 to 2001 to about 0.25 percent in

Table 13.1 Development Assistance for Health, Selected Years (US\$ millions)

Source	Annual average, 1997–99	2002
Bilateral agencies	2,560	2,875
Multilateral agencies	3,402	4,649
European Commission	304	244
Global Fund to Fight AIDS, Tuberculosis, and Malaria	0	962
Bill & Melinda Gates Foundation	458	600
Total	6,724	9,330

Sources: Michaud 2003; OECD 2004a.

2003, still well below the target of 0.7 percent set by the OECD's member states in 1970. Only five countries—Denmark, Luxembourg, the Netherlands, Norway, and Sweden—currently achieve this target, and six others have now set prospective dates for its achievement—namely, Belgium (2010), Finland (2010), France (2012), Ireland (2007), Spain (2012), and the United Kingdom (2013).

Bilateral assistance for health rose from an annual average of US\$2.2 billion (3.8 percent of the total) during 1997–99 to US\$2.9 billion (6.8 percent) in 2002. Among the bilateral arrangements, the United States accounted for about 40 percent of the total, even though as a percentage of gross domestic product (GDP), its allocation to international development was among the lowest of all the high-income countries.

Within the UN system, DAH rose from an average of US\$1.6 billion per year during 1997–99 to US\$2 billion in 2002. Commitments from the development banks remained stationary at about US\$1.4 billion. However, changes in accounting by the World Bank to include financing for health activities contained in projects managed by other sectors (such as urban, water and sanitation, transportation, and social development), suggest that its new commitments for health actually rose from about US\$1 billion in 2001 to US\$1.3 billion in 2002 and US\$1.7 billion in 2003.

In the future, consensus will need to be reached on whether allocations by the multilateral development banks to projects in other sectors or to projects that are classified as multisectoral—especially broad budget support to governments, which may be specifically tied to domestic spending and policy reforms in health—should be counted as DAH. Another issue in DAH accounting involves distinguishing between allocations for health from the multilateral banks that take different forms—namely, outright grants (a recent innovation for the World Bank and the regional banks); subsidized loans for the poorest countries, which at the World Bank are IDA credits; and loans for the middle-income developing countries that reflect the actual costs of borrowing by the development banks. For example, of the US\$1.7 billion in World Bank commitments for

health in 2003, about US\$1 billion took the form of IDA credits, and most of the rest was in the form of loans that reflected the costs of borrowing. Because the face value of the financial commitment can be considered to be reduced by repayments in the case of subsidized and market rate loans, some argue that the net financial value of such loans, rather than their face value, should be used in calculating DAH. This calculation further complicates the task of monitoring DAH.

Despite these various cautions and qualifications, it is clear that DAH has grown in recent years. This upward trend has been driven by several factors, including (a) donors' increasing attention to the challenges presented by the Millennium Development Goals (MDGs), which are heavily centered on maternal and child health and control of communicable diseases; (b) strong global mobilization to confront the AIDS pandemic in developing countries since 1998–99, especially in Africa; and (c) donors' expanding interest in research and development (R&D) in relation to new health technologies to address the major diseases prevalent in poor countries. In contrast, external funding for health system development, human resources, and noncommunicable diseases has increased more slowly.

In terms of the areas that have benefited from the growing volume of DAH, three stand out: HIV/AIDS, immunization, and new health product development. According to Michaud (2003), in 2002 about US\$900 million in DAH was for HIV/AIDS, followed by US\$210 million for tuberculosis (TB), and US\$160 million for malaria control. The Joint United Nations Programme on HIV/AIDS (UNAIDS) also reports a substantial rise in external financing for AIDS prevention, treatment, and social mitigation activities over the past four years (UNAIDS 2004). Most of the increase in assistance for immunization has taken place through the Global Alliance for Vaccines and Immunization (GAVI), which has amassed commitments of about US\$1.3 billion to finance the expansion of existing childhood immunization programs and the accelerated introduction of hepatitis B and *Haemophilus influenzae* type B vaccines. Assistance for health technologies directed at diseases that are prevalent in the developing world has been channeled through new public-private partnerships. Examples include the International AIDS Vaccine Initiative (IAVI), the Medicines for Malaria Venture, and the International Partnership for Microbicides. Estimates indicate that the 10 largest public-private partnerships have raised more than US\$1 billion over the past five years (IPPPH 2004).

In terms of the sources of the expanded volume of DAH, a small number of institutions account for much of the recent increase. Among the traditional donors, these institutions include the World Bank and the governments of Canada and the United Kingdom. At the same time, as a share of GDP, contributions from Ireland, the Netherlands, Norway, and Sweden remain high. Among nontraditional sources, the Bill &

Melinda Gates Foundation stands out as a major new player as of the late 1990s. With a focus on the development of new drugs, vaccines, and diagnostics for the developing world, the Gates Foundation's commitments for health started in 1998 and rose rapidly to some US\$600 million in 2002, with annual commitments expected to approach US\$1 billion in 2004 and beyond.

Development assistance for health is channeled to a large number of low- and middle-income developing countries, but the largest recipient region is Africa. In 2002, about 35 percent of all such assistance went to Africa, followed by Latin America and the Caribbean with around 14 percent, East Asia and South Asia with 11 percent each, and the Middle East with 7 percent. The remaining 22 percent was for global programs (Michaud 2003).

This growth in funding for the control of communicable diseases and new health technologies to address them is important, given the high burden of illness and premature death these diseases cause. Nevertheless, the focus on AIDS, TB, and malaria should be matched by similar increases in investments in broader health system improvements. Relatively little DAH is being channeled to address the serious problems of shortages in health workforces in poor countries and their low productivity or to deal with weaknesses in health management information systems, in supply chain logistics for drugs and commodities, and so on. Even though focused spending on AIDS, TB, and malaria will clearly touch on these weaknesses, it will not on its own go to the core of the problem or lead to sustainable solutions. For example, GAVI allocates resources to strengthen immunization infrastructure such as cold chains and to train health workers to deliver vaccinations more effectively. The Global Fund to Fight AIDS, Tuberculosis, and Malaria provides funds to prepare health workers to deliver and monitor compliance with antiretroviral treatments. Useful as those activities are, they will not address the underlying weaknesses in human resources for health in poor countries, such as low levels of pay, unattractive conditions of service, and uncertain prospects for career advancement.

The recent rise in DAH is encouraging, but it is still far short of the volume of external financing for health that is needed, according to recent estimates and political pronouncements. On a global level, estimates of what donors need to provide to help countries reach the MDGs for health have typically ranged from US\$15 billion to US\$35 billion per year. The Commission on Macroeconomics and Health suggested a figure of about US\$30 billion a year. While preparing for the Monterrey Summit on Finance for Development, the World Bank calculated a funding gap of US\$15 billion to US\$25 billion a year (Devarajan, Miller, and Swanson 2002). For the United Nations General Assembly special session on AIDS in June 2001, UNAIDS suggested that spending on HIV/AIDS alone in the developing countries needed to rise to about US\$9 billion annually by 2005, with about two-thirds of this amount to

come from external sources (UNAIDS 2001). At the 2004 International AIDS Conference in Bangkok, UNAIDS raised its estimate of resources needed to more than US\$15 billion a year by 2010 (UNAIDS 2004).

These global calculations have been followed by more detailed costing exercises at the country level, which hold the promise of yielding more accurate and meaningful figures than the global estimates. Donors working with government specialists in developing countries have tested a variety of methods. The UN Millennium Project has used a bottom-up approach, which is based on expanded coverage of key interventions and fixed unit costs, assuming no shared costs or benefits among different interventions, omitting the possibility of private financing, and adding a rough amount for system improvements (UN Millennium Project 2004). The World Bank has followed two other approaches. One, in India, is based on observed elasticities of change in children's health and nutrition outcomes in relation to public expenditures on health, primary education, water, and so on (World Bank 2003a). Another, in Ethiopia, Mali, and other countries, is based on detailed modeling of the costs of removing bottlenecks in health service delivery to enhance the coverage, utilization, and quality of key health interventions proven to have a positive effect on maternal and child health outcomes (Soucat and others 2003; World Bank and Ministry of Health, Ethiopia 2005).

A comparison of the Millennium Project's and the World Bank's results for East Africa is interesting. The Millennium Project calculates that nearly US\$30 per capita are needed in additional spending for health, whereas the World Bank calculates that about US\$4 per capita are needed for Ethiopia to reduce child and maternal death rates by 30 to 40 percent by 2015. The large difference between the two sets of results suggests that more work needs to be done to move toward consensus on the best methodology for countries to use.

Part of the difference is due to technical factors. The Millennium Project approach covers all the health MDGs, whereas the bottlenecks method has focused on the MDGs pertaining to child and maternal health only. The Millennium Project also calculates costs to achieve the MDGs in their entirety, whereas the bottlenecks method addresses incremental improvements. For example, in relation to the child mortality goal, the bottlenecks analysis for Ethiopia considers a substantial decline to be from 176 to 107 deaths per 1,000 live births, but the MDG is 59 deaths per 1,000 births. In addition, the Millennium Project multiplies additional units of service by a standard cost per unit, whereas the bottlenecks method estimates the cost of system improvements and then divides this amount by the additional services rendered to derive incremental unit costs.

The two approaches also have important differences in political philosophy. The Millennium Project approach sets high targets for DAH and health spending, which are based on full achievement of the MDGs, regardless of the starting points and

gaps and without addressing the feasibility of reaching the targets. The World Bank's approach is less ambitious but may be seen as more realistic and as pointing the way to implementation based on gradual improvements—improvements that countries can pursue as additional financial resources and capacity to manage them effectively are combined on the ground.

MAKING DEVELOPMENT ASSISTANCE FOR HEALTH MORE EFFECTIVE: LESSONS LEARNED

More assistance is part of the answer to helping developing countries achieve more rapidly the improved health outcomes they seek and that are enshrined in the MDGs. To this end, we need to know how effective DAH has been and what can be done to make it more effective.

Despite valid criticisms of DAH, some health programs—inspired and supported by donors—have worked at scale and contributed to more than four decades of steady improvements in health, as measured by under-five mortality and overall life expectancy. The record of public health successes in developing countries is becoming increasingly clear, as noted in a recent review of four decades of experience (Levine and What Works Working Group 2004). The success stories cover a broad spectrum of circumstances. They are found in all regions and cover both communicable and noncommunicable diseases. They have been driven by new technologies, including vaccines, drugs, and diagnostics; community- and clinic-based care; and knowledge for behavior change.

Significant gains have occurred even in the poorest countries and in those with weak institutional environments. Consider, for example, the high levels of TB case detection in the Democratic Republic of Congo and in Myanmar (Stop TB Partnership 2003), the successes in polio eradication in African countries experiencing civil wars, and the growing availability of antiretroviral therapy in Haiti.

Some of this progress can be attributed to the general effects of economic growth and improvements in education, water, and sanitation. However, specific, compelling examples of the success of DAH-backed initiatives are available. For example, programs to immunize against measles, to control river blindness and guinea worm, and to fortify salt with iodine have had sustained and widespread effects (Levine and What Works Working Group 2004). These programs have been successful at scale, have generated sustainable health improvements at the population level, and have succeeded in a broad range of institutional environments.

Recent analyses and reviews of donor-supported successes in international health have noted a set of factors that tend to contribute to positive outcomes:

- strong internal (governments) and external (donors) political leadership

- collaboration across governments, donors, and nongovernmental organizations (NGOs) in program design and implementation
- consistent, predictable funding support, even after success has been achieved
- simple and flexible technologies that can be adapted to local conditions and do not require complex skills to operate and maintain
- programmatic approaches that recognize and address the need to help build health system infrastructure, especially in human resources
- household or community participation in the design, execution, and monitoring of program activities.

Policy Environment

Development assistance for health supports a vast array of activities and services, some focused on specific diseases (polio, TB, HIV/AIDS), some on strengthening health systems (disease surveillance, nurse and midwife training), and some on particular services (reproductive and child health services). But has DAH actually changed health outcomes? Recent work from the World Bank, the Commission on Macroeconomics and Health, and others suggests that it has (Rajkumar and Swaroop 2002). However, DAH does not work as effectively in countries where the policy environment is poor, even though some carefully targeted disease control activities can confer limited benefits. With good policies and institutions (strong property rights, reduced corruption, an efficient bureaucracy), an extra 1 percent of GDP in aid is estimated to reduce infant mortality by 0.9 percent. By contrast, where policies are average, the decline is estimated at only 0.4 percent, and where policies are poor, aid is estimated to have no significant effect on infant mortality (World Bank 2004b).

The issue is not black and white: there are gradations of good policy, and as policies improve, the productivity of aid increases. For example, Bangladesh has made large strides in reducing under-five mortality in recent years, relying on NGOs to deliver many services. If Bangladesh were able to raise the quality of its governance from below average to above average, even at its same public spending levels, it would realize more rapid gains. An additional dollar of government health spending would reduce under-five mortality by 14 percent, compared with 9 percent without such improvements (World Bank 2003c).

Tradeoffs may be necessary between targeting assistance toward the neediest countries and achieving the greatest effect from DAH, but even in needy countries with weak policies, some kinds of carefully targeted assistance for health (for example, immunizations delivered by reputable NGOs) can have a positive effect. In addition, in countries with weak policies, a focus by donors on policy dialogue and technical

assistance to improve the environment for DAH can set the stage for a larger infusion of financial support down the road.

Conditionality

Conditionality is making the availability of funding dependent on a government completing an agreed task, such as enacting a new health law or spending a certain share of its budget on health activities. It can work, but only if the government is committed to making such a change. Tying aid to policy changes is a common practice, but recent studies have cast doubt on the ability of such conditionality to bring about reform (World Bank 1998, 2003a). If governments are not committed to reform, conditionality will not make them reform. Donors themselves often undermine the rigor and credibility of conditions because they usually face strong internal pressures to continue disbursement of the funds anyway, even when governments do not adhere to the agreed-on conditions. On the other hand, if governments are committed to reform, conditions can help by enabling governments to commit publicly to certain reforms and persuade private investors of their seriousness. For example, the government of Uganda's commitment to decentralizing the management of basic health services and to making local authorities accountable to communities was reinforced by conditions in the Uganda poverty reduction support credit, which several donors financed. Similarly, the Chinese government's commitment to reaching the poor with TB control services was reinforced by stipulations in donor-funded TB projects that they target the country's poorest provinces and reach out to deprived households (World Bank 2003c).

Donors cannot force policies on governments, but they can help with policy design. Donors can alert governments to the reasons for reform and help nurture commitment, but at the end of the day, it is governments that have to sustain any reforms (box 13.1). Undertaking analytical work, providing training and technical assistance, disseminating ideas about policy reform and development, and stimulating debate in civil society can all be valuable activities for donors to support while a government's commitment to reform is growing.

Vietnam in the late 1980s and early 1990s is a good example. At a landmark meeting in 1986, the ruling Communist Party decided to break with the past and introduce sweeping economic reforms. In the health sector, the reforms included introducing user fees at public facilities, legalizing private medicine, deregulating the pharmaceutical industry, and opening the pharmaceuticals and medical equipment subsectors to international trade. Initially, Vietnam saw no increase in aid, but such agencies as the United Nations Development Programme and the World Bank helped facilitate the reform process by organizing international workshops for the Vietnamese to exchange ideas on policy with their neighbors.

This effort set the stage for a large inflow of donor financing, starting around 1995 and continuing to the present.

Fungibility of Development Assistance for Health

Much aid is earmarked, both across sectors and within them. One part of a development agency gives a grant to the ministry of health for a health sector reform, while another does the same for a primary education project. An agency makes a loan to the ministry of health for a TB project, while another makes a loan for a malaria control project. The donors' intent is that these activities remain tightly sealed: the funds for health sector reform are to be kept separate from the funds for the primary education project; the TB project funds are to be kept separate from the malaria control project funds. The idea is to ensure that the government makes a certain spending choice. It is based on the assumption that the choice would not be made if the government had been handed a blank check for the same amount.

The implied view of such aid is that what you see is what you get; that is, a government receives US\$1 million for a water project and the net effect is US\$1 million worth of extra spending on the water sector. This view has recently been challenged, with the alternative view being that aid is at least partly fungible (Burnside and Dollar 2000; World Bank 1998). Hence, as a result of the inflow of development assistance for a specific health activity, the government changes the way in which it spends the rest of its resources, both in the health sector and in terms of allocations between health and other sectors. As a result, for each dollar earmarked for a specific health project, spending on health rises by less than a dollar but by more than would have been the case had the government received an extra dollar in its overall budget. Similarly, spending for the specified purpose in the health sector rises by less than a dollar, but by more than would have been the case had the government allocated an extra dollar of its own resources to health generally.

Assessing whether aid is indeed fungible is not straightforward. The difficulty is knowing how the government would have responded had its own resources increased by the amount of the aid or had it received a blank check for the same amount. Recent research suggests that, despite considerable variation across countries, on average only 29 cents of each additional dollar of aid goes into government development programs, with the rest leaking out into nondevelopment programs such as military spending (World Bank 2004b).

One important implication of those findings is that donors should spend less time and effort trying to channel their external funding to specific programs for priority diseases and populations. Instead, a more useful exercise would be to engage in a dialogue with the government on basic changes in the overall patterns of public spending for health—that is, the total

Box 13.1

Donors and Commitment: Nutrition in Bangladesh and Thailand

In most countries, nutrition has not become a visible issue on the national political agenda, because nutrition advocates have not succeeded in linking improved nutrition with political and economic goals or in creating popular demand to eliminate malnutrition. In Bangladesh in the early 1990s, the United Nations Children's Fund and the World Bank joined forces to present a case to the government showing how the country could not achieve its economic goals unless it reduced malnutrition. This effort persuaded the government's financial planners that funding a national nutrition program was a good investment, and the government approved a new nutrition project in 1995.

However, the issue is not just how to build initial commitment, often the main focus of organizations such as the World Bank. Commitment can be fragile, and the issue is how to broaden and maintain commitment and complement it with systematic investments in institutional capacity development. The first nutrition investment in Bangladesh was completed in 2001. Children's nutritional status and households' health-seeking behaviors improved substantially in project areas, and malnutrition rates declined. A follow-on nutrition investment was approved, but because of weak government commitment, it is struggling in the challenging policy environment in which the social sectors operate. The Ministry of Health has not assigned high priority to the program, and conflicts

between the government and the NGOs involved in community activities have complicated the situation. Contradictory messages from donors and frequent changes in leadership within the government have added to the challenge.

More recently, donors and advocates for nutrition within the government have proposed that nutrition activities that build on earlier successes be included in the Health, Nutrition, and Population Sector Program, which is scheduled to be finalized and approved in early 2005.

In contrast, in Thailand, building commitment for nutrition was achieved during the 1980s and nurtured with little external support. Government-sponsored efforts through studies, workshops, and media outreach generated commitment for nutrition by building broad consensus (in the government, NGOs, and the private sector) on the benefits of nutrition—not as a welfare issue, but as a human development issue. This initial commitment was sustained by ensuring that policy statements were closely linked to national investment plans, by building strong technical and managerial capacity for nutrition in the country (often by means of external aid), and by linking those actions with a strong buy-in and demand from communities. Malnutrition rates in Thailand declined from 51 percent in the early 1980s to 18 percent in 1990 and continue to fall.

Source: Heaver 2002.

allocation and the amounts for, say, providing child health and communicable disease control services and for improving community and primary-level health delivery systems. If the government followed through on those basic changes, then donors would transfer their financial assistance to the health sector as a whole.

The finding that aid is indeed fungible has encouraged some donors to search for broader development assistance mechanisms that recognize the importance of the entire expenditure program and explicitly avoid earmarking. Such mechanisms include the Multi-Country AIDS Program in Africa, which supports national HIV/AIDS strategies; sectorwide approaches in health; and poverty reduction support credits (PRSCs) that back a broad public spending agenda.

An opposing viewpoint is that although, in general, good policies matter and the fungibility of aid tends to undermine

donors' ability to earmark their funding effectively, many high-impact health services can be delivered to the population on a targeted basis even when national policies and institutions are weak—and this aid would not occur in the absence of DAH. This argument applies especially to services with simple technologies—for instance, basic childhood vaccinations that can be delivered on a single occasion through annual campaigns or disease treatment programs (such as short-course drug therapy for TB) that can be provided through tightly managed top-down efforts (Jamison 2004). The high coverage and treatment success using the directly observed short-course therapy approach for TB in the Democratic Republic of Congo in recent years, even during the civil war, can be cited as an example of how a well-protected enclave project with strong donor backing can be successful (Stop TB Partnership 2003).

Another argument against broad budget support of health sector funding or in favor of the more traditional earmarking of DAH is that it helps maintain governments' and donors' focus on implementing and monitoring specific health service interventions and on the necessary technical and managerial improvements to ensure the achievement of targets in those areas. On the basis of experience in countries such as Bangladesh, Ghana, Mozambique, and Zambia, donors are increasingly of the view that broad support to a national health sector program leads to superficial oversight of bureaucratic processes and a corresponding loss of technical focus and depth (Foster, Brown, and Conway 2000). Although a sector-wide approach is theoretically fully compatible with careful monitoring of key outputs and health outcomes and with in-depth technical improvements, in practice, achieving this mix of objectives may prove difficult.

In summary, the debate on earmarked versus broad DAH support for national health programs continues. More analysis is needed to produce clearer conclusions on the advantages and disadvantages of the two approaches.

Transaction Costs of Aid

In a single low-income country, more than 20 donors—including bilaterals, multilaterals, global programs, foundations, and large NGOs—may be involved in the health sector. The demands placed on recipient countries can be huge, and donors are starting to acknowledge this burden. They are recognizing that their individual procedures for reporting, accounting, and managing funds—which often encompass different budget structures; different ways of measuring progress toward objectives; different regulations for the procurement of goods, services, and works; and different approaches toward and cycles for disbursing funds—place heavy and unreasonable demands on recipient countries. Demands are particularly heavy in poor countries that are forced to allocate limited human resources away from service delivery to manage donor funding.

The donor community is working to harmonize and simplify its procedures to reduce these transaction costs. In the health sector, experiments are taking place in several developing countries, including Bangladesh, the Kyrgyz Republic, Mozambique, and Zambia, to determine how best to lower the costs (OECD 2004b). Some of the principles of improved donor action include the following:

- ensuring that countries, not donors, drive the coordination
- fostering strategic coherence through a poverty reduction strategy and the health, nutrition, and population analyses that feed into it
- promoting financial coherence through a medium-term expenditure framework and an agreement that all donor

funding will respect the government's overall spending plans and limits

- pooling donor funds in a single account and untying aid so that the government can procure goods and services from the lowest-cost source and not just from the donor countries
- limiting the number of country coordination bodies that can bring together national and international actors involved in health.

At the same time, some of the experiments in country-level coordination of DAH reveal the difficulties of implementing the principles of better donor harmonization. In some instances, persuading donors to pool their funds and sever the links between funding and procurement has proven difficult. Some donors face pressure from their legislatures to maintain separate accounting for the use of their DAH allocations so they can claim credit for achieving progress and thus “plant flags” on individual health projects. In addition, monitoring and evaluation systems have frequently not been strong enough to yield timely and meaningful data on progress, a critical failure if disbursements are linked to performance rather than to spending on specific inputs. Multiple national coordination bodies for government, donors, and NGOs for different diseases (AIDS, TB) and services (immunization, polio eradication) also persist in many settings. In short, a number of political and technical changes are needed to ensure the successful implementation of a harmonized donor agenda at the country level in the poorest developing nations.

Unpredictability of Development Assistance for Health

Some donors have taken steps to put in place instruments for DAH that extend the length of their financial commitments. The development of multiphase funding “slices” of 3 to 5 years embedded in a 10- or 15-year program of support is one way to lengthen commitments. Nevertheless, donor financing for health is not yet as reliable or sustained as is often claimed or hoped for, even under these new, long-term arrangements. In some developing countries, cuts in DAH have been sharp. Donors' budgets are subject to the usual business and political cycles and may go up or down during their annual budgetary processes. For such countries as the Comoros and Eritrea, where the year-to-year changes in external funding can amount to as much as a fifth of all public spending for health, the fluctuations are so great that they make planning and implementing coherent national health programs nearly impossible (figure 13.1).

Further work is needed to design mechanisms for DAH that provide greater assurance of sustained financial support. The challenges are to overcome the factors that result in interruptions to long-term DAH. Those factors include changes in

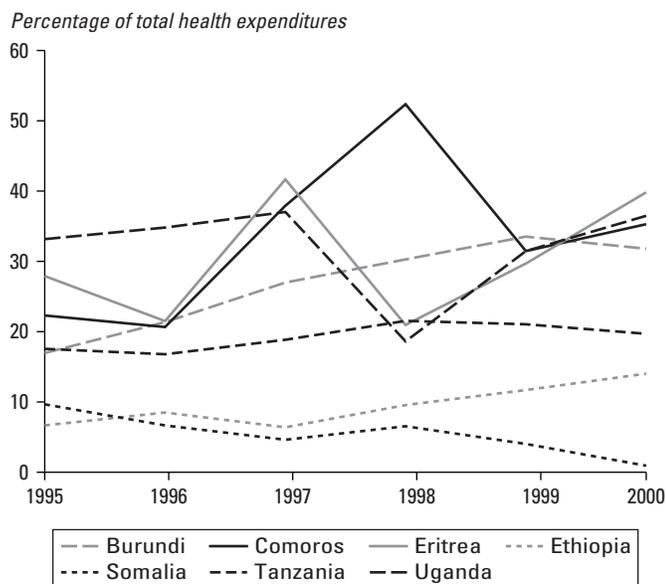

Figure 13.1 External Financing as a Percentage of Total Health Expenditures, Selected Countries, 1995–2000

political leadership and aid agency management that lead to modifications of earlier agreements and end up reducing external funding levels or reallocating those funds to other activities.

One example of an innovative approach is the recently proposed establishment of an international finance facility. This facility would use financial commitments from governments of developed countries to tap funds in capital markets and would use those funds to frontload development assistance so as to accelerate progress toward the MDGs. The International Finance Facility for Immunization, which the United Kingdom formally announced at the World Economic Forum in January 2005 and is aiming to launch later in the year, will expand external financing for childhood vaccinations. The pilot project could be used to pledge funding against multiyear advance-purchase contracts for new vaccines (such as rotavirus vaccine) that may not reach the market for several years. Such an effort could help create a more assured market and reduce the risks for vaccine companies, thereby speeding up the introduction of these new health commodities to low-income countries (GAVI 2004b).

RECENT INNOVATIONS TO IMPROVE THE EFFECTIVENESS OF DEVELOPMENT ASSISTANCE FOR HEALTH

In recent years, donor agencies working with developing countries have been testing—and in some cases rolling out on a

large scale—a series of innovative approaches and instruments to improve the effectiveness of DAH. Those innovations include the use of broad budgetary support to countries with strong governance and institutions, the implementation of sectorwide approaches in health, the use of performance-based financing mechanisms, a shift to direct engagement with the private sector, and the implementation of programs designed to move resources expeditiously to the frontlines of the battle for improved health (that is, to communities). Evidence on the effectiveness of those innovative approaches and the conditions under which they tend to work is starting to accumulate.

Budget Support in Strong Policy Environments

In low-income settings where policies, governance, and institutions are sound, donors have increasingly sought to provide broad, untied, and flexible budget support to governments to help support a full public expenditure program aimed at raising the level of spending and the effectiveness of resource use for health. Frequently, this support has taken the form of PRSC operations, including grants and credits. The PRSC is typically built on the foundations of a national poverty reduction strategy that analyzes the links between poor health outcomes and income poverty and identifies policies that can improve the health of the general population, especially that of poor households. The policies are then used to design a medium-term public expenditure program or framework that, in turn, is backed by external funding from donors in the form of a PRSC.

This approach draws on three of the key lessons from decades of experience with DAH:

- A good policy environment improves the use of external financing.
- The fungibility of DAH makes it logical to allocate external funds to a general budget that prioritizes health rather than to narrow projects in the health sector.
- An integrated system for managing public finance for health improves national ownership of policies and programs to improve the health of the poor and raises the chances that such funding will be sustained over a long period and eventually will use domestic resources.

Plenty of examples are now available of the use of DAH for PRSCs that focus on improvements in health. The earliest health-oriented PRSCs were in Mozambique and Uganda, followed since by similar operations in Benin, Mauritania, and other low-income African countries. In Mauritania, for example, the country received a transfer of US\$25 million in external financing to back a public spending plan that doubled health spending from about US\$8 per capita in 2000 to US\$16 per capita in 2004. The plan also emphasized increasing health investments that are designed to lower maternal and child

deaths and combat communicable diseases by expanding rural health facilities, by providing higher pay and other incentives for health personnel working in rural areas, and by improving the availability of drug supplies at lower-level facilities. External financing was not earmarked for these actions in the health sector. Instead, the government committed itself to spending for these purposes from a consolidated national budget that was closely monitored by civil society, government officials, and donor representatives (World Bank 2004a). The early results from Mauritania are encouraging. Spending for health has risen, with most of the increase going to those parts of the country and for those kinds of services likely to have the largest effect on the health of the poorest households.

In middle-income countries, an analogous shift of DAH in strong policy environments has been the increasing use of single-tranche, programmatic, sector adjustment loans. These loans have emerged as a favored instrument for DAH in certain Latin American countries with sound management of public finances and internationally accepted procurement practices. Unlike the PRSCs, the programmatic sector loans have tended to target a single sector (such as health) or, occasionally, two sectors (such as health and education in the case of Brazil or health insurance and pensions in the case of Ecuador). Whereas the PRSCs have their analytical roots in poverty studies, the programmatic sector loans tend to be based on sector assessments. After the government has taken key legal, institutional, and spending actions to improve the efficiency of health spending or to target services for poor households, donor funds are transferred in a block or *tranche* to the government. In 2003, the World Bank approved four programmatic sector loans—for Brazil, Colombia, Ecuador, and Peru—totaling US\$900 million (D. Cotlear, personal communication, December 12, 2003).

Another recent example is the World Bank's US\$750 million Maternal and Child Insurance Program sector adjustment loan to Argentina, which followed decisions made by that government in 2003 to create a mother and child health insurance scheme for poor provinces, to increase spending for communicable diseases, and to establish a national health council to set policies on the sharing of revenues to be used for health between the central government and the provinces. The central pillar of this project, as well as the follow-on operation in 2004, is the implementation of the Maternal and Child Insurance Program. It delivers a publicly financed package of essential services to uninsured mothers and children at the provincial level. The donor funding is used in an innovative way to provide matching grants from the national to the provincial level, on the basis of a capitated payment per mother and child enrolled plus additional transfers to the province for performance. That performance is measured in terms of key health service goals (for example, coverage of vaccine programs, incidence of low birth-weight, and number of prenatal consultations). In the first four

months of program execution, more than 100,000 eligible women and children joined the insurance scheme.

Pooling and Donor Harmonization

As mentioned earlier, another innovation in recent years has been the use of sectorwide approaches as a way for multiple donors to pool their funds for a commonly agreed-on program and to use similar, streamlined procedures for procurement, monitoring and evaluation, and reporting. Sectorwide approaches grew out of sector investment programs for health that were launched in the early 1990s as a way to bring donors together to support broader government objectives in health.

The main features of sectorwide approaches are as follows:

- a. a partnership among a broad coalition of donors, with the government taking the lead;
- b. a comprehensive sector policy framework to achieve goals over the short and medium terms;
- c. an agreed-on expenditure program;
- d. the improvement of management systems and capacity building (Swedish International Development Cooperation Agency 2003).

The main difference between sectorwide approaches and PRSCs is that, in the former, pooled donor funding is disbursed against specific expenditure items—for example, construction of health facilities or purchase of drugs—whereas in PRSCs, donor funds are transferred to the general budget, with disbursements triggered by policy actions.

A prime example of a sectorwide approach is the Ghana health sector support program, in which 17 donor organizations have committed US\$442 million over a five-year period to improve the health status of the population while focusing efforts on reducing inequalities in health. The program includes the following main spheres of action aimed at strengthening priority health interventions: developing human resources for health services, enhancing infrastructure and support services, fostering partnerships for health, improving regulation, reforming organizational arrangements, improving health sector financing, enhancing financial management systems, strengthening management information systems and performance monitoring, and linking with traditional medicine.

Performance-Based Financing

Developing countries and their international partners are increasingly adopting methods for financing health care activities that link the availability of funding to concrete, measurable results on the ground. Such performance-based financing was advocated a decade ago in the 1993 *World Development Report* (World Bank 1993) and in other policy documents in the early 1990s, although relatively little practical knowledge of this type of financing was available at the time.

Since then, much more experimentation has taken place, and the important potential—as well as the challenges—of performance-based financing for achieving national and global health goals is becoming apparent.

Performance-based financing is now being widely and actively tested at several levels of the health care system. These tests include situations in which the following occurs:

- Governments of developing countries pay health care providers in NGOs and the private sector to deliver essential health services to poor households.
- Central governments determine the transfer of funds to local governments on the basis of their performance in strengthening health services.
- Donors release funding to recipients in developing countries as and when they achieve certain key health targets.

Performance-Based Contracts with Nongovernmental Organizations. A number of governments in low-income countries are funding NGOs to deliver basic health services on

a performance basis (Hecht 2004). Many of the earliest experiments are from Latin America and the Caribbean. In Haiti, for example, the government contracted NGOs to provide child health and family planning services. The government gave the NGOs an advance each year and then a quarterly sum based on a negotiated budget. At the end of the year, performance was measured against various indicators, including the extent of immunization coverage, the percentage of families using oral rehydration to treat acute diarrhea, the share of pregnant women attending prenatal care, and the average waiting times in clinics. The NGOs' performance determined the bonus they received, which could be up to 10 percent of the original negotiated budget. As a result, the Haitian NGOs made changes in their service delivery schemes and improved their performance in immunization and oral rehydration in particular (Eichler, Auxilia, and Pollack 2001). In Guatemala, the government is implementing a large performance-based program with NGOs that currently covers nearly 4 million people, mostly among the country's indigenous population (box 13.2). Similar schemes have been implemented in Argentina, El Salvador, and Nicaragua.

Box 13.2

Large-Scale Performance Contracting with Nongovernmental Organizations in Guatemala

Guatemala has successfully implemented contracting on a large scale with NGOs to deliver health services. The government started the Program to Extend Coverage of Basic Health Services in 1997, soon after the end of a long civil war. The program has continued under successive administrations. By 2000, a total of 89 NGOs were involved in providing health care to about 3.7 million people under 137 contracts.

The contracts specify a range of maternal and child health services, as well as the prevention and treatment of a number of diseases, including malaria. The NGOs are paid about US\$8 per person served, mostly in cash, but also in kind in the form of such items as vaccines and medicines. Payments are released quarterly after the NGOs' performance has been checked and verified.

Performance is measured according to a series of indicators, including coverage of immunization and prenatal care, distribution of iron sulfate tablets to pregnant women and to children, and frequency of home visits by NGO outreach staff. The government has hired private firms to develop the monitoring system, which also looks at the NGOs' accounting practices.

Source: Hecht 2004; World Bank 2000.

The contracting system under the program appears to have resulted in important gains in health service delivery. Immunization rates rose from 69 percent in 1997 to 87 percent in 2001. Household surveys currently under way will be able to assess the program's effect on mothers' and children's health outcomes.

During the program's early years, the government had to overcome a number of obstacles. Government health workers resisted the scheme because they feared that contracting with NGOs was a hidden form of privatization of government health services. The NGOs were initially reluctant to get involved, because they thought that the government was demanding too much in the way of improved performance and also doubted that the government would pay them in a timely manner. Given the financial fragility of many local NGOs in Guatemala, the government had to make advance payments to the NGOs and release quarterly payments without delay to build confidence in the relationship between the public and private sectors.

More recently, countries in South Asia have begun to enter into performance-based health programs with NGOs. In Afghanistan, under a recently approved World Bank–financed project for health service rehabilitation, the government is contracting with NGOs to run health centers. NGOs that achieve specified targets will be eligible to receive additional payments of up to 10 percent of their baseline subsidies from the government.

In a similar vein, the central and state governments in India have started to reimburse NGOs and private providers on the basis of performance. The national TB program reimburses private laboratories for testing sputum samples to detect TB; it also pays NGOs and private doctors a fixed sum per infected patient who is cured using the directly observed short-course therapy approach. In one district of Kerala state where this scheme is well advanced, NGOs and private providers have helped boost coverage from some 55 percent of those infected with TB to 78 percent.

In Cambodia, government agreements and funding to NGOs to operate district health services showed impressive results compared with the standard approach, whereby the government ran district services. The NGOs operated in one of two ways: (a) on a fully contracted-out basis, with complete responsibility for service delivery, including hiring and firing staff members and setting wages and procuring and distributing essential drugs and supplies, or (b) through a pure management contract, in which the NGOs worked within the Ministry of Health system and had to strengthen the existing district structure. The NGOs that were fully contracted out raised immunization rates by 40 percentage points between 1997 and 2001, twice the rate of improvement produced by the government-run districts. The rate of growth in prenatal care in the contracted-out districts was more than triple that in the government-run districts, and the use of modern contraception methods expanded 50 percent more in the contracted-out districts (Bhushan, Keller, and Schwartz 2002).

Central Government Transfers to Local Authorities. In Brazil's Family Health Project, the central government is making per capita transfers to local municipalities on the basis of planned increases in certain services, such as safe deliveries for low-income women and poor children treated for various illnesses and monitored for their nutritional status and growth. For example, at least 40 percent of babies are to be delivered in maternity facilities managed under the government's family health program. Participating outreach workers are to provide an average of at least nine home visits to targeted low-income families each year. All doctors enrolled in the program are to undergo special training. If the municipalities reach those targets and several others, they will continue to be eligible for future financial transfers; otherwise, the level of central government support will be reduced, and remedial measures will be put in place to try to improve the targeting and effectiveness

of the activities run by the underperforming municipalities (G. M. LaForgia, personal communication, October 21, 2003).

Donor Disbursements to National Governments and Other Recipients. A number of innovative approaches are in place that make donor financing of health programs conditional on successful performance on the ground. One example is the World Bank's credit buy-down program for polio eradication (box 13.3).

GAVI has also been a pioneer in the performance-based approach to grant assistance. Through its sister organization, the Vaccine Fund, which raises and disburses funds for the alliance, GAVI provides commodity assistance to countries in the form of new and underused vaccines (hepatitis B, *Haemophilus influenzae* type B, and yellow fever, with new products for rotavirus and pneumococcus to follow); safe injection supplies; and support for strengthening national immunization systems. In addition, GAVI allocates grant funds to countries on the basis of their performance in increasing coverage rates for diphtheria-pertussis-tetanus immunizations. Countries' applications to GAVI specify current coverage levels. On the basis of these data, their performance is assessed annually, and US\$20 per child is given to the country for each additional child immunized with the diphtheria-pertussis-tetanus vaccine.

In 2004, GAVI made its first payment for performance verified by means of externally audited health data. Eight countries received US\$15 million in performance-based payments for their achievements in increasing immunization rates to reach an additional 750,000 children. Sierra Leone, for example, qualified for these payments on the basis of its performance in raising coverage from 44 percent of children in 2000 to 62 percent in 2002, as the country emerged from civil war (GAVI 2004a).

Stronger Engagement with the Private Sector

As donors have increasingly become aware of the extent of private sector involvement in the health sector in developing countries—that is, both the share of health services delivered by private providers and the share of total health spending coming from private sources, including out-of-pocket payments—they have sought to use DAH to engage the private sector in pursuit of basic health goals.

Innovative approaches include both the transfer of development assistance to the private sector through government channels in developing countries and the provision of direct financial support to private institutions (World Bank 2003b). In the former category, social investment funds have been established in many regions as a way to channel DAH to community groups and NGOs involved in running health centers and disease control programs (Jorgensen and Domelen 2001), especially in Africa and Latin America. In a similar vein, donors

Box 13.3

IDA Credit Buy-Downs for Polio Eradication

To ensure financing for the MDGs, governments, foundations, agencies, and development banks are all exploring new financing approaches that have the potential to increase resource flows, adjust the concessionality of funding (that is, reduce interest rates and thus increase the grant element) where appropriate, and help focus more attention on effects.

The IDA credit buy-down mechanism was recently piloted in several projects supporting polio eradication, clearly a global public good. The mechanism enhances the concessionality of IDA's assistance in priority areas, mobilizes additional resources from external partners, and focuses the attention of governments, partners, and World Bank staff on clearly defined performance objectives.

Working in partnership with the Bill & Melinda Gates Foundation, Rotary International, and the United

Nations Foundation, the World Bank implemented two projects in fiscal 2003, one in Pakistan and the other in Nigeria. The partnerships will buy down a country's IDA loans on successful completion of the country's polio eradication program. Because of the generous loan terms, each grant dollar unlocks roughly US\$2.50 for countries to fight polio. To fund the buy-downs, the partnership has established a trust fund with US\$25 million from the Bill & Melinda Gates Foundation and US\$25 million from Rotary International and the United Nations Foundation. This US\$50 million investment has the potential to buy down roughly US\$125 million in IDA loans. In this way, developing countries can mobilize what ultimately becomes grant funding to eradicate polio and to contribute to the global campaign to eliminate the transmission of polio.

Source: World Bank 2004d.

have been prime movers behind schemes to encourage governments to contract with NGOs and private hospitals and laboratories for basic services targeted to the poor, such as cataract surgery and TB case detection and treatment in India (Central TB Division 2002; World Bank 2002).

In terms of direct DAH financing to the private sector in developing countries, the most common and longstanding examples are in the social marketing of health-related personal products, such as contraceptives, kits for treating sexually transmitted infections, insecticide-impregnated bednets to prevent malaria, and point-of-use water purification kits. Donors are currently providing millions of dollars each year to subsidize the purchase of these items by poor families in developing countries. More recently, other donor engagements with the private sector have included the Global Alliance for Improved Nutrition, in which a consortium of donors that includes the Bill & Melinda Gates Foundation and the governments of Canada, the Netherlands, and the United States have pooled funds that can be used to expand the fortification of basic foods with micronutrients by private manufacturers. The Global Alliance for Improved Nutrition is helping to fortify wheat with iron in western China and in Morocco and fish sauce with vitamin A in Vietnam.

Another recent example of DAH going directly to the private sector is Avahan, the innovative AIDS prevention program that the Bill & Melinda Gates Foundation is financing in six Indian states. The program uses external financing to leverage

financial and in-kind support from major Indian companies that can then be used to support a range of HIV prevention programs, such as condom promotion, peer education, and voluntary counseling and testing targeted at truck drivers, commercial sex workers, and others at high risk (Sengupta and Sinha 2004).

The other area in which donor funds are increasingly being used to stimulate private sector action and leverage private funding is through public-private partnerships for new health technologies, including vaccines, drugs, and diagnostics. Private financing, technical input, and management make sense in this area, because typically it is the private sector that has the technical knowledge and the manufacturing and distribution capacity to create and market new health products, but major scientific risks and the lack of an attractive market in poor countries are barriers to investment. The public-private partnerships aim to overcome those barriers through a combination of up-front financing for R&D (so-called push funding) and market guarantees for effective products (so-called pull financing). The 20 largest partnerships for new products have raised more than US\$1.5 billion over the past decade and are beginning to see results, such as the development of new drugs for malaria and TB, promising vaccines for malaria and AIDS, and microbicides to protect against HIV infection (IPPPH 2004; Rockefeller Foundation 2004). The largest partnership, the IAVI, illustrates the innovative nature of these partnerships and the effective use of DAH (box 13.4).

Box 13.4

The International AIDS Vaccine Initiative

The International AIDS Vaccine Initiative was established in 1996 with support from the Rockefeller Foundation as an innovative way to give a boost to AIDS vaccine R&D. Optimism about AIDS vaccines in the late 1980s had given way to a series of failures and to discouragement by the end of the decade. R&D efforts were spending less than US\$100 million a year. Neither governments nor private vaccine companies were investing much in research into AIDS vaccines.

IAVI's mission was defined as ensuring the development of a safe, effective, and accessible vaccine for use throughout the world. IAVI's activities were to include a combination of global advocacy, policy analysis and reform, and investments in carefully chosen R&D projects focusing on the most promising vaccine candidates.

IAVI's collaboration with the private sector has occurred at several levels. Funding for IAVI has come from six governments (Canada, Denmark, the Netherlands, Norway, the United Kingdom, and the United States); the European Union; and the World Bank, as well as from private foundations and companies. IAVI's vaccine development partnerships take many forms. They typically include an academic developer and a biotechnology company, plus researchers, laboratories, and clinical trial sites in developing countries such as India, Kenya, and Uganda. Private companies generally manufacture test lots of the AIDS vaccines and undertake bioengineering studies and enhancements to the vaccine. IAVI generally shares the risks and costs of the partnerships with the private code-

Source: IAVI 2004.

velopers, while ensuring that developing countries will have access to the vaccine at an affordable price if it turns out to be effective.

Since IAVI embarked on these vaccine development partnerships in 1999, it has spent a total of about US\$200 million in this area. Five vaccine candidates are undergoing clinical trials in eight countries in Africa, Asia, Europe, and North America. IAVI is poised to spend another US\$300 million in R&D during 2005–7 in an effort to accelerate the discovery, development, and licensing of a vaccine to prevent HIV infection. IAVI is also trying to stimulate expanded use of donor funding for R&D in the field of AIDS vaccines and is calling for governments to increase public financing from the current amount of around US\$600 million a year to US\$1.2 billion annually. At the same time, IAVI has proposed that donors create a purchase fund of several billion dollars to serve as a promise to buy large numbers of doses of an efficacious vaccine from qualified manufacturers. The U.K. government has committed itself to joining such an advance purchase fund and is urging others to join it (“Gordon Brown to Earmark” 2004).

The health and economic stakes are enormous. Without improved HIV prevention tools, an additional 100 million HIV infections are likely over the next two decades, resulting in huge economic losses. IAVI estimates that an efficacious vaccine could prevent 2 million AIDS deaths a year and generate billions of dollars in lives saved and antiretroviral treatment costs averted.

Getting Funds to the Front Line

Central government funds can easily leak as they move through the pipeline from the center to local levels. In addition, in the absence of local initiative and the right incentives, service provision can fail to reflect the views of local people. Effective DAH needs to address those impediments. It needs to channel technologies, ideas, finance, and technical assistance closer to households, health providers, and supervisory officials in ways that are consistent with national policies and are amenable to monitoring and reporting.

Development assistance for health is more likely to reach communities if they have the following:

- a decentralized system of fiduciary and technical management in the public sector

- a strong financial capacity in NGOs and private providers in cases in which the government's strategy for local development is to rely on private institutions
- a government body that is appropriately equipped and responsible for regulating the quality of public and private providers
- a balanced approach to community-driven development in health to ensure that financing for community health initiatives of the social fund type is sustainable.

Examples of DAH reaching frontline workers in an expeditious and sustainable way include block grants for districts in Uganda; social development funds in Central America; contracts with urban and rural NGOs under India's Reproductive and Child Health Program; and support to community-led

initiatives under the Multi-Country AIDS Program, which financed an average of 10,000 local initiatives in each of its first four years in several African countries (World Bank 2004c).

CONCLUSIONS

Despite the promising trends in DAH over the past five to seven years, the outlook for the next few years is uncertain. What happens will depend on overall trends and innovations in development assistance, which in turn are driven by such factors as political changes and the rate of economic growth in OECD countries, and the willingness of high-income countries to honor their pledges to increase the share of GDP they devote to development.

Under most scenarios, the share of overall assistance going to health will likely continue its recent rise, given the current political focus on the global AIDS pandemic and the growing awareness of the challenges and opportunities associated with the MDGs for maternal and child health and communicable diseases.

Under a more conservative scenario, a number of factors could have a negative impact on DAH. Those factors could include an overall slowing in the rate of growth of development financing and the donor fatigue that could set in if the larger allocations for HIV/AIDS, TB, and malaria are not fully disbursed, are misused, or yield disappointing results on the ground.

Under a more optimistic scenario, DAH will continue to grow as developing countries and donors find new ways to disburse a higher volume of funds and use them effectively—for example, through subcontracts with NGOs and private health service delivery organizations. Sectorwide approaches and budget support through national poverty reduction programs may also result in expanded flows of DAH. New generations of technologies adapted to the developing world, such as more effective antimalarials, better TB diagnostics, and a vaccine to prevent HIV infection, would almost certainly attract increasing amounts of DAH.

Even under the more optimistic scenario, DAH will still face major challenges. The expected volume of financial assistance is unlikely to match the large needs of the developing world and the requirements to attain the MDGs. Countries and donors will therefore face difficult decisions in relation to priority setting and require better tools to make such allocation decisions. Cost-effectiveness analysis offers one such tool. Effective absorption of DAH will also continue to pose difficulties for countries with weak capacity. In such cases, increased use of NGOs and the private sector in general to complement public sector action may help make the information and services that poor households need to improve their health status more accessible.

Another issue is that the current architecture of development assistance does not contain a mechanism to ensure that

adequate funds flow to the upstream stages of R&D on new health technologies, where the private sector lacks the market incentives to invest and where national research bodies have so far not been up to the task. The multilateral banks do not have the instruments to channel major funding to global, as opposed to national, health technology programs, and the bilateral agencies alone are not equal to this task. Even with the modest external funds allocated to the recently established public-private partnerships (such as the IAVI, the Medicines for Malaria Venture, the Global TB Drug Alliance, and the International Partnership for Microbicides), new technologies are emerging. However, they need to be reinforced with additional funding. One option would be to design a new funding facility within the multilateral banks that would allow them to allocate significant resources to global health research and product development. Another would be to use the nascent international finance facility to provide funds for global research.

To address those challenges, strong political will is the essential baseline ingredient, as recent experience with HIV/AIDS has clearly demonstrated. The United Nations and the multilateral agencies must remain firmly behind more robust DAH, as they are currently doing by means of the Millennium Project and the High-Level Forum on the Health-Related MDGs. Individual bilateral donors and foundations must continue to demonstrate their leadership. Finally, and perhaps most important, leaders and civil society organizations in poor countries need to continue to speak out for more and more effective DAH, indicating that health is their priority and that they are prepared to commit domestic resources to match the larger external flows provided through DAH.

Ethical Issues in Resource Allocation, Research, and New Product Development

Dan W. Brock and Daniel Wikler

The ethical justification for developing and providing the means to reduce the burden of disease in developing countries is self-evident. Nevertheless, those who pursue these laudable ends encounter ethical dilemmas at every turn. The development of new interventions requires testing with human subjects, an activity fraught with controversy since the dawn of scientific medicine and especially problematic with poor and vulnerable participants in developing countries. Ethical dilemmas arising in setting priorities among interventions and among individuals in need of care are most acute when needs are great and resources few.

We address some of these concerns in this chapter, identifying some of the principal ethical issues that arise in the development and allocation of effective interventions for developing countries and discussing some alternative resolutions. We omit discussion of two other aspects of these ethical decisions: ensuring that the process of decision making is fair and involves the subject population (Daniels 2000; Holm 1998), and respecting legal obligations under international human rights treaties (Gruskin and Tarantola 2001).

HEALTH RESOURCE ALLOCATION

Resource allocation in health and elsewhere should satisfy two main ethical criteria. First, it should be cost-effective—limited resources for health should be allocated to maximize the health benefits for the population served. A cost-effectiveness analysis (CEA) of alternative health interventions measures their respective costs and benefits to determine their relative efficiency in

the production of health. Costs are measured in monetary terms; benefits are measured in health improvements. By dividing costs by benefits, one can obtain a cost-to-effectiveness ratio for each health intervention, and interventions can be ranked by these ratios. Although a CEA is typically an economic analysis performed by health economists, it is also a measure of one ethical criterion for the evaluation of health programs. Cost-effectiveness is not merely an economic concern, because improving people's health and well-being is a moral concern, and an allocation of resources that is not cost-effective produces fewer benefits than would have been possible with a different allocation. Producing more rather than fewer benefits for people is one important ethical consideration in evaluating actions and social policies.

Second, the allocation should be equitable or just; equity is concerned with the distribution of benefits and costs to distinct individuals or groups. The maximization of benefits, which is associated with the general philosophical moral theory of utilitarianism or consequentialism, however, is routinely criticized for ignoring those considerations (Rawls 1971). Equity in health care distribution is complex and embodies several distinct moral concerns or issues that this chapter delineates (Brock 2003a). There is no generally accepted methodology comparable to CEA for determining how equitable a distribution is; nevertheless, allocations are unsatisfactory if equity considerations are ignored.

Efficiency and equity can sometimes coincide. In some of the world's poorest countries, for example, health budgets support tertiary care and travel to clinics abroad for the elite and the well connected, even as the poor are denied effective,

low-cost prevention or treatment for life-threatening diseases (Birdsall and Hecht 1995). Moreover, because equity concerns the relative treatment of different individuals, CEA is largely unobjectionable when it is used only for evaluating alternative health interventions that would serve the same patients. However, considerations of equity may conflict with cost-effectiveness and so may provide moral reasons for an allocation that is not cost-effective. The discussion in this chapter accepts that CEA identifies one important ethical criterion in evaluating health care interventions—producing the most benefits possible for individuals served by those interventions—and then focuses on the other ethical criterion of ensuring equitable distribution of those benefits.

This chapter considers two types of equity issues: first, those that arise in the general construction of a CEA—that is, in determining the form of a CEA; second, those that arise in the use of the results of a CEA for resource allocation in the health sector. It is worth noting that, when applied appropriately and broadly to all social conditions and programs that significantly influence health, CEA may often support using resources to affect the so-called social determinants of health—which largely affect the incidence of disease, disability, and premature mortality—rather than using those resources on health care to treat disease. However, we shall focus largely on CEA in the evaluation of health care and public health programs.

Issues in the Construction of a Cost-Effectiveness Analysis

Cost-effectiveness analyses require decisions about which costs to include, which if any financial gains should be counted as offsetting costs, whether to include benefits beyond the effects of the intervention on health, and whether all health gains should be valued alike. None of those decisions, in our view, is exclusively a technical issue, and CEA results reflect the analysts' ethical judgments on those issues.

Evaluation of Benefits. Evaluating health benefits within a CEA involves several issues. This chapter assumes that some version of a quality-adjusted life year (QALY) is used to combine the two main benefits of health care—(a) protecting or improving health or health-related quality of life and (b) preserving life. Disability-adjusted life years (DALYs) are a variant of QALYs in that they measure the losses from disability or premature death; a CEA will determine which interventions will maximize QALYs or minimize DALYs. Calculating QALYs requires a metric evaluating the effect of different states of limitations in function on health-related quality of life, such as the Health Utilities Index (Horsman and others 2003). The Disease Control Priorities Project uses the health state valuations or disability weights of the World Health Organization (WHO). The relative value of any particular health state, typically on a scale in which “0” represents death and “1” represents full,

undiminished function (or health) is generally determined by soliciting a group of individuals' preferences for life in that state using standard gambles, time tradeoffs, visual analog scales, or person tradeoffs. In all these methods, a common issue is whose preferences to use for valuing health states. The main debate has been whether to use a randomly selected group of citizens or to use people who have the particular disability or limitation in function being evaluated.

This issue matters because a number of studies have shown that persons without disabilities generally evaluate the quality of life with a particular disability as significantly worse than do persons who have that same disability (Menzel and others 2002). If the preferences of persons without disabilities are used, their lower evaluation of quality of life with various disabilities will mean that fewer QALYs will be produced by life-saving interventions for persons with disabilities than if the preferences of persons with disabilities had been used. However, if we use the preferences of persons with disabilities, then both prevention and rehabilitation will receive less value than if the preferences of persons without disabilities had been used.

This difference in evaluations in part results from ignorance, prejudice, and stereotypes on the part of persons without disabilities about what it is like to live with various disabilities. The difference results as well from the process of adaptation to disability in which disabled persons adjust by learning new skills, cope by adjusting their expectations to their new circumstances, and accommodate by substituting new aims and activities for ones made difficult or impossible by their disabilities (Solomon and Murray 2002). They thus adopt a new valuational perspective for making health and quality-of-life evaluations. Because the adoption of this new perspective resulted from a disability, it will represent a set of values for making choices that reflects a restricted set of abilities. Nevertheless, neither the nondisabled perspective nor the adapted disabled perspective is mistaken; they are only different (Brock 1995). These differences create controversy in the literature over which perspective is correct for cost-effectiveness evaluations in health care.

A second issue is whether, in evaluating interventions that preserve or extend life, we should use life years saved (as QALYs do) or lives saved. Certainly individuals offered two interventions that would preserve their lives for different lengths of time would prefer, all other things being equal, the alternative with the longer period of survival. Moreover, when the differences are extreme—for example, extending group A's lives by a week or extending an equally numerous group B's lives by 10 years—virtually everyone would judge this difference to support giving priority to group B. This fact suggests that even the proponent of counting lives saved should require that the lives saved for a shorter period of time must still be saved for a significant period of time; what is significant will depend in part on the

duration of lives saved by the alternative with which it is being compared. Some empirical studies indicate that ordinary people tend not to give much weight to differences in the duration of health benefits to different groups of persons when prioritizing between them, as long as the lesser duration benefits are viewed as significant; this attitude suggests that they favor lives saved over life years saved (Nord and others 1996). The life years saved versus lives saved controversy remains unsettled.

Should Life Years Be Age Weighted? The standard assumption in most CEAs using QALYs is that one QALY has the same social value, regardless of the age of the recipient (Gold and others 1996). Thus, equality is adopted as the weighting for QALYs achieved by recipients at different ages, and that is the approach adopted in this volume. The use of any age weighting that gives less value to benefits for the elderly than for younger persons is often charged as unjust age discrimination. Even the use of equally weighted QALYs is often charged as unjust age discrimination because, other things being equal, saving the lives of younger persons will produce more QALYs than saving the lives of older persons. The goal of lives saved, as opposed to life years saved, removes this disadvantage to the elderly from CEAs that use QALYs. However, if the relevant benefit is adding years to life, then standard CEA is neutral or impartial regarding age, in the sense that it gives the same value to a year of life extension whatever the age of its recipient.

WHO, in its burden-of-disease and resource prioritization studies that use DALYs, rejected the equal age weighting that is standard with QALYs. Instead, it gave less value to DALYs prevented for infants, young children, and the elderly, in comparison with persons in their productive adult years. WHO justified this weighting by the fact that the very young and the elderly both tend to be economically, socially, and psychologically dependent on adults during those adults' productive working and child-rearing years (Murray 1994). This justification is ethically problematic, however, because it assigns different value to meeting people's health needs on the basis of differences in the instrumental value to others of meeting their needs. This approach differentiates people solely on whether they are a means to benefiting others. The same reasoning would justify giving priority to rich over poor patients with the same medical needs because the rich are more socially productive than the poor, a practice that would be widely regarded as unjust.

Writers in this field have provided different reasons for giving greater value to QALYs for younger patients, however, that are not subject to this moral objection and that are specifically grounded in fairness. For example, Alan Williams has developed an argument to the effect that fairness requires that individuals should each receive "fair innings" of QALYs in their lives (Williams 1997). In this view, the earlier a preventable death could occur and the worse a person's past health is, the greater is the unfairness the person suffers—so the greater is

the moral urgency, grounded in fairness, of preventing the death. The younger a person is, the greater is the moral value of providing a QALY to him or her. This view leaves open to what extent the moral value of QALYs should decline with the age of the recipient. This age weighting to favor the young has been attacked by some as unjust age discrimination, but because an explicit moral justification in terms of fairness is offered for it, critics must show why that justification is unsound.

What Costs Should Count in Health Cost-Effectiveness Analyses? No controversy surrounds the inclusion in a CEA of direct costs of a health intervention program or direct health benefits to the intervention's recipients. Ethical issues do, however, arise in other aspects of the cost calculation (Brock 2003b). A full CEA of alternative health programs should take account of all the economic effects on public or private expenditures of the alternative health interventions or programs under analysis. An example is provided in the consideration of treatment for two alternative health conditions judged to have equally detrimental effects on patients' health: the first condition permits patients to continue working, and the second interferes with regular work and so has large economic costs to the patients' employers. Should the costs of treating the second be reduced by the cost savings to the employers from returning the patients to work on a regular basis? If so, the second treatment program will have a more favorable cost-effectiveness ratio than the first, even if it may be no better or worse without consideration of those economic effects. The same issue arises in many other contexts.

From the moral perspectives of both a consequentialist and a standard CEA, these indirect economic effects for others are real benefits or cost reductions and should be part of the CEA. The fundamental moral objection to giving higher priority to treating those who can be treated at lower net cost because of the economic savings to their employers is the same as that with WHO's instrumental rationale for its age weighting. One condition or group of patients gets higher priority solely because treating it or them is a means to producing economic benefits to others, thereby reducing the net social costs of their treatment. This approach violates the Kantian injunction against treating people solely as means—the first group has lower priority for treatment solely because treating that group is not a means to the economic savings to employers. It fails to give equal moral concern to the health needs of each group of patients because it discriminates against the less socially valuable patients. Conversely, at the macro level of the allocation of resources to health instead of other social goods, the WHO Commission on Macroeconomics and Health has supported increasing health investments in developing countries because such investments often more than pay for themselves in their economic and development benefits (CMH 2001). Using a "separate spheres" view, only the health benefits and health

costs of alternative health interventions should determine their priority for obtaining resources, but this view remains controversial.

Another aspect of cost calculation concerns whether future health care and other costs, such as old-age payments, that will be incurred as a result of a person's life being saved should be added to the costs of treating that person now. Persons who do not die now because of a life-saving intervention will typically go on to incur future health costs that would not have been incurred had they died now. The U.S. Public Health Service Panel on cost-effectiveness recommended that inclusion of these costs be optional in CEAs (Gold and others 1996). Others have argued that, if CEA is designed to maximize lifetime utility, the future costs should be included (Meltzer 1997). These are costs that would not be incurred if the patient was not saved, but virtually no one would argue that, because of those costs, we should judge a life-saving intervention as not cost-effective and thus deserving of lower priority than interventions that do not have those effects. What does this thinking show? That we are not prepared to allocate health resources on the basis of a full CEA that accounts for all the costs incurred and saved by those interventions—that is, that some should be disregarded on ethical grounds.

Should Health Benefits and Costs Be Discounted in Cost-Effectiveness Analyses? As standard practice in CEAs, both health care costs and benefits are discounted at the same rate, for example, 3 percent or 5 percent, and the Disease Control Priorities Project applies a 3 percent discount rate to costs and benefits (Gold and others 1996). Little controversy surrounds the idea that future monetary costs and benefits should be discounted to their present value in a CEA. The same amount of money is worth more if received today than in 10 years because it can be invested at the market rate of interest if received today. For the same reason, costs that can be deferred require fewer present dollars to meet them.

The controversial issue is whether health benefits should be discounted—that is, whether the same magnitude of health benefit has progressively less social value the farther into the future it occurs. This issue is complex and has engendered an extensive literature that cannot be reviewed here, but we can at least try to focus the issue. It is appropriate to discount for the uncertainty about whether potential beneficiaries will survive to receive a future health benefit and to discount for any increased uncertainty about whether a benefit will occur because it is more distant. However, these uncertainties are reflected in the calculation of expected future benefits and do not require that future benefits be discounted. Likewise, if individuals receive a health benefit (such as regaining mobility) sooner rather than later, their total lifetime benefit may be greater, but this fact, too, is reflected in the estimation of the total benefit without discounting.

The ethical issue about discounting is whether, after taking account of such considerations, a health benefit of the same size has progressively less social value the farther into the future that it occurs. To make the issue more concrete, suppose we must decide between two programs: one will save 100 lives now, and the other, say a hepatitis vaccination program, will save 200 lives in 30 years. The vaccination program will save twice as many lives, but if we apply even a 3 percent discount rate to the future lives saved, they are equivalent to only 78 lives saved now, and we should prefer the first program. This example illustrates not only the theoretical issue, but its practical import, too, because discounting future health benefits will systematically tend to disadvantage prevention programs that must be undertaken now but whose benefits occur only at some point in the future. This reasoning applies not only to many vaccination programs, but also to most programs to change unhealthy behaviors in which the benefits generally occur at some later time.

Arguments for discounting health benefits at the same rate as costs have included consistency arguments (Weinstein and Stason 1997), avoidance of paradoxes in allocation concerning research and deferral of spending (Keeler and Cretin 1983), individual or social rates of time preference, and so forth. Those arguments cannot be reviewed here, but whether to discount health benefits is squarely an ethical question about the valuing of health benefits over time and should be explicitly addressed as such in allocating resources.

Issues in the Use of Cost-Effectiveness Analysis for Resource Allocation

It is now widely recognized that CEA alone is not a satisfactory guide to resource allocation in all cases. CEA, as customarily formulated, measures the sum of costs and benefits and largely ignores the pattern of their distribution across the affected population. In some cases, the resulting allocation will strike most observers as unfair. Health resource allocators need to take distributional issues into account along with cost-effectiveness.

Priority to the Worst Off. Justice requires a special concern for the worst off, as is reflected in aphorisms such as “you can tell the justice of a society by how it treats its least well-off members,” in the well-known Difference Principle in John Rawls's theory of justice, and by the special concern for the poor within many religious traditions (Brock 2002; Rawls 1971). This concern is often understood to reflect a concern for equality—in particular, equality in outcomes or welfare between people. In the health context, it takes the form of a concern for reducing inequalities in health between persons or groups. A variety of ethical bases underpin a concern for equality in general and for equality in health in particular, and they cannot be explored

here. It is important, however, to understand that concern for the worst off is different from a concern for equality, because the two can be and often are confused. Raising the position of the worst off will typically reduce inequality, but it need not always do so. Sometimes improving the position of the worst off may unavoidably improve the position of those who are better off even more and thereby increase inequality. Moreover, the concern for equality in outcomes is subject to the “leveling down” objection, in which equality is achieved by making the better-off members worse off, even when doing so in no way benefits those who are worst off. In the face of that objection, many have rejected equality in outcomes in favor of a prioritarian view, according to which benefiting people has greater moral value the worse off those people are (Parfit 1991).

A number of possible lines of reasoning support prioritarianism. For example, the worse off that people are, the greater is the relative improvement that a given size of benefit will provide them, so the more the benefit may matter to them. Alternatively, the greater the undeserved health deprivation or need that an individual suffers, the greater is the moral claim to have it alleviated or met.

However priority to the worst off is justified, an important issue is who the worst off are. In the context of resource allocation in health care, the worst off might be those who are globally worst off, those with the worst overall well-being (such as the poor), or those with the worst health (that is, the sickest). General theories of justice usually focus on people’s overall well-being, often allowing a lower level in one domain of well-being to be compensated for by a higher level in another domain. However, there are both moral and pragmatic reasons for what has been called a *separate spheres view*, according to which the worst off for the purpose of health resource allocation should be considered to be those with worse health. Morally, for example, Scanlon has argued that “for differences in level to affect the relative strength of people’s claims to help, these differences have to be in an aspect of welfare that the help in question will contribute to” (Scanlon 1997, 227). Pragmatically, it may generally be too difficult, costly, intrusive, and controversial, as well as too subject to mistake and abuse, to have to inquire into all aspects of people’s overall levels of well-being.

Even if health allocation to the worst off should be based on levels of health, other issues remain. For example, are those with worse health those who are sickest now, at the time a health intervention would be provided for them, or those with worse health over time, taking into account past and perhaps expected future health? The latter would give special weight to meeting the health needs of those with long-term chronic diseases and disabilities. Separate spheres would still include past and future health. Should special priority also be given to those whose health is not worse now but is especially vulnerable to becoming worse?

Finally, how much priority should the worst off receive? Giving absolute priority to the worst off is implausible because it faces the bottomless pit problem—using very great amounts of resources to produce very limited or marginal gains in the health-related quality of life of the severely ill or disabled. However, there is no apparent principled basis for determining how much priority the worst off should receive.

Aggregation and Cost Differences. The aggregation problem occurs when determining at what point small benefits to a large number of persons should take priority over very large benefits to a few, because the former result in greater aggregate or total benefits (Daniels 1993; Kamm 1993). The issue can be illustrated by the initial effort to prioritize different treatment-condition pairs in the Medicaid program in the U.S. state of Oregon by what was essentially a cost-effectiveness standard. As was widely reported, capping teeth for exposed pulp was ranked just above performing appendectomies for acute appendicitis, even though appendicitis is a life-threatening condition. A variety of methodological problems affected Oregon’s analysis, but this kind of result is to be expected from CEA. The Oregon Health Services Commission estimated that it was possible to provide a tooth capping for more than 100 patients for the cost of one appendectomy, so the aggregate benefits of the many tooth cappings were estimated to exceed the benefit of one appendectomy. As a consequence of results of this sort, the commission fundamentally changed its prioritization methodology to largely ignore cost differences, except in the case of roughly equally beneficial interventions. The commission essentially adopted what might be called a relative effectiveness or benefit standard (Hadorn 1991).

What Oregon’s experience shows is that most people’s sense of priorities is determined by a one-to-one comparison of the benefits of different interventions, in which case appendectomies are clearly a higher priority than tooth capping. That ignores the great differences in costs between different health interventions that a CEA will reflect. Is it then simply a mistake to ignore those cost differences in allocating health resources? At least two moral considerations suggest not. First, empirical studies have shown that many people ignore the cost differences because they believe that patients should not be at a disadvantage in priority for treatment simply because their condition happens to be more expensive to treat than are other patients’ conditions (Nord and others 1995). Second, according to many moral theories, individuals should confront other competitors for scarce resources as individuals, and their priority for treatment should be determined by the urgency of their individual claims to treatment (Scanlon 1997).

Then again, most people and most moral theories do not reject all aggregation of different sizes and costs of health benefits in setting priorities and allocation, although there is no consensus either on when aggregation should be permitted or

for what reasons. However, at a minimum, we suggest that individuals should not be denied very great health benefits—in the extreme case, life-saving interventions—merely to provide small health benefits to a large number of other persons.

Fair Chances and Best Outcomes. The thesis that resources should be targeted to interventions in which they will do the most good ascribes a higher priority to those who can be helped more easily or cheaply. This thinking, in turn, implies that some patients will lose out simply because their needs are more difficult or expensive to meet. Consider, for example, a ward with 100 patients, 50 of whom require one pill and 50 of whom require two pills to recover. The patients are otherwise similar. The clinic has 50 pills and must decide how to distribute them. To achieve the best outcome, all 50 pills should be given to the patients who need only one to recover. However, to give each patient an equal chance to recover, entitlement to treatment should be awarded randomly. Seventeen fewer cures would result.

Limited surveys indicate a sharp difference between health professionals and the general public in their responses to this conflict. Most health professionals favor distribution to one-pill patients only, and most members of the general public insist that people should not be penalized for needing two pills (Nord 1999). This division of opinion goes to the heart of CEA, which is precisely a guide to identifying the route to the best outcomes that can be hoped for with existing resources. It also creates a dilemma for those health professionals who maintain that health policy should be based on values most frequently endorsed by the population affected.

The conflict between fair chances and best outcomes arises not only from differences in the costs of treating otherwise similar groups of patients, but also when one group of patients will receive somewhat greater benefits than another at the same cost. The appeal of a fair-chances solution is greater when the difference in cost-effectiveness between the two programs is relatively small compared with the potential gain or loss to individual patients. Suppose that health program A will produce 5,000 QALYs while program B will produce 4,500 QALYs and that the effect on the health or life of each patient served is large—in the extreme, life saving. Patients who would be served by program B could complain that it is not fair that all the resources go to program A and none to B when they have nearly as pressing health needs and would be benefited by treatment nearly as much as the patients served by program A. If all cannot be treated, they might go on to argue, they deserve a fair chance to have their needs met rather than having no chance for treatment only because treating them would produce slightly less benefit than treating the patients served by program A. The small difference in benefits produced for the two groups—for example, a slightly greater life expectancy or more serious disability averted in program A—they argue, is too small to justify the tremendous difference in how the two

groups are treated. In the extreme case, some live and others die. The better outcome is produced by funding program A rather than program B, but that additional good is insufficient to justify morally the huge difference in the way the two groups of patients are treated. The conflict between fair chances and best outcomes can arise in a variety of contexts (Kamm 1993).

Preferring the most cost-effective program can also seem unfair because it compounds existing unfair inequalities. For example, screening slum-dwelling black men for hypertension targets the group with the highest incidence and greatest risk of premature death. However, it is more cost-effective to target well-to-do suburban white men, because they have more ordered lives, comply better, have personal doctors and the means to obtain medical services, are more educated, and are more likely to modify their lifestyles wisely. However, if the poor black men are not screened for this reason, it only compounds their existing unjust deprivation and, of course, is also in conflict with giving priority to the worst off.

If those who need a less cost-effective program deserve a fair chance to have their needs met, what would be a fair chance? Some argue that a fair chance is an equal chance, so some random method of selecting which program to fund should be used (Broome 1991). Others suggest proportional chances or a weighted lottery, in which the chance of each program being selected is proportional to the amount of health benefit each would produce, as a way of balancing fair chances against best outcomes (Brock 1988). Alternatively, some resources might go to each program (which is usually possible at the macro level), thereby benefiting some patients in each group—at least if their relative benefits are not strikingly dissimilar—instead of all going to the most cost-effective programs.

Another consideration supports spreading some resources to less cost-effective programs instead of devoting them all to the most cost-effective: to give all—or at least more—patients a reason to hope that their health needs will be met. This consideration may be especially important in developing countries where resource scarcity is more severe and adhering strictly to cost-effectiveness criteria could result in large numbers of patients with serious—or even life-threatening—health needs having no hope that their needs will be met.

Discrimination against Persons with Disabilities. The use of CEA in resource allocation to maximize the QALYs produced by available resources will often discriminate against persons with disabilities. Many persons with disabilities such as cystic fibrosis, HIV/AIDS, and chronic pulmonary or heart disease have reduced life expectancies or health-related quality of life as a result of their disabilities. Life-extending health care for those people will produce fewer QALYs than for people without them, all else being equal.

When health interventions are aimed at improving quality of life rather than extending life, similar discrimination can

arise. The presence of disabilities can act as comorbidities, making treatment less effective or more expensive (or both) than it would otherwise be, thereby worsening its cost-effectiveness ratio relative to comparable treatment for persons without disabilities. These effects of treatment can result from a disability that exists before treatment and is unrelated to the treatment provided. So it seems that a cost-effectiveness standard for resource allocation discriminates against such persons specifically because of their disabilities. Moreover, this effect will arise not only in the case of preexisting disabilities, but also in the case of patients who become disabled as a result of treatment that is only partially effective.

Several strategies to avoid this discrimination in resource allocation have been suggested. Perhaps the most plausible, at least for the case of life-sustaining treatment, is to ignore differences in patients' posttreatment quality of life as long as each patient accepts and values that quality of life and to ignore differences in life expectancy after treatment as long as each will receive a significant gain in life extension; obviously, what counts as significant is vague and needs finer definition. Ignoring differences in life expectancy posttreatment fits with empirical evidence that individuals give little weight to duration of benefits in prioritizing between health interventions that serve different individuals.

Cutoffs for Cost per Quality-Adjusted Life Year. It is not uncommon in health care allocation to suggest the use of cutoffs tied to cost per QALY, although the cutoffs suggested vary substantially depending on the overall wealth of the country and on the amount that it spends on health care. The cutoffs can be of some value in identifying health interventions that are either good or poor buys, given the society's overall wealth and overall level of health spending. However, it is important to be clear that such cutoffs should never function as anything more than a rough initial guide in health resource allocation. The various equity considerations discussed briefly above can serve as justification for departing from or violating any cutoffs related to cost per QALY.

Responsibility for Health Needs. Some have suggested that health needs for which individuals are morally responsible should have lower priority than health needs for which individuals are not responsible (Moss and Siegler 1991). If individuals are responsible for their health needs and could have taken steps to avoid them, they have weaker claims on social resources to meet those needs than do individuals whose health needs are no fault of their own and could not have been prevented. Smoking and substance abuse are two of the most prominent examples of behaviors often cited. However, differentiating patients by whether they deserve care on the basis of whether they are responsible for their health needs does not fit

the practice or norms of medicine, which have the goal of meeting patients' medical needs.

There are strong moral reasons for considerable caution in letting health resource allocation depend on individuals' responsibility for their health needs (Wikler 2002). For that practice to be fair to those whose needs receive lower priority because of behavior, (a) the needs must have been caused by the behavior, (b) the behavior must have been voluntary, and (c) the persons must have known that the behavior would cause the health needs and that if they engaged in it their health needs resulting from it would receive lower priority. Smoking shows that these conditions are not easily satisfied. Smoking is one causal factor in much cancer and heart disease, but many smokers do not get those diseases, indicating that other factors, no doubt in part genetic differences for which individuals are not responsible, also play an important causal role. Smoking is typically begun when individuals are young adolescents, and as discussed in chapter 46, it is highly addictive, which undermines the voluntariness of continuing to smoke. Individuals in industrial countries are now generally familiar with the health risks of smoking, but this is less true among less educated populations in developing countries, where smoking is an increasing problem. No one anywhere has been informed before they smoke that, if they do, their health needs from smoking will receive lower priority for treatment than will other health needs.

Thus, it would generally be unfair to give smokers lower priority for treatment of smoking-related diseases on the grounds that they were morally responsible for those health needs, although there may be other behaviors for which individuals could more justifiably be held responsible. Moreover, attempting to make those judgments in individual cases would be extremely difficult and controversial. Given the difficulty of instituting a fair practice that allocates health resources according to people's moral responsibility for their health needs, we generally have good moral reason to preserve the egalitarian feature of the practice of medicine that looks to patients' needs for care rather than to whether they deserve care.

ETHICS IN RESEARCH AND NEW PRODUCT DEVELOPMENT

All new drugs and other medical products must be tested on human subjects before they are sold. Although participation in health research is often a valuable opportunity for participants, what happens to them is determined not only by their clinicians' therapeutic intent (if any) but also by the need to ensure that the research yields useful information. Managing the potential conflict between those motivations is often an ethically challenging task, and the issues become particularly contentious when research is conducted in developing countries.

Developing Consensus on Ethics and Human Subjects Research

The central ethical question in health research that involves human subjects is what may be asked of some individuals so that others may benefit. The question arises in any research in which human subjects are asked to participate, but is most pressing if the care that is offered to subjects provides no therapeutic benefit or if that care is compromised by the requirements of the study design. Informed consent, while in most cases a requirement for ethical justification of research involving risk, does not relieve the scientist of responsibility. The ethical question is what potential subjects may be recruited for, even if they do consent.

A rough consensus exists worldwide on the elements of research ethics and, increasingly, on the central role of the ethical review committee, or institutional review board (IRB). This consensus can be traced back to the post–World War II international determination to ensure that the kind of barbaric research practiced by Nazi scientists would not again stain the good name of medical science.¹ Three advisory documents have been particularly influential. The Nuremberg Tribunal that conducted the postwar Doctors’ Trial promulgated a code of conduct for medical research that stressed the requirement of informed consent. The World Medical Association issued the first version of its Declaration of Helsinki in 1964 and has revised it several times. A further set of guidelines, issued in 1993 and revised a decade later, was published by the Geneva-based Council for International Organizations of Medical Sciences. Although they lack the force of law, these documents are widely acknowledged as international standards. Indeed, the World Medical Association’s periodic revisions of the Declaration of Helsinki have become focal points for international debates over outstanding issues in research ethics.

The most elaborate codification of research ethics is the so-called Common Rule of Conduct of the U.S. Code of Federal Regulations (title 45, section 46), which derived from the work of the National Commission for the Protection of Human Subjects of Biomedical and Behavior Research of the mid 1970s. In addition to proposing rules governing many aspects of research with human subjects, the commission proposed that the IRB be given the central role in research ethics and be responsible for prior review of research proposals.² The IRB was a compromise, granting a measure of self-regulation to scientists and an assurance of ethical conduct to the government and the public for publicly funded investigations.

The basic elements of research ethics engender little disagreement. The research must never be brutal or inhumane, and all unnecessary risks should be eliminated. Any net risks to subjects must be justified by the prospect of potential benefits to others. Prospective participants must be told that they are in a study and must be informed of its nature and its risks and benefits. In the case of research that offers therapeutic benefit,

scientists must explore the range of reasonable therapeutic alternatives with the patient. Potential subjects must understand that their participation is completely voluntary and that they may withdraw at any time and for any reason. Because they cannot voluntarily shoulder risks, further protection must be provided to those who cannot give consent. Such people include, among others, mentally incompetent or immature participants and those involved in research (chiefly in social psychology) that requires initial deception. Consent, however, is not sufficient to ensure fairness; there should be additional safeguards against unfair distribution of the burdens and benefits of research. Finally, all research that involves potential risks should be reviewed by an IRB acting on the basis of internationally recognized ethical principles.

The global acceptance of these principles and the rapid development of capacity for ethical review attest to the perceived validity of this system of rules and procedures of ethical review. However, there has been relatively little research on how IRBs actually perform. Many IRBs in smaller institutions lack the necessary expertise to review novel or complex proposals, and their institutional setting creates a potential conflict of interest. Government investigations of the adequacy of IRBs for the tasks that are now assigned to them have often been critical (for example, Office of the Inspector General 1998, 2000). IRBs are often overworked and understaffed, resulting in ever-lengthening delays between initial submission of protocols and final approval. Regardless of the value of IRBs, predicting what will pass through them and what might provoke delay or rejection has become a significant concern for medical researchers. The system thus has costs as well as benefits, a fact that lends additional gravity to the controversies that it must resolve.

Goals of Ethical Review of Research

Although the overall purpose of ethical review is to ensure that research with human subjects is ethically defensible, the international consensus specifies several distinct goals that are sometimes in tension with each other:

- *Protection.* Ethical review committees can protect subjects by alerting investigators to unforeseen hazards and by suggesting research designs that can avoid unnecessary risk or reduce the number of subjects exposed to risk. By insisting that a clear explanation of risks and benefits be provided to potential participants, ethical review committees also help potential participants to protect themselves. Ethical review committees often take the name “Committee for the Protection of Human Subjects,” reflecting a central preoccupation of research ethics today.
- *Assurance that participation is voluntary.* Some research cannot be conducted without asking some participants to

endure discomfort or pain, to delay relief from symptoms of their disease, or to risk other harm so that future patients may benefit. Permitting investigators to approach potential subjects in these cases requires an ethical judgment. In approving such a proposal, the function of the ethical review committee is not, strictly speaking, only to protect the subjects (the goal of protection would often be served more effectively by declining to do the research), but also to permit them to be enlisted in the effort to improve health care for others. Thus, a second function of ethical review is to ensure that those who agree to participate do so voluntarily and freely and that they understand what is being asked of them.

- *Equality and fairness.* Although research ethics committees have little authority to address persistent social injustices, a third concern of research ethics is that the benefits and burdens of health research be distributed fairly. This function receives relatively little attention in the literature of research ethics, despite its prominence in such well-known documents as the Belmont Report of the National Commission for the Protection of Human Subjects (1979). Many of the most notorious abuses of research subjects, including the Nazi investigations in the concentration camps, the Japanese biowarfare experiments on Chinese and other civilians, and the Tuskegee research on African Americans suffering from syphilis, were committed on subjects chosen exclusively from disadvantaged groups.

Those three goals of ethical review—protecting subjects; ensuring voluntary, informed participation; and reviewing the fairness of recruitment—are promulgated in the international guidelines and in the Common Rule (and in the regulations of other countries), but they do not always point in the same direction. For example, a research project that asks participants to endure a burden or risk—thus failing to offer full protection—can still meet the requirement of equality if the burden is equally shared.

Ethical review, thus, is not a matter of applying a checklist, but it imposes an obligation of substantial ethical judgment. A key challenge for IRBs is to earn and retain the trust of participants and of the public, a task made more difficult by the unavoidable absence of explicit criteria for approval. This problem is exacerbated by the institutional conflict of interest inherent in the placement of the IRB within the research institution, which prompts concern that the committees will downplay risks to subjects for projects that profit or benefit the institution or its influential staff members. Conversely, IRBs that are fearful of institutional embarrassment or legal sanction in the event of any harm befalling research participants might lean too far in the direction of overprotection of subjects, at the expense of important scientific research initiatives. Both concerns have been raised about the IRB system.

Current Controversies in Research Ethics

Some of the most sharply disputed issues have arisen in international collaborative research involving scientists and sponsors from wealthy countries conducting experiments in developing countries. Some of the problems are procedural. For example, U.S. agencies have insisted on the same kind of recordkeeping for IRBs in developing countries that is required of IRBs in U.S. research institutions. IRBs in developing countries may accept the same principles of accountability, but they do not have the elaborate staffs and budgets that leading IRBs rely on.

The most difficult disputes involving the ethics of research in developing countries are, however, substantive rather than procedural.

Standard of Care. The international guidelines used in navigating the ethical dilemmas of research in developing countries were created for the very different purpose of ensuring that what happened at Dachau and Auschwitz would not recur. It is not clear whether those rules usefully resolve the kinds of dilemmas that arise in, say, Uganda or Peru.

The Declaration of Helsinki, following the Nuremberg Tribunal, requires informed consent of all competent research subjects, and in section 29 states that “the benefits, risks, burdens, and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods.”

To its supporters, any departure from the letter of the Declaration of Helsinki that would permit an experiment in a poor country that would be forbidden in a rich one would constitute a double ethical standard. In their view, this clause of the Declaration of Helsinki affirms the equal importance of human lives, regardless of wealth or nationality, and stands as a safeguard against exploitation of those made vulnerable by poverty, sickness, and absence of governmental protection.

Opponents, however, argue that this position seems to rule out the possibility of testing cheap new products that may be effective, although perhaps not as effective as other products that the population could not afford. If so, it would be difficult to understand whom the single-standard-of-care position would be protecting, for surely it is better for a seriously ill person to receive a good drug, even if it is not the best, than to receive no drug at all.³

Both points of view deserve respect. The single-standard approach is consistent with the postwar consensus on principles of research ethics, and it offers a bright line between research that amply respects human subjects and that which might result if sponsors and scientists were tempted to roam the globe in search of human subjects who could be used as experimental material with a minimum of expense or trouble.

Opponents of the universal-standard view, however, challenge its premise. It made sense to insist on a single, universal

standard when the problem was Nazi barbarity, because the prevailing standard was high and the medical criminals in the death camps denied it to the imprisoned minority—people unjustly stripped of their entitlements. In Uganda or Nepal, however, care at the highest world standard is available, if at all, to only a small elite.

A full reconciliation of those points of view may not be possible. The authors suggest that a relativized standard should be considered only when the beneficiaries will include the impoverished, sick population. Even in those cases, however, the local standard of care could be adopted in the experiment only if it met or exceeded the standard provided by other countries at similar levels of development.

Placebo Controls and Other Issues Involving Research Design.

For certain purposes, scientists use a placebo control even though a proven treatment exists. Patients in these control groups thus receive care that is inferior to what they would experience in good clinical care. Until very recently, the Declaration of Helsinki flatly condemned this practice (its current language is somewhat less restrictive), but the U.S. Food and Drug Administration (FDA) accepted results of these trials in applications for approval of new drugs. The FDA's justification for this acceptance rests on two claims, one scientific and one ethical. The first is that in certain contexts (for example, for conditions such as depression, in which eligibility criteria and outcomes are subjective, to an appreciable extent, and in which symptoms fluctuate in both treated and untreated patients), active controls may produce misleading indications of equivalency, yielding seemingly positive results that may be spurious. The second is that when only placebo controls can be informative, it is sometimes justifiable to ask participants to be randomized with placebo and thereby to risk discomfort and distress (but not any appreciable risk of death or long-term impairment).

Debates over placebo controls are often joined in the context of disputes over the appropriate standard of care that arise in the case of research in developing countries, but placebo controls are controversial in trials in high-income countries, too. Placebo controls are one instance of a large category of ethical issues in research that require weighing the importance of a scientifically ideal research design against the well-being of participants. For example, a study of long-term chemotherapy to prevent the recurrence of breast cancer was halted before the designated endpoints had been reached after the study's Data Safety and Monitoring Board decided that continuing the study after a strong trend had been established favoring the chemotherapy would be unfair to the control group. It is notable that in this instance severe criticism of this decision was voiced by an organization representing women at risk for breast cancer, as well as by the editorial board of the *New York Times*. Critics of the early termination of the trial were, in effect, aligning themselves with the interests of future

beneficiaries of the research and possibly against the immediate interests of the women in the control group.

Rights of Host Communities. Ideally, research involving human subjects would be a cooperative endeavor for mutual advantage among free citizens who understand and endorse the need for research and who expect to share both in the burden of serving as research subjects and in the eventual benefit of improved health care. Societies that recruit subjects primarily from lower socioeconomic strata fall short of this ideal; those that do not offer new advances in care to all of their citizens fall even further short, raising serious questions about fairness. Furthest of all from this ideal are some instances of the increasingly common practice of recruiting research subjects among the poorest people in the poorest countries. The means for protecting human subjects in these countries are often nonexistent. Most of their citizens will be unable to afford new drugs developed by firms in industrial countries. It is not clear that these subjects participate voluntarily. Their lack of scientific education or even literacy limits their ability to understand the terms of the proposed agreement with the scientists and sponsors (particularly when consent forms, on legal advice, run to 20 dense pages), and poverty often deprives them of any alternative means of recovering their health.

Despite these potential ethical shortcomings, international collaborative research is assured of continued growth. Some of this research targets diseases affecting mainly poor people, who as a group suffer more from too little research on their populations than from too much. Even research intended to develop therapies that will be affordable only to much wealthier patients can be defended. Individual participants may receive better care than they would otherwise, and visiting scientists offer employment and technical training.

To right the perceived imbalance in what is asked of research subjects in poor countries and the value that is obtained by scientists who experiment on them, some have proposed that sponsors of research in the poorest countries compensate their hosts by offering a supplementary benefit (Glantz and others 1998). One much discussed option is access following the end of the study to any drugs or other therapies whose effectiveness is confirmed in the research. The most limited proposals would restrict this entitlement to individuals who were enrolled in the study (those who received placebo as members of a control group, for instance), and time limits (such as three years) have been proposed in the case of chronic diseases such as HIV/AIDS. More expansive community benefit proposals have called for lifetime access to the treatments by all participants, their families, other members of the local community, or even all citizens of the country. Other proposed benefits include a specified amount of technology transfer, including scientific training and the construction of clinics and laboratories, and cash payments earmarked for health care. A moderate proposal

is to encourage these benefits but to require only that they be discussed and agreed on before investigations are initiated (National Bioethics Advisory Commission 2001).

These proposals are intended to restore fairness to the relationship between participants and those who benefit from research, including scientists and their sponsors and also future beneficiaries of advances in medical science. Among the potential drawbacks are the inability to specify, even roughly, how much is owed to host communities; the inability to determine whether community benefit should be required even of research funded by governments or philanthropists for the benefit of people living in the host communities; and the risk that placing these demands on proposed research projects will drive them away from these very needy sites. Some of these uncertainties may be resolved over time as a variety of approaches are attempted, particularly if they are studied and reported to officials in potential research sites.

These international collaborations would draw less scrutiny if it were clear that all subjects knew what they were getting into and participated of their own free will. Although evidence on this point is mixed, special circumstances in some countries introduce problems that will have to be addressed over the long run. Cultural differences between host populations and scientists may lead to conflicts over who has the authority to speak for the individuals invited to participate in a given study. Regulatory authorities in high-income countries have been reluctant to accept permission by a woman's husband or by a village chief on behalf of his people in lieu of individual consent. It is often unclear—particularly from the vantage point of an IRB in Europe or the United States—whether the cultural norms of the host population designate the husband or village chief as decision makers in these transactions and whether insistence on concurrent individual consent would be viewed as intrusive or insulting.

Another recurring issue is whether people enrolled in a trial of a promising therapy who are ill and very poor can rightly be viewed as volunteers. The prospect of a cure for a person who would otherwise die would seem to be irresistible, even if the treatment is not up to the standards that even less well-to-do citizens of richer countries would expect. Financial incentives, too, would predictably have a powerful effect on an individual who may always be looking for a day's wage to feed hungry children. Some IRBs limit payments to compensation for lost wages and travel expenses, but even at this level researchers are asked to change the amounts offered to avoid forcing a choice on the potential participant. As with alleged cultural differences regarding individual informed consent, IRBs operate with scant evidence on this point. It is difficult from a long distance to decide what amount of compensation undermines freedom of choice. It is also unclear whether the moral categories used in these disputes have been adequately thought through. The fact that a poor person finds an attractive offer irresistible will

be viewed as evidence of coercion by some observers but nothing more than common sense by others.

Most of these controversies can be traced back to underdevelopment and the inequalities of wealth and education that prevail among and within nations today, but progress in resolving the ethical controversies that have become obstacles to badly needed health research must be made even as these disparities persist. Viewing health research in the context of development and emphasizing research that is targeted to the needs of the poor majorities in poor countries can provide a context in which trust rather than fear or suspicion is the default response in host countries. Efforts to build capacity for ethical review within the host countries, such as financial support for ethical review committees, can place the locus of decision making closer to the people who serve as subjects. Research on the effectiveness of current ethical and regulatory requirements and mechanisms might enhance the process of ethical review while reducing its bureaucratic burden. Meanwhile, the quality and appropriateness of ethical review of this research that takes place in the sponsors' countries would be enhanced by eliciting the views of officials in developing countries, clinicians, scientists, and community leaders.

NOTES

1. Because our current system of ethical review and regulation of research with human subjects derives from our resolve to prevent the recurrence of earlier abuses, it deserves mention that the standard historical account of research ethics has been seriously incomplete. While the Allies sat in judgment of the Nazi scientists at Nuremberg, abuses of similar scope and savagery practiced by Japanese biowarfare researchers on Chinese and other civilians and prisoners of war were kept secret (and their perpetrators were unpunished) following a pact with the criminal scientists to exchange data for war crimes immunity. Moreover, the Allied governments did not always honor the Nuremberg principles. In the Soviet Union, scientists attempting to develop for clandestine operations poisons that would not be identified on autopsy practiced their craft, with predictably lethal results, on hapless prisoners (Birstein 2001). Abuses in the United States, such as the Tuskegee syphilis study (Brandt 2000), have been more widely publicized, but ethical lapses in large-scale Cold War-related studies, ranging from radiation studies on urban populations (Advisory Committee on Human Radiation Experiments 1995) to surreptitious administration of mind-altering drugs such as LSD (Rockefeller Commission 1975), were state secrets.

2. In the United States, the Office of Human Research Protections, an agency of the Department of Health and Human Services, has overall responsibility for oversight of IRBs administering research using U.S. government funds. Its Web site is <http://ohrp.osoph.dhhs.gov/>.

3. Supporters of the single-standard view might point out that, in its current version, the Declaration of Helsinki does not require that everyone in an experiment receive the best available care, but rather that new treatments be tested against the best available care. But this defense faces further objections. In some cases, testing against the best available care (rather than against the care currently provided to the population or against placebo) will fail to provide the evidence needed to convince the ministry of health or potential donors that funds should be provided. There is a potential contradiction in any view that claims both that all patients in experiments deserve the best care and that it is ethically acceptable to test a new treatment that is not expected to be quite as good as the best currently available.

Chapter 15

Cost-Effectiveness Analysis for Priority Setting

Philip Musgrove and Julia Fox-Rushby

The economic analyses in this volume focus on activities whose main objective is to improve health. Although the chapters vary considerably, all possess, nonetheless, a common core of definitions, assumptions, and methods of analysis. These are drawn primarily from concepts and applications in the *Oxford Textbook of Public Health* (Jamison 2002), drawing partly on the 1993 *World Development Report* (World Bank 1993). In this chapter, we summarize and explain the common features and some of the variations of economic analysis and point the reader to examples throughout the book.

First is a general discussion of cost-effectiveness analysis (CEA), which is the principal analytic tool used here. Here we explain what such analysis does and does not provide, how it is related to the concept of burden of disease, and how it can be used, along with other criteria, in setting priorities.

Because CEA is applied to specific interventions, the next section describes the several meanings of that term and the way that interventions are classified and evaluated. It is essential to understand what is being analyzed before considering in detail how the analysis is conducted.

Estimating the effectiveness of an intervention requires specifying the units in which that concept is measured. This action in turn requires choices of several parameter values, including, in the analyses reported here, the discount rate applied to future years; the disability weights that describe the severity of diseases and conditions, corresponding to the health losses that they cause; and the life expectancy at different ages, which determines how many years of healthy life can be saved by averting a death or preventing or treating a long-term health problem. We also consider briefly the nonhealth benefits that may result from a health intervention.

The subsequent section deals with the costs of interventions: first with the question of which costs to include in the analysis, and then with the conversion of costs in national currencies to equivalents in U.S. dollars for international comparisons.

Despite the common assumptions and parameter values, the economic analyses differ from chapter to chapter in how comprehensive and how exact they are, including how they deal with a variety of approximations and how the results vary from place to place or according to differences in the assumptions. This section also contains a brief description of the differences in the quality of the basic evidence and in how widely conclusions are applicable.

Estimates of the cost-effectiveness of interventions often describe what happens at the level of the individual patient or beneficiary. In the next section, we suggest two ways to consider costs and outcomes at the population level, allowing for large differences among countries in the size of population; the incidence or prevalence of a disease, condition, or risk factor; and the amount spent or available to spend on an intervention.

In the final section, we indicate how the type of analysis presented in this volume might be improved and how it can be applied to help set priorities among the large number of interventions to which limited resources can be applied.

COST-EFFECTIVENESS AND PRIORITY SETTING

The principal analytic tool throughout this volume is CEA, which compares the cost of an activity, called an *intervention*, with the known or expected health gain. The result is summarized in a cost-effectiveness ratio (CER), as explained more fully below. This ratio corresponds to the concept of

(health) value for money. Favoring activities that are more cost-effective over those that are less so is consistent with the ethical view that “limited resources for health should be allocated to maximize the health benefits for the population served” (chapter 14).

Cost-effectiveness provides the clearest simple way to promote value for money in health: hence, the emphasis on it here. CEA allows comparisons throughout the health sector and not only for the same health outcome. It does not allow comparison to nonhealth outcomes unless these outcomes can be incorporated into costs, and the calculation of the CER by itself makes no pretense of monetizing the intrinsic value of health. To use CERs for choosing what to buy and what not to, decision makers must determine a maximum willingness to pay for units of health gain, unless other criteria are considered to justify buying something with relatively poor cost-effectiveness.

For risk factors, CEA requires estimating the gain in health consequent on introducing an intervention to reduce the risk of acquiring or transmitting a condition. For packages of interventions or elements of the health system, such as hospitals, effectiveness is estimated by judging how much mortality and morbidity would be reduced by providing the whole package or set of services or by operating the facility. With some exceptions, the analyses may describe but do not quantify the non-health benefits of an intervention. Apart from the difficulty of obtaining enough data, such quantification requires attaching values to nonhealth outcomes, which is problematic when comparisons are made over large cultural and income differences.

All comparisons are relative, with no absolute distinction between being and not being cost-effective. In assigning priorities among interventions for public funding or for other policy actions, one must also consider the magnitude of health problems to which interventions apply because that affects what is affordable. Calculations of the effect of spending US\$1 million or the total cost and health gain in a population of 1 million people offer ways of looking at such choices. Equity, poverty, and risk of impoverishment from ill health may also influence priorities; so do the budgets available—and the decisions of how much to make available—for buying interventions. Finally, the effectiveness of an intervention and, therefore, the degree to which it deserves priority depend on how far it is culturally appropriate or acceptable for the population it is intended to benefit. The identical intervention, technically speaking, may lead to different degrees of use or compliance in different population groups, and information and incentives may be needed to achieve the full potential outcomes.

Cost-effectiveness is only one of at least nine criteria relevant for priority setting in health if the object is to decide how to spend public funds (Musgrove 1999). Cost matters by itself, as do the capacities of potential beneficiaries to pay for an intervention. The other criteria that may affect priorities include horizontal equity (equal treatment for people in equal

circumstances); vertical equity (priority for people with worse problems); adequacy of demand; and public attitudes and wants. Two criteria—whether an intervention is a public good and whether it yields substantial externalities—are classic justifications for public intervention, because private markets could not supply them efficiently, just as in other sectors. As noted in chapter 1, the interventions analyzed in this volume are not limited to public or semipublic goods. The emphasis is on value for money—that is, whether an intervention is worth buying, not who pays for it. Nonetheless, when one is choosing which public goods to buy, several criteria become irrelevant, and cost-effectiveness can be used as the chief or even the only consideration. Cost-effectiveness can similarly determine what to include in a mandatory universal public package of health care alongside competitive voluntary insurance (Smith 2005).

Cost-effectiveness can conflict with both kinds of equity—that is, the more cost-effective of two interventions may also lead to a less equitable distribution of health benefits. Equity and cost-effectiveness are compatible when a cost-effective intervention is provided to only part of the population that would benefit from it because everyone in the group suffers from the same problem. Then expanding coverage will generally also promote horizontal equity. These equity effects are reinforced when those who are better off already benefit while the poorer and sicker population does not. Choices about vertical equity—doing more for those in greatest need—are more complicated. Doing very little for people with severe health problems—because the available interventions for those problems are not very effective at reducing their suffering—is not necessarily preferable to doing more for people with less severe problems that are more amenable to intervention. When an intervention is reaching only part of a potential beneficiary population and those not benefiting tend to have more severe illness, then expanding coverage can improve both horizontal and vertical equity. Where possible, chapters consider the equity effects of expanding or changing interventions.

Cost-Effectiveness and Disease Burden

Cost-effectiveness and disease burden are related because effectiveness is the reduction in burden caused by an intervention. This relationship holds true at the individual level. The magnitude of a health problem—the total burden in the population—is irrelevant for marginal changes in resource allocation. However, it matters for large changes from the status quo. Health interventions demand managerial capacity as well as financial and physical resources, and managerial ability may be stretched thin if it has to deal with a large number of interventions. In consequence, it may be efficient to concentrate on relatively few and somewhat less cost-effective interventions, provided they attack substantial burdens, rather than many other interventions that are more cost-effective but affect only small burdens. Moreover, even for a cost-effective

intervention, high prevalence or incidence may make the cost of covering the whole potential beneficiary population prohibitive. The authors of chapter 21 indicate how expensive it would be to protect all at-risk African children from malaria with bednets, even though bednets are highly cost-effective. Conversely, an intervention that costs more per health gain may be affordable and given priority if it treats a manageable burden of disease and corresponds to a small beneficiary group. Priority turns on the available budget relative to the cost of a program; on how divisible a program is (that is, how easily it can be operated at different scales, as a technical or political matter); and on whether interventions are mutually exclusive (Karlsson and Johannesson 1996).

Because of the interaction between cost-effectiveness, disease burden, and available funds, no single threshold of maximum cost per health gain exists below which an intervention is “cost-effective.” A rule of thumb, such as that any intervention is worthwhile if it costs less than two or three times income per capita, ignores this interaction and is an inadequate guide to priority setting. However, even an intervention that is considered justified by cost-effectiveness may be infeasible to deliver, for example, if the costs are monetary and come from the public budget but the benefits are nonmonetary and diffused over the population. Economic theory would suggest removing the current budget constraint by raising more revenue until the marginal social cost of the interventions plus the cost of obtaining the revenue equals the marginal social benefit. Although theoretically attractive, this escape from resource limitation may not be possible because of political reasons or because the economic cost of raising extra taxes is prohibitive.

Because so many criteria can affect priority setting and because evidence on cost-effectiveness in low- and middle-income countries is so scarce, health system policies and budgets seldom derive purely from considerations of cost versus outcomes. Even in high-income countries, where more such analyses are available, their effect has been limited, although it is growing (Gabbay and le May 2004; Glick, Polsky, and Schulman 2001; Hoffmann and others 2002; McDaid, Cookson, and ASTEC Group 2003; Sheldon and others 2004; Taylor and NICE 2002). Cost-effectiveness studies are now required by, for example, the U.S. Food and Drug Administration for labeling claims, the National Institute for Clinical Excellence before advising national policy on treatments and care in England, and the Ministry of Health in the Netherlands for new drugs (iMTA 2005).

DEFINITION AND CHARACTERISTICS OF INTERVENTIONS

The object of a CEA—the thing to which it is applied, the costs and outcomes of which are to be analyzed—is an intervention. An *intervention* is an activity using human, physical, and finan-

cial resources in a deliberate attempt to improve health by reducing the risk, duration, or severity of a health problem (Jamison 2002, table 2). The term usually refers to an activity undertaken by a health system rather than by an individual. The emphasis on a deliberate, systemic effort means that an intervention is not simply anything that improves health; for example, if more rainfall leads to higher crop yields and better nutritional status, the rain does not count as an intervention. Similarly, although breastfeeding protects infants’ health, it is not itself an intervention as the word is used in this volume. In contrast, a program to encourage new mothers to breastfeed is an intervention (as described in chapter 27). How effective such a program is, of course, depends on how many mothers it persuades to adopt the practice when they are neither currently breastfeeding nor planning to do so.

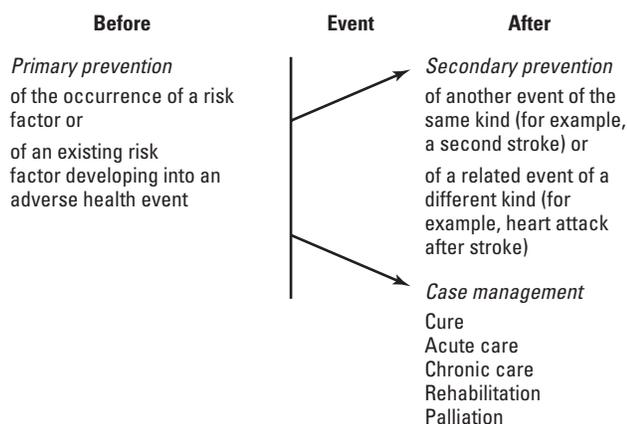

Interventions can be directed against an injury or disease (such as trachoma), a condition associated with or deriving from a disease (such as blindness), or a risk factor that makes the disease or condition more likely (such as the lack of hygiene that leads to trachoma). An intervention may pursue primary prevention at the population level—promoting personal behavior change, controlling environmental hazards, or delivering a medical intervention such as immunization to a large population—or individual action for primary prevention, cure, acute management, chronic management, secondary prevention, rehabilitation, or palliation. Box 15.1 defines these terms, and the figure in the box illustrates how interventions may prevent ill health events or deal with their consequences. Characterizing an intervention fully also means distinguishing the level at which it is delivered (home, primary care facility, district hospital, or referral hospital); indicating whether it involves drugs, immune enhancement, surgery, or physical or psychological therapy; and determining whether it requires a physician or uses diagnostic, laboratory, or imaging procedures. Such procedures are most often evaluated relative to the interventions they screen for or lead to, because they produce no health gain by themselves (although the information they provide can be valuable for reassurance or for promoting behavioral changes).

An intervention in the everyday sense includes such activities as immunizing a child, performing a surgical procedure, or treating an infection with antibiotics. The authors of some chapters use the term only in this sense—for example, in discussing interventions that contribute to meeting the Millennium Development Goals (chapter 9). Authors of other chapters use the term in several other senses as well. It can mean modifying an existing intervention—for example, adding *Haemophilus influenzae* type B (Hib) antigen to the Expanded Program on Immunizations (EPI). Immunization against Hib is itself an intervention, but instead of analyzing it separately, one can use CEA to evaluate the additional cost of incorporating that antigen and the additional health gain that

Box 15.1

Intervention Categories, with Examples

The following figure illustrates how interventions are related to a health event; the definitions of these categories are given below.

Interventions Related to the Occurrence of an Adverse Health Event

Population-based interventions all aim at primary prevention (as defined later), are directed to entire populations or large subgroups, and fall into three categories:

- Promoting personal behavior change (diet, exercise, smoking, sexual activity)
- Control of environmental hazards (air and water pollution, disease vectors)
- Medical interventions (immunization, mass chemoprophylaxis, large-scale screening, referral).

Personal interventions are directed to individuals and can be intended for the following:

Source: Authors.

- Primary prevention—to reduce the level of one or more risk factors, to reduce the probability of initial occurrence of disease (medication for hypertension to prevent stroke or heart attack), or to reduce the likelihood of disease when the risk factor is already present (prophylaxis for sickle cell anemia).
- Secondary prevention following the occurrence of disease—either to prevent another event of the same kind or to reduce the risk of a different but related event (medication to reduce the likelihood of a second coronary event or a first heart attack after stroke).
- Cure—to remove the cause of a condition and restore function to the status quo ante (surgery for appendicitis)
- Acute management—short-term activity to decrease the severity of acute events or the level of established risk factors, to minimize their long-term impacts (thrombolytic medication following heart attack, angioplasty to reduce stenosis in coronary arteries).
- Chronic management—continued activity to decrease the severity of chronic conditions or prevent deterioration (medication for unipolar depression, insulin for diabetes). Chronic management can include some secondary prevention.
- Rehabilitation—full or partial restoration of physical, psychological, or social function that has been damaged by a previous disease or condition (therapy following musculoskeletal injury, counseling for psychological problems).
- Palliation—to reduce pain and suffering from a condition for which no cure or rehabilitation is currently available (analgesics for headache, opiates for terminal cancer).

is expected to result (see chapter 20). The intervention studied is then not Hib immunization as such but the change in the full vaccination procedure. A change in the scale of an existing activity can also be considered an intervention, even if the activity itself is unchanged: that is, one can analyze the change in costs and in outcomes associated with expanding or contracting the coverage of the activity—for example, extending antiretroviral treatment for HIV and AIDS to a larger population (chapter 18) or screening more newborns for sickle cell anemia (chapter 34). In most chapters, the authors assume that expansion affects costs and outcomes linearly, so that the CER does not change. The chapters on vaccine-preventable diseases

(chapter 20) and malaria (chapter 21) provide explicit estimates of the differential costs of expanding coverage.

Adding one intervention to another to deal with the same disease or condition is also an intervention, and combinations of interventions can be analyzed to determine which is most cost-effective or how the cost-effectiveness of one intervention depends on the other activities with which it is combined. Examples include successively adding drugs for treatment of epilepsy (chapter 32) or secondary prevention of cardiovascular disease (chapter 33) or combining several quite different interventions to control tobacco addiction or alcohol (chapters 46 and 47, respectively). The analyses of community health and

nutrition programs (chapter 56) and integrated management of infant and childhood illness (IMCI; chapter 63) define “the intervention” as a whole program incorporating several different activities. Generally, even less empirical evidence exists concerning combinations of interventions than for individual activities, but IMCI is an exception; it has been evaluated more thoroughly than most single interventions.

Box 15.2 includes a more detailed discussion, using a hypothetical example of three different ways to deliver immunization, of how CEA can be applied to four of the meanings of *intervention* used here: an existing intervention at its current coverage, changes in the scale of that intervention, the addition of one intervention to another when expanding coverage, and the complete shift from one intervention to a different (and more cost-effective) one.

Depending on the comparison undertaken, the result may be an average cost-effectiveness ratio (ACER) or an incremental cost-effectiveness ratio (ICER). The former compares total costs and total results, starting from zero, whereas the latter compares additional costs and additional results, starting from the current or some other level of coverage of an intervention.

Either shifting completely from one intervention to another or partially replacing one with another may reduce costs while producing more health gain. For example, if spending is high on hospitalization for acute myocardial infarction, a program using a “polypill” (several medications in a single pill) would reduce expenditures by lowering incidence (chapter 33) and would be cost saving, because less hospitalization would be needed. If the status quo is no hospitalization (as is typical at low incomes), a polypill program increases costs but may more than correspondingly increase health gains and therefore be more cost-effective. If the polypill both reduces costs and improves outcomes compared with hospitalization, it is said to dominate a hospital-only strategy. The second figure in box 15.2 illustrates the concept of dominance; table 45.4 and box 45.1 of chapter 45 provide examples of interventions that are dominated by others.

Unfortunately, reliable information on current intervention coverage, costs, and results is not always available even in high-income countries (iMTA 2005) and is extremely scarce in low- and middle-income countries. Studies showing whether an intervention is effective or cost-effective seldom cover the entire potential beneficiary population, and service provision in the private sector is often not recorded. Many chapter authors describe only the ACER of an existing or potential intervention, whereas others explicitly compare alternatives to current practice (for an example, see chapter 16).

Many of the activities analyzed here aim at promoting changes in personal behavior, by informing and persuading individuals to eat differently, to avoid smoking and excessive alcohol, to reduce the risks of sexually transmitted infections, or to practice better hygiene. Such efforts can be considered

interventions in themselves, and as such are crucial for controlling HIV and AIDS (chapter 18), promoting better infant and child care (chapters 20 and 27), preventing inherited disorders (chapter 34), encouraging healthful diets and exercise (chapters 44 and 45), and avoiding addiction (chapters 46–48). But they can also be used to improve the effectiveness of other interventions by increasing awareness and demand, combating mistaken beliefs about diseases and risks, or reducing anxiety and stigma. In that sense, information, education, and communication delivered to consumers or providers or both are examples of policy instruments. They can facilitate or promote the use of such interventions as condom distribution, screening for diseases or congenital disorders, prenatal care, or immunization.

Other activities that can be classified either as interventions or as policy instruments include the following:

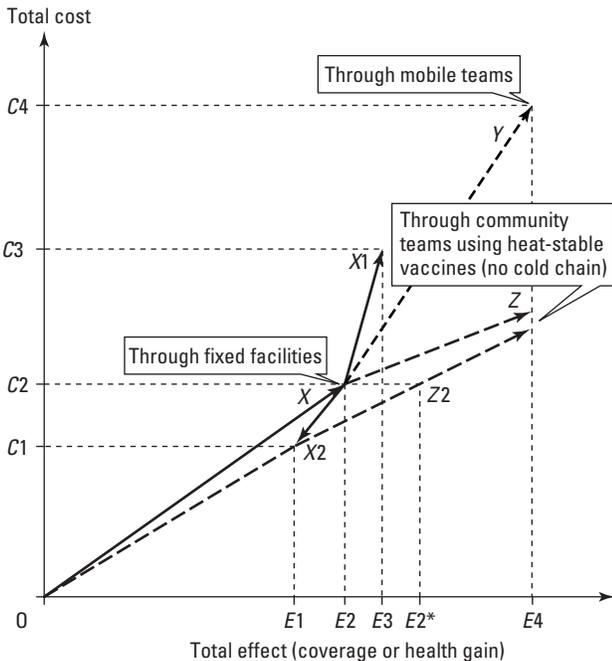

- *Measures to increase the quality of care*, such as some kinds of staff training or the introduction of better recordkeeping. These activities may simultaneously affect a large number of specific interventions in a health facility (chapter 70).
- *Legislation and regulation* to impose an intervention (for example, limiting the salt content of foods, chapter 45, or requiring that salt be iodized, chapter 28); to limit or prohibit an intervention that is ineffective or dangerous or to reduce unhealthful behavior such as smoking and excessive drinking (chapters 46–47); or to codify how an intervention should be delivered and determine who may provide it, as by licensing doctors, nurses, and health facilities (chapter 71).
- *Economic incentives*, which can take the form of subsidies or taxes (chapter 11) for particular items of consumption other than health goods or services, such as tobacco and alcohol (chapters 46–47) or condoms to reduce HIV transmission (chapter 18), or can be provided through protection of property rights, as for patented drugs (chapter 72).

These activities of informing, mandating, legislating, regulating, and taxing or subsidizing, which are at one remove or more from medical interventions, are also often called functions of the health system (WHO 2000, chapter 2; see also chapter 9 in this volume). Several of these instruments may be used together, such as increased taxes on tobacco or alcohol along with measures to educate consumers and to restrict the times, places, or quantities of consumption. Sometimes the instrument is needed before introducing or expanding an intervention to overcome barriers to its use or to make it cost-effective enough to be worth pursuing. Educating the affected population, for example, is crucial to screening and treatment of cancers and hemoglobin disorders. The need for a particular instrument may vary from country to country even if the

Box 15.2

Average and Incremental Cost-Effectiveness and Intervention Choices

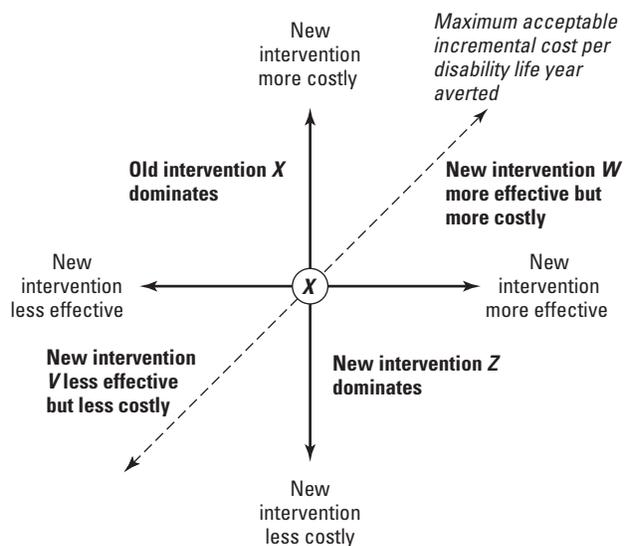

In the figure below, which compares three ways of delivering immunization, point *X* describes the status quo of a current intervention, delivering immunization by means of fixed facilities. At point *X*, the intervention achieves a total effect *E2* (measured as coverage or as disease reduction) at a total cost *C2*. The ratio *C2* to *E2* is the average cost-effectiveness ratio (ACER), shown by the slope of the line *O–X*. Beyond point *X*, expanding coverage becomes very costly, perhaps because the population not yet immunized is dispersed and hard to reach. (Chapter 20 includes estimates of how costs increase as immunization coverage expands but without introducing a sharp increase in costs.) Expansion to point *X1*, which increases the cost from *C2* to *C3*, yields only a small increment *E3–E2* in effect. The slope of the line *X–X1* represents the incremental cost-effectiveness ratio (ICER) of that expansion, which would raise the ACER to line *O–X1*. The line *X–X2* shows the alternative of reducing coverage, which would improve the average cost-effectiveness (to *C1/E1*) because marginal costs are rising steeply near point *X*. The ICER of the reduction in coverage is the ratio of *C2–C1* to *E2–E1*.

Average and Incremental Cost-Effectiveness and Intervention Choices: Comparison of Three Ways to Deliver Immunization

Raising immunization coverage at an affordable cost may require adopting the alternative of mobile vaccination teams, intervention *Y*. The hypothetical combination of fixed facilities and such teams allows increasing the effect to *E4* (complete or nearly complete immunization) at a total cost of *C4*. The ICER of the mobile teams is shown by the slope of the line *X–Y* and the resulting overall or combined ACER by the slope *O–Y*. Adopting intervention *Y* would be clearly preferable to trying to expand coverage through intervention *X* by building and staffing more fixed facilities.

An alternative even better than *Y* might subsequently be developed, represented by point *Z*—for example, community-based immunization teams that could operate either near or far from fixed facilities because they use heat-stable vaccines that do not require a cold chain. The ICER of turning to that choice, represented by the line *X–Z*, is not only more favorable than intervention *Y*, but it is even better than the current ACER, and preferable to intervention *X* at any coverage level beyond *X2*. The cost-effective choice, therefore, is not to retain intervention *X* at its current level and add *Z* beyond that point but to switch entirely from *X* (or from *X* plus *Y*, if *Y* has already been adopted) to *Z*. Because it costs less but provides a better outcome, *Z* is said to *dominate* both *X* and *Y*. The following figure illustrates dominance of one intervention by another, as well as cases in which neither of two interventions is dominant.

Comparison of Cost and of Effectiveness between Interventions: Conditions for Dominance

If intervention Z is divisible (meaning that it can be operated at any desired scale, such as $Z/2$), then it is preferable to X at a cost of $C/2$ because of the additional effect $E/2 - E_0$. It can be extended all the way to E , just as with intervention Y , provided only that the ICER represented by the slope $X-Z$ is still acceptable to decision makers choosing how far to expand the intervention. That is, the cost must still appear to be justified by the increased coverage. Under either of these conditions, an obstacle to switching, or to doing so quickly, would exist only if substantial fixed costs accompanied the transition from one intervention to the other, such as recruiting or retraining staff, building health posts in communities, or setting up the system for distributing the new heat-stable vaccines.

Compared with intervention X , intervention Z is better in both dimensions (lower cost and greater effectiveness), so it is to be preferred, and is said to dominate X . However, intervention X would dominate any other treatment that is both more costly and less effective and, therefore, falls in

Source: Authors.

the upper left quadrant. An intervention such as V or W may or may not be considered preferable to X (V is cheaper but also less effective, and W is more effective but also more costly). Whether either such intervention would be selected over X depends on the relation of the increased (or decreased) cost to the increased (or decreased) effectiveness. That ratio corresponds to an ICER. If a maximum acceptable, or threshold, value for the ICER is determined, as shown by the dashed diagonal line, then any intervention that falls below the dashed line would be acceptable (preferable to X), and those that fall above the dashed line would not be. Uncertainty about the estimates of cost and effectiveness means that, instead of a sharp line as in the figure, the division of preferable from nonpreferable interventions corresponds to a zone of some width that depends on the confidence intervals around the estimates. This kind of comparison can start from an existing intervention such as X in the first figure or, when there is currently no intervention, from point O in the first figure.

intervention that it facilitates is identical, because the legal, regulatory, or financial environment differs.

ESTIMATING EFFECTIVENESS IN HEALTH

Using cost-effectiveness for resource allocation requires health effects to be represented in common units in order to facilitate comparison across interventions, diseases, or conditions. All analyses start with some natural unit: cases of disease or injury, deaths, or numbers of people who quit smoking or adopt some other health-improving behavior. All interventions that avert death are alike in that regard. Preventing a child's death at a particular age, independent of the cause, means that the averted death alone is an adequate measure of outcome. However, when lives are saved at different ages—averting death from malaria at age 2 versus death from beta thalassemia at age 10–15—the outcome is no longer identical, and some measure must account for the difference in years of life saved. These cases provide another natural unit, subject to estimating how much longer a person spared death might live. The choice of life expectancy to assume for such calculations is discussed later.

The unit of time becomes a less natural and more synthetic measure if the future is discounted, as in all these analyses. *Discounting* means reducing the value of each variable in each future year by an amount that increases the further in the future that year is. The discounting procedure reflects inherent

uncertainty about the future and preferences for timing of consumption, and it avoids two problems. First, outcomes that potentially generate benefits forever, such as smallpox eradication, appear to have infinite benefits if the future is not discounted and therefore seem to justify any finite cost at all. Second, it makes little sense to postpone interventions forever simply because funds to finance them could be invested today and be worth more tomorrow. Even discounting the future at the low rate of 3 percent annually has a substantial effect—that is, dividing the values for future years by successive powers of 1.03. That means dividing values for year 1 by 1.03; those for year 2 by 1.03 squared, or 1.0609; and so on. At that rate, averting an infant death saves not all the 80 calendar years of life expectancy at birth (or fewer in low-income countries) but at most 30 discounted years.

For interventions that avert mortality, analysis starts by estimating the deaths prevented, uses age at death to yield numbers of life years saved, and then discounts those years as described above. When interventions improve health by averting or reducing nonfatal disability, different disabilities must be compared in severity. As with mortality, age at the time of intervention matters for long-lasting conditions, and so does discounting. In contrast, age is irrelevant for episodes of illness or injury that are self-limited or quickly resolved by intervention, because the duration of ill health does not depend on age, and all ages are treated alike in this analysis. Discounting also makes little difference over short intervals.

Unit of Measurement of Health

The common unit of health loss or gain used here takes into account duration and severity, as well as discounting the future. The disability-adjusted life year (DALY) is a unit introduced by the World Health Organization (WHO) and the World Bank (Jamison and others 1993; Murray 1996; World Bank 1993). As previously discussed, the DALY incorporates assumptions and measurements about severity of nonfatal conditions, age at incidence or intervention, duration with and without intervention, and remaining life expectancy at that age. For interventions directed to risk factors rather than diseases, the analysis incorporates estimates of reductions in diseases that result from changes in the level of risks. Smoking cessation, for example, reduces deaths from both cardiovascular disease and cancer (chapter 46).

Published analyses, particularly in high-income countries, often use not DALYs but quality-adjusted life years (QALYs), an alternative measure of how much a year of life is worth if a person suffers one or more limitations of various kinds and degrees. QALYs can be estimated directly using a valuation method such as the *time tradeoff* (comparing and varying the time spent in one health state with time spent in another state until the quality of life is judged the same in both). Alternatively, a prescored questionnaire such as the EQ5D (a European quality of life measure) could be used. The EQ5D distinguishes three grades—no problem, an extreme problem, and total disability—on each of five dimensions of life quality—mobility, self-care, performance of usual activities, pain or discomfort, and anxiety or depression (Brooks, Rabin, and de Charro 2003). Discounting of QALYs occurs as an additional step, although some concern exists that discounting values derived from the time tradeoff approach is double discounting (Dolan and Jones-Lee 1997).

QALYs allow comparison among interventions and can easily account for comorbidity. Although the concept of DALYs averted by an intervention is similar to that of QALYs gained, no systematic formula exists for converting between DALYs and QALYs except in broad approximations (Fox-Rushby 2002). This gap is partly because DALY disability weights are specific to diseases whereas the QALY system of evaluation is not (it is based on overall health status). Authors sometimes report effectiveness results in QALYs, because they cite studies in high-income countries that often use QALYs. When some interventions are evaluated in DALYs and others in QALYs, ranking interventions according to cost-effectiveness may still be possible (see chapter 29 for examples of the use of both units).

Priority setters sometimes stop exercises in priority setting after concluding that something is or is not cost saving, without asking whether an intervention yielding a different outcome (against a different disease, for example) would be still more cost-effective. In this volume, the intent is to estimate both

costs and effects, permitting all such comparisons. Knowing that one intervention achieves the same results as another at lower cost, which would be relevant if they were the only two possible interventions against a common problem, is not enough. Comparing both with another intervention with different effects may also be necessary. For example, a coronary artery bypass graft for myocardial infarction costs, on average across regions, US\$37,000 per DALY gained, compared with an average of only US\$409 for the polypill discussed earlier. However, both are much more expensive than saving life years for a middle-aged person by treating active tuberculosis (and thereby preventing transmission), an intervention that costs only US\$15 per DALY in the absence of HIV infection, or US\$102 on average where coinfection makes treatment more difficult. (In only a few cases do chapters deal explicitly with comorbidity, in part because the DALY approach considers conditions only individually.)

Parameter values for effectiveness are required in order to conduct CEA: how to value disability, compared with mortality; how to treat the future; and whether to distinguish people according to age, sex, or other characteristics. Because effectiveness is related to reduction in disease burden, nearly all these parameter choices coincide with those adopted to estimate the existing burden (see Mathers and others 2005 for a full explanation).

Because disease burden estimates discount the future at 3 percent annually, CEA in this volume does the same, for both effects and costs. This method follows the recommendations of the U.S. Public Health Service Panel on Cost-Effectiveness in Health and Medicine (Gold and others 1996) and appears appropriate whenever the benefits of an intervention begin immediately. Constant discounting (using the same percentage rate each year) undervalues interventions for which the benefits appear long after the costs have been paid. Immunization against hepatitis B can prevent liver cancer decades later (chapter 20) but, compared with the costs incurred at the moment of vaccination, appears less cost-effective if the health gain is heavily discounted during that interval. Slow discounting, with the rate falling close to zero for the more distant future, would yield a higher present value of benefits (Jamison and Jamison 2003), but given the absence of consensus on the correct form, the analyses here use constant discounting.

The limitations from a disease or condition in the absence of intervention are measured by disability weights (Mathers and others 2005), despite some controversy as to whether they adequately capture all the disability (see chapter 24 on helminthic infections). These weights range from zero for perfect health to 1.0 for death. Authors have made their own estimates whenever WHO did not provide any disability weight because the corresponding condition was not explicitly included in the burden of disease. For example, weights for anemia caused by hemoglobin disorders (chapter 34) were taken from other

causes of anemia. Note that years lost to early death also are DALYs, since they include the disability weight of 1.0.

When an intervention prevents or completely cures a condition, the postintervention disability is zero. For partially successful interventions leaving residual disability, the disability weight is reduced but not eliminated. WHO has sometimes estimated weights for “treated” as opposed to “untreated” conditions (Murray and Lopez 1996, annex table 3) without specifying the intervention. This distinction is introduced for some consequences of chronic conditions: cancers not yet in the terminal stage, diabetic conditions, major psychological disorders, cataracts, various cardiovascular conditions, chronic respiratory conditions, ulcers, arthritis, cleft lip and palate, edentulism (total loss of teeth), and some burns. Chapters 31 and 33 use these values to describe intervention outcomes.

WHO burden-of-disease estimates used in the first edition of *Disease Control Priorities in Developing Countries* (Jamison and others 1993) incorporated age weights—that is, numbers attempting to describe the relative value of life at different ages. These numbers were calculated to keep the discounted integral from age 0 to 80 the same, as if no age distinction were made. The weights are zero at birth, ignoring health losses from still-birth prior to live birth; reach a maximum at age 25; and decline almost to zero at advanced age. They are a particularly controversial element in the burden estimates (Musgrove 2000) because they value some years of life more than others, and little evidence suggests what an appropriate weight should be. In consequence, only constant age weighting (treating all years alike) is used in these analyses. Removing age weights makes no difference to an intervention that averts an infant death, but it changes the relative importance of interventions at later ages. Because life is more highly valued at advanced ages, death and disability after age 38 become more important compared with events before that age, and interventions later in life become more cost-effective. Some estimates used here therefore differ from those published previously by WHO even when all the other parameters are unchanged.

The only parameters for CEA that differ from those in the burden of disease concern life expectancy. In estimating burden, people at any age and in all regions are assumed, on the ethical criterion of valuing all lives equally, to have the same life expectancy. The only exception is that at birth males appear to have a biologically determined (not behavior-related) life expectancy of 80 years, which is shorter than the life expectancy of females by 2.5 years. However, applying these expectancies to CEA will overstate the effects of interventions when life expectancy in a population is low. Averting a death at age 5 in Sub-Saharan Africa or South Asia does not confer a high probability of living to age 80 or longer. Competing causes of death reduce the effectiveness of any single intervention, unless it affects so large a population that it actually increases life expectancy. An intervention that completely interrupted the

transmission of HIV and AIDS or prevented all deaths from malaria would do that. Given the absence of evidence that any intervention actually has such a substantial effect, it is assumed in this volume that individuals face the same probability of death at each subsequent age as the existing population does.

This assumption makes interventions appear less effective when overall mortality is high than when mortality is low. For example, averting an infant death in Sub-Saharan Africa will save, on average, only 44 to 49 undiscounted life years and should not be credited with saving 80 or more. Cost-effectiveness calculations and estimates of burden of disease are inconsistent in that fully effective interventions appear able to deal with only part of the burden they aim to control. Regional rather than standard life expectancy also makes interventions in a high-mortality region appear more effective relative to outcomes where mortality is lower, when they avert deaths later in life.

Nonhealth benefits of health interventions sometimes should be taken into account, because many health interventions also yield other kinds of benefits. They often make beneficiaries mentally or physically more productive, better able to continue in and learn from school or to work and earn more. This benefit occurs particularly with interventions against non-fatal consequences, as indicated in the chapters on malnutrition (chapter 28), malaria (chapter 21), helminthic infections (chapter 24), tropical diseases (chapters 22–23), psychiatric disorders (chapter 31), and learning and developmental disorders (chapter 49). Interventions that prevent injury or restore work capacity also have such effects (chapters 39–40 and 60), as do interventions against diseases that kill in the prime of life, notably tuberculosis and AIDS (chapters 16 and 18). Nonhealth benefits also occur as time is saved when piped water is made available, as less cleaning is needed when air pollution is reduced (chapter 42), or as property damage is reduced by improved traffic safety (chapter 39).

Several chapters include discussions of the nature and, where possible, the magnitude of nonhealth benefits from health interventions. This factor is important when the health benefits, although substantial, are so costly that interventions do not appear cost-effective on health grounds alone but may be justified by large nonhealth returns. Safe water and sanitation services are the classic example (chapter 41). Because different types of benefits—health gains, increased income, time saved—cannot be compared directly, the only way of combining them into a single expression is usually to evaluate all outcomes in monetary terms. (An exception occurs when some monetary gains can be measured directly—for example, increased worker productivity from better health. Those gains can be subtracted from costs and incorporated into CEA without attributing a monetary value to the health gains.) Most chapters that account for any nonhealth benefits simply offer descriptions of them rather than incorporating them into

monetary outcome indicators. Chapter 7 is an exception; it compares gains in welfare from living longer or in better health with those from higher income.

Estimating the monetary value of all benefits and adding them together for comparison with cost is what cost-benefit analysis does. Interventions are considered justified in absolute terms if the benefits exceed the costs. However, when faced with constrained budgets that cannot finance all interventions whose benefits are greater than costs, policy makers need to establish some minimum acceptable rate of return. This choice is parallel to the need to set a maximum on cost per unit of health gain when choosing according to cost-effectiveness.

Published analyses of health interventions sometimes use cost-benefit analysis, so results following that method are incorporated in some chapters here. The decision to emphasize CEA instead derives from two chief considerations. One is that, for most interventions, the health consequences seem more relevant or more important than any nonhealth outcomes. The other is that, conceptually, it is unclear what dollar value to assign to improved health, as would have to be done in most cases. Two approaches to valuing health, particularly for judging how much a life is worth, are known respectively as (a) the *value of a statistical life*, or the *human capital approach*, and (b) the *willingness-to-pay valuation*, or *contingent valuation*. The former depends on estimating earnings lost from premature death or retirement, and the latter on what people pay or indicate they would pay for care to protect or restore their health.

Both approaches reflect a society's level of income. Although they may be appropriate within a homogeneous society, if applied globally they imply that better health is worth less among poor populations than among those who are better off. Both methods are arguably more appropriate for marginal improvements (like saving travel time for commuters) than for valuing life-or-death differences, although willingness to pay is sometimes used in analyses of policies to reduce mortality. Avoiding monetary evaluation of health benefits sidesteps most of the ethical problems of valuing individual lives and requires fewer assumptions about what benefits are worth. The cost of this simplification is that occasionally substantial nonhealth benefits are not explicitly valued, so interventions may look less justified than they would be if all benefits were analyzed.

DETERMINING COSTS FOR INTERVENTIONS

Whatever outcome measures are used to evaluate an intervention, its costs must be estimated. This need raises several questions about which costs to attribute to the intervention and how some of them should be valued.

Direct and indirect costs should be distinguished, and choices should be made about which, if any, of the latter to include. In addition to the direct costs to the health system of

producing an intervention, the U.S. Public Health Service guidelines (Gold and others 1996) recommend including the indirect costs to patients and their families of consuming it. This recommendation means, in particular, the value of time needed for travel, waiting, and undergoing medical tests and procedures, or the value of time used in caregiving, as well as any income forgone during treatment. Externalities, or costs imposed on third parties, such as on the school system or the environment, should also be included. The analyses in this volume generally exclude such costs and report only the direct costs of delivering interventions, partly because published analyses seldom include the various indirect costs, and they are harder to estimate. Walker and Fox-Rushby (2000) found that only 20 of 101 studies included some element of indirect costing. Valuing time according to local wages or income, for example, may underestimate how valuable time actually is to poor people. Estimating such costs, even if time is not valued in money, may show whether time or monetary costs or both account for a relatively low level of use and therefore impede expanding coverage. Applying one or more of the policy instruments discussed earlier, along with the intervention, may then be important in order for it to be cost-effective.

Including such costs also raises a question of interpretation. If an intervention appears low in cost-effectiveness because it requires much travel or waiting time, the fault may lie not with the intervention itself but with health facilities that are located too far from the beneficiary population, are understaffed, or are inefficiently managed. For this reason, cost-effectiveness is estimated assuming a functional health system that does not impose prohibitive time costs on users.

Not only the characteristics of the interventions themselves, but also the capacity to deliver interventions greatly affect cost-effectiveness across many activities. In a complete analysis, each intervention is characterized by how demanding it is of managerial or institutional capacity. This element is difficult to measure directly, but authors often provide at least an intuitive description of how easy or hard delivery of an intervention is or what factors facilitate or impede its implementation. Where capacity to deliver several interventions together is important, authors deal explicitly with the issue, as in the chapters on health facilities (chapters 64–66), resources (chapters 71–72), service management (chapter 73), and whole packages of interventions (chapters 56 and 63).

Dollar values of unit costs need to be calculated for international comparisons. The inputs used to produce an intervention—the time (and training) of human resources; drugs and supplies; and depreciation or rental value of equipment, vehicles, and buildings—are either produced in the country or imported. If the latter, they already have prices in U.S. dollars; if the former, prices in local currency must be converted to U.S. dollars for comparison with other interventions and other countries. The usual distinction between tradable

and nontradable goods is that tradables move from producing to importing countries at relatively constant “world” prices. In fact, the same good may be imported at different prices to different countries or may be imported to one country but locally produced in another, so that it has both an international and a local price. This situation is increasingly true of drugs and supplies, which middle-income countries (Brazil, for example) and some low-income countries (India) now produce and sometimes export.

Prices in local currency can be converted to U.S. dollars by exchange rates or by purchasing-power parity rates (as estimated in World Bank 2003). The former may reflect under- or overvaluation of the local currency, making goods systematically cheaper or more expensive than at world prices, and they may change quickly and substantially in response to changes in a country’s trade balance, indebtedness, or capital flows. Nonetheless, they represent what is actually paid for locally produced inputs at any given moment. Purchasing-power parity rates, in contrast, attempt to say what local currency is worth in purchasing power, correcting for systematic price differences. Such rates can be calculated for the country as a whole, for the health sector, or for specific inputs or combinations thereof (Wordsworth and Ludbrook 2004). This calculation means valuing local inputs at external prices, assuming they are equally productive or of equal quality in the particular country as in the countries from which purchasing-power parity rates are derived. A doctor in South Asia or Sub-Saharan Africa is treated as costing just as much as a physician in high-income countries. This approach approximates measuring the real resource cost of intervention by comparing *quantities* of inputs among countries, eliminating *price* differences as a source of cost variation. Estimates of real national income are derived this way, making poor countries usually look less poor in dollar terms than if income in local currency were valued at exchange rates.

Granted that purchasing-power parity rates are reasonable for comparing large aggregates such as income across countries, but they bear little relation to the allocation of resources and budgetary choices within a country. The cost calculations in this volume are, therefore, all based on exchange rates. Exchange rates more accurately reflect what a domestic buyer—or a foreign donor or investor—has to pay for imported versus domestic inputs and, therefore, are more relevant for choices between interventions with high or low imported content. (If exchange rates are artificially fixed, the country pays a cost for that distortion that affects all interventions to the extent that they require foreign exchange.) In general, the more an intervention is produced with local inputs, the more cost-effective it will appear when priced using exchange rates, compared with its cost at purchasing-power parity rates. For decision makers and purchasers in the country, efficiency means choosing interventions according to what they actually

cost, not according to what they would cost if prices were more nearly uniform among countries. If, in local currency, physicians are paid little more than nurses are, it may make sense to employ more doctors per nurse—even if at international prices doctors would cost much more and should be replaced by nurses when possible. Of course, the staffing decision turns on the competencies of the two groups as well as on their costs; for certain health problems, more nurses might be the better choice even if they cost more.

Two other reasons besides that of efficiency in buying interventions support basing cost-effectiveness on exchange rate prices. First, authors who have used published costs (which usually involve exchange rates) rather than building up estimates from individual prices and quantities seldom break down costs into imported and domestic components. Local inputs cannot be repriced at purchasing-power parity rates or can only be repriced very approximately. Second, for readers accustomed to dealing with prices converted using exchange rates, real resource estimates may simply appear to penalize the use of local inputs by valuing them at unrealistic prices. The problem with exchange rate prices, in contrast, is that when rates change, so may the relative cost-effectiveness of interventions, as imported inputs become relatively more or less expensive. Cost-effectiveness is not static or intrinsic but depends on prices as well as on quantities and on the results of an intervention—and prices can change individually or generally, through exchange movements. Priorities sometimes need to shift because of such price changes, as well as because of technological changes that make interventions more effective, and so analyses should be kept up to date.

MORE AND LESS COMPREHENSIVE DATA AND ANALYSIS

Several authors (Drummond and others 1997; Gold and others 1996; Sloan 1995) provide similar guidance and recommendations for relatively comprehensive economic evaluation in general or for specific medical procedures. This volume aims at estimating cost-effectiveness for interventions against many different problems in all low- and middle-income regions, for which varying amounts and quality of information are available. It has therefore not always been possible to conduct as complete an analysis as would be desirable. Some degree of modeling is usually inescapable (Buxton and others 1997).

More complete analysis starts by characterizing, in each regional setting where an intervention is relevant (where the health problem causes some measurable burden and the intervention appears feasible), estimates of the quantities of inputs required (Q), the unit costs of those inputs (P), and the effectiveness or health gain (E). Authors were provided regional estimates of unit costs for the major inputs—salaries, facility costs,

fuel and vehicle operation, drugs, representative equipment, diagnostic tests, and buildings (Mulligan and others 2003). The total cost of delivery is the sum of the input costs PQ , which is compared with effectiveness E and the CER calculated from the total costs and total effects of the proposed intervention or from the changes in those costs and outcomes compared with current practice.

The data on unit costs, quantities, and outcomes may all derive from published literature; what is original is how that information is combined to calculate cost-effectiveness rather than taking the ratios from existing studies. Estimates are built up using prices and physical inputs in the chapters on tuberculosis (chapter 16), vaccine-preventable diseases (chapter 20), malaria (chapter 21), cancers (chapter 29), psychiatric disorders (chapter 31), neurological disorders (chapter 32), cardiovascular disease (chapter 33), hemoglobin disorders (chapter 34), water and sanitation (chapter 41), indoor air pollution (chapter 42), tobacco (chapter 46), alcohol (chapter 47), community programs (chapter 56), family planning (chapter 57), surgery (chapter 67), emergency care (chapter 68), and complementary medicine (chapter 69). Several chapters analyze some interventions more fully and others less fully, depending on the available information.

As indicated in box 15.2, expanding or contracting the scale of an intervention may change the CER because of difficulty in reaching more of the population. The ratio may also vary because of the cost of identifying who would benefit most from the intervention—for example, whether to screen all newborns for sickle cell disease or only those of African origin (chapter 34). And expansion may change the cost-effectiveness because it would require considerable fixed investment. The costs of expanding capacity to deliver an intervention, including physical capital and training of human resources, should be amortized over a reasonable interval (10 years is the standard in this volume) and included in the total costs. Ideally, one would know the complete production function of the intervention, including the possibilities of substituting one input for another to minimize costs in response to differences in prices. However, analysis of this level of complexity is difficult to achieve, so most chapters assume fixed input proportions. Q , then, does not depend on P , and the CER varies (at most) only with coverage, prices, and outcomes. This result could be an underestimate of the true cost-effectiveness if much substitution is possible (see chapter 16 on tuberculosis).

Approximations are required when the average and incremental CERs have to be taken directly from the literature and when key parameter values are not easily available. Existing estimates of total cost or effectiveness may or may not incorporate the standard assumptions about discounting, disability weights, and life expectancy. Authors then need to judge how to adjust the available estimates for a more consistent analysis.

Local cost and outcome estimates that have not been constructed transparently from inputs and prices provide a less complete basis for secondary analysis. Where such estimates are used, information about how costs are constructed or how results vary with the scale of the intervention is usually not available, but the data may explicitly show regional differences in one or both elements, thereby permitting regionally differentiated recommendations (or may show differences so small that recommendations need not differ regionally). If costs and results refer to only one moment or are specified year by year, they can be discounted at 3 percent. Published analyses often use higher constant rates of 5, 6, or even 10 percent and may specify only total costs and outcomes rather than the respective streams through time. In that case, both costs and health gains occurring in the future are valued less, but conversion to a CER based on 3 percent discounting may be impossible and is at best only approximate. Some published analyses discount costs but not health outcomes, which makes interventions look more cost-effective when costs are spread over long intervals (for examples, see chapter 29). Imported estimates of cost and effect—that is, estimates from other regions, commonly from high-income countries—are often all that is available. Sometimes data on costs and outcomes derive from the same source; in other cases, they come from different sources and even different regions and are difficult to compare directly. More appropriate adjustments to total costs are possible with information on quantities of inputs. In the absence of data on quantities of resources used, differences in average cost can sometimes be calculated using estimates of input proportions. Such an approximation characterizes the analysis for diabetes (chapter 30), in which proportions were known in one region and assumed to be the same elsewhere and costs were estimated from regional cost ratios.

Variation of Results and Uncertainty of Estimates

Variation and uncertainty are two different aspects of cost-effectiveness estimates that also need to be accounted for in setting priorities. Because costs of inputs differ among regions, intervention costs vary even if effectiveness does not—and there are often reasons why the same intervention is more effective in one place than another. Such variation means that a single estimate of incremental or average cost-effectiveness of an intervention is not universally applicable. All estimates should ideally be local, and regional values capture only part of the real variation. For example, the average cost per DALY of chemotherapy for active or contagious tuberculosis, in the absence of HIV and AIDS, is US\$15, but that figure varies from US\$6 to US\$31 across regions, and such wide variation is common in many chapters. Whenever the estimates of cost-effectiveness in different chapters use the same input prices, their results are comparable within a given region. Analyses that draw on published

estimates for price or unit cost information are necessarily less comparable across interventions and introduce another element of variation, even in the same locale. Still more variation arises when costs or outcomes are extrapolated from one country or region to another.

Because the CER depends on many parameters and variables, of which only the discount rate and the disability weights are uniform, good analytic practice calls for sensitivity analysis to see how the ACERs and ICERs change with plausible variation in one or more parameters. Many chapters (such as chapter 26) provide such analyses, varying one value at a time, to sketch the likely range of estimates. This method is one way of dealing with uncertainty (which differs from real, known variation) about the true values of the data and seeing whether the ranking of interventions changes when those values change. Such analyses do not indicate the probability that the true CER falls in a particular interval, only under what input values it would do so. Estimating such probabilities requires knowing or assuming the statistical distributions of the parameters in question and using that information to derive confidence intervals around the point estimates. Guides to CEA recommend these approaches (Gold and others 1996), and the National Institute for Clinical Excellence requires probabilistic sensitivity analysis before approving medical treatments in the United Kingdom (NICE 2004).

Data for estimating probability distributions around mean parameter estimates are seldom available in low- and middle-income countries. Simply having available several different estimates of a parameter is inadequate for deriving a distribution, because the differences may be caused by variation in regional costs or expected life years rather than uncertainty. However, assumptions about the shape of distributions can be applied within modeling exercises to give an indication of the likely distribution of ICERs. Only a few chapters, therefore, include confidence intervals. The analyses for tuberculosis (chapter 16) and malaria (chapter 21) do, but ranges associated with most cost-effectiveness estimates (see chapter 2) reflect other causes of variation, not statistical accuracy.

Although calculations are often reported to several significant digits, such precision is not really feasible given the uncertainties in the original data: “economics is a one- or at most a two-digit science” (Morgenstern 1963). However, even crude findings can be valuable, either as guides to value for money if inaccuracies do not affect the relative order of magnitude of the results or for understanding and exploring the sources of variation and their effect on priorities as well as indicating future research needs (Claxton, Sculpher, and Drummond 2002). These issues arise, for example, when considering whether to expand the EPI or to add new antigens (chapter 20), how far to extend screening procedures (chapters 29 and 34), and when to change drugs in response to vector or parasite resistance (see chapters 21 and 23).

The quality and relevance of evidence can vary considerably, depending on whether information comes from randomized controlled trials or systematic overviews, nonrandomized studies with multivariate analyses and well-defined endpoints, or case studies or expert opinion. For these analyses, the quality of evidence also depends on geographic coverage, as distinguished in chapter 2:

- literature review of one cost-effectiveness study, in one country
- literature review of several studies in different countries in different regions
- literature review of several studies in different countries in the same region
- original analyses starting with price and quantity data in one country
- original analyses starting with price and quantity in one or more regions.

The first three categories differ in how representative published findings are; the latter two categories differ according to the data used in constructing total effects and total costs.

Besides the quality of the evidence at its source, how the results will apply to other settings matters, particularly when the data are limited to high-income countries. The more that outcomes depend on underlying biology, the more the findings will apply to low- and middle-income countries. Outcomes depending more on cultural or environmental factors are less readily transferred and require judgment and evidence as to their applicability elsewhere. Sometimes the only detailed studies refer to high-income countries, as for abuse of substances other than alcohol and tobacco (chapter 48). At the other extreme, in a few cases all or nearly all the information comes from low- and middle-income countries, and there is no need to extrapolate, as for nutritional interventions (chapter 28) and community health and nutrition programs (chapter 56).

COST-EFFECTIVENESS AND POPULATION IMPACT

An intervention CER, whether average or incremental, is based on assumptions about introduction, expansion, contraction, or modification of the activity compared with current (or sometimes “best”) practice. Comparison of ratios indicates whether one intervention offers better or worse value for money than another at the individual level but says nothing about how either one affects the whole population. The analysis, therefore, includes, wherever possible, two ways of describing the latter effect. One is to consider a population of 1 million, with a typical regional age and sex structure, and to suppose that the intervention were delivered to all the potential beneficiaries. That number of people is just the prevalence or incidence of

the condition times 1 million. The total cost would then be the unit cost times that number (or the cost of reaching that many people if the unit cost varies with coverage). The total health gain would be the individual effectiveness times that same number (or the overall outcome if that depends on externalities, such as the transmission of communicable disease, that are sensitive to coverage). Standardizing on a population of 1 million allows comparisons among regions and interventions in which the incidence or prevalence may vary greatly.

A second approach standardizes not on population but on expenditure: if an additional US\$1 million were devoted to the resources needed for an intervention, how many people could benefit from it and how large would the health gain be? The coverage of the intervention would be US\$1 million divided by the average cost, and the total gain in DALYs would be that number of people times the average effectiveness. This approach is applied in relatively few chapters because of the information requirements; its advantage is to facilitate judgments as to where increased spending would be most justified—where it would yield the largest improvement in health, reach the most people, or account for the largest share of burden from a condition. Table 1.3 in chapter 1 provides examples for some interventions to reduce child mortality, prevent or treat HIV and AIDS, reduce smoking prevalence, treat heart attack and stroke, detect and treat cervical cancer, and operate a basic surgical ward. The estimates of DALYs gained per US\$1 million vary from less than 100 to more than 100,000—a thousandfold difference in value for money. Annex 26.A of chapter 26 provides both kinds of calculations, per million population, to compare the cost-effectiveness of interventions for improved maternal health in South Asia and Sub-Saharan Africa.

IMPROVEMENTS AND FURTHER APPLICATIONS

What would improve the kind of estimates and conclusions reported in this volume? Most crucially, more and better data are needed in low- and middle-income countries to reduce reliance on extrapolation from high-income countries and on expert judgments. The need for information starts, in some cases, with better estimates of incidence and prevalence, but even where the epidemiology is well known, data on coverage and outcomes of existing interventions are scarce. Evidence of what it would cost to change coverage of existing interventions or add new interventions, and with what results, is particularly scarce and depends heavily on assumptions. This situation is sometimes true even for activities that have been conducted widely for many years and have been extensively analyzed, notably the EPI (chapter 20). Analyses should when possible be conducted at the level of a country or even smaller units, to take full account of all the reasons cost-effectiveness varies from place to place

and to develop priorities on the basis of analyses appropriate to local circumstances. The methods used here are intended to help guide such efforts, and they can and should be refined through research to provide more robust help to policy.

Finally, a more concerted approach is needed for clarifying the options facing different decision makers and incorporating the results from systematic literature reviews into analytic models that compare the costs and effects of alternative interventions (Buxton and others 1997; Kuntz and Weinstein 2001). Modeling encourages explicit decision making and can deal comprehensively with the inputs and outcomes of decision options, which allows a range of uncertainties to be reflected. Thus, hypotheses about interventions can be formulated and tested statistically. Specifying models explicitly (as in chapter 16, for example) can also help identify gaps in current evidence and can capture details specific to particular populations and settings.

ACKNOWLEDGMENTS

The authors are grateful to Jo Mulligan for the estimation and explanation of input costs used in this volume; to Sonbol A. Shahid-Salles for help in drawing methodological examples from numerous chapters; to George Alleyne, Joel G. Breman, Mariam Claeson, Anthony R. Measham, and Elinor Schwartz for helpful comments; and to Dean T. Jamison and Anne Mills for overall guidance.

Chapter 16

Tuberculosis

Christopher Dye and Katherine Floyd

Despite the availability of drugs to cure tuberculosis (TB) since the 1940s, TB remains an important cause of death from an infectious agent, second only to the human immunodeficiency virus, or HIV (WHO 2004f). TB control is high on the international public health agenda, not only because of the enormous burden of disease, but also because short-course chemotherapy (SCC) is recognized as one of the most cost-effective of all health interventions (Jamison and others 1993). That recognition is partly attributable to an influential series of studies done in three of the poorest countries of southeastern Africa (Malawi, Mozambique, and Tanzania), which suggested that a year of healthy life could be gained for less than about US\$5 (de Jonghe and others 1994; Murray and others 1991). This evidence has been central to the global promotion of the DOTS strategy, the package of measures combining best practices in the diagnosis and treatment of patients with active TB, in which direct observation of treatment during SCC is a key element (WHO 2002a, 2004c).

Although the World Health Organization (WHO) has fostered the implementation of DOTS over the past decade, four recent developments have drawn attention to a wider range of options for TB control:

- First, many more studies have investigated the costs, efficacy, and cost-effectiveness of different approaches to TB control. They are mostly studies of ways to improve the delivery of first-line drug treatment for active disease, but they include some investigations of preventive therapy (treatment of latent infection), treatment of multidrug-resistant TB (MDR-TB) using both first- and second-line drugs, and different approaches to diagnosis. They have been carried out in a variety of settings, in richer as well as poorer coun-

tries. The results have not been fully synthesized but may suggest ways to enhance DOTS.

- Second, striking increases in TB have been associated with the spread of HIV infection and drug resistance, suggesting that DOTS alone may not be enough to bring TB under control, especially in Africa and in the countries of the former Soviet Union.
- Third, there is now substantially more investment in new tools for TB control, including multimillion-dollar initiatives to develop better diagnostics, drugs, and vaccines, many of which operate under the umbrella of the Stop TB Partnership (see <http://www.stoptb.org>). Some of the possible products of this new research would stimulate reevaluations of the current reliance on chemotherapy, especially the development of a new high-efficacy vaccine.
- Fourth, interest in TB is renascent, not simply as the outcome of mycobacterial infection, but also as the consequence of exposure to exacerbating risks, such as tobacco smoke, air pollution, malnutrition, overcrowding, and poor access to health services. Research directed at quantifying these risks will also suggest ways to minimize them.

These developments set a big agenda for analysis. To make some inroads, this chapter presents an overview of the value for money and potential effect of the principal modes of TB control around the world. The starting point is a review of the natural history and clinical characteristics of TB and the geographical distribution of and trends in TB cases and deaths. This introduction sets the context for a discussion of the interventions that are now available to control TB and of how they have been used. We use a new method for evaluating the cost-effectiveness of infectious disease control and apply

this method systematically to four groups of TB interventions as they could be implemented in six regions of the world.

The internationally agreed-on targets for TB control, embraced by the United Nations Millennium Development Goals (MDGs), are to detect 70 percent of sputum-smear-positive cases and successfully treat 85 percent of such cases by the end of 2005. The expectation is that, if these targets can be reached and maintained, incidence rates will be falling by 2015, and the TB prevalence and death rates of 1990 will be halved by 2015. Meeting these targets requires a set of interventions that are not only cost-effective but also affordable and capable of having an effect on a large scale. The final sections of the chapter discuss the absolute costs and benefits of global TB control and the potential for achieving the effect defined within the MDG framework. The main themes of the text that follows are elaborated in a series of annexes available online at <http://www.fic.nih.gov/dcpp> as well as at <http://www.who.int/tb/publications/en/>.

TUBERCULOSIS INFECTION, DISEASE, AND DEATH

Human TB is caused by infection with mycobacteria, principally *Mycobacterium tuberculosis*. Individuals with pulmonary or laryngeal TB produce airborne droplets while coughing, sneezing, or simply talking. Inhaled infectious droplets lodge in the alveoli, and bacilli are taken up there by macrophages, beginning a series of events that results in either the containment of infection or the progression to active disease (Frieden and others 2003). Following uptake by macrophages, *M. tuberculosis* replicates slowly but continuously and spreads through the lymphatic system to hilar lymph nodes. In most infected people, cell-mediated immunity, associated with a positive tuberculin test, develops two to eight weeks after infection. Activated T lymphocytes and macrophages form granulomas, which limit the further replication and spread of bacilli. Unless a later defect occurs in cell-mediated immunity, the infection remains contained within the granulomas.

The immune mechanisms are, in their details, far more complex. For example, following antigenic challenge, a suite of different T cells is responsible for the induction and suppression of protective immunity, delayed hypersensitivity, cytolysis, and the production of antibodies and memory cells. Helper T cells mature into two functionally different populations: in *M. tuberculosis* infection, the T_H1 response is associated with granuloma formation and protection, whereas the T_H2 response results in tissue-necrotizing hypersensitivity and the progression of disease. The processes that determine the balance of the two responses affect, for example, the interaction between *M. tuberculosis* and other infectious agents (Grange 2003).

When the immune response cannot suppress replication, primary infection leads to active TB (progressive primary TB).

The most common clinical manifestation is pulmonary disease, typically in the parenchyma of the middle and lower lung. In the most infectious patients, bacilli can be seen microscopically on stained sputum smears (60 to 70 percent of pulmonary cases; Marais and others 2004; Styblo 1991). Smear-negative patients may also be infectious but, per patient, contribute relatively little to transmission (Behr and others 1999; Hernandez-Garduno and others 2004). Extrapulmonary tuberculosis accounts for 10 to 30 percent of the disease but is more common among women and children (particularly lymphatic TB) and in people infected with HIV (Aaron and others 2004; Rieder 1999; Rieder, Snider, and Cauthen 1990; Shafer and Edlin 1996).

In the absence of other predisposing conditions, only about 5 percent of infected people develop progressive primary disease within five years of infection (Comstock, Livesay, and Woolpert 1974; Sutherland 1968, 1976). After five years, the annual risk of developing TB by the reactivation of latent infection is much lower ($\approx 10^{-4}$ per capita per year). The risk of progressing to active disease is relatively high in infancy and lower in older children; it increases quickly during adolescence (earlier in girls) and then more slowly throughout adulthood (Comstock, Livesay, and Woolpert 1974; Nelson and Wells 2004; Sutherland, Svandova, and Radhakrishna 1982; Vynnycky and Fine 1997). Whether latent bacilli remain viable for the full life span of all infected people is unknown, but the risk of reactivation certainly persists into old age. The lifetime risk of developing TB following infection clearly depends on the prevailing transmission rate; the rule of thumb is 10 percent, but it has been calculated at 12 percent for all forms of pulmonary disease in England and Wales during the second half of the 20th century (Vynnycky and Fine 2000).

Besides the strong innate resistance to developing disease, infection is associated with an acquired immune response. This response is only partially protective (Dye and others 1998; Sutherland, Svandova, and Radhakrishna 1982; Vynnycky and Fine 1997), which helps explain why developing an effective vaccine has been difficult (few manufactured vaccines are more protective than natural immunity; Andersen 2001; Fordham von Reyn and Vuola 2002; Young and Stewart 2002). Consequently, individuals who carry a latent infection and who continue to be exposed are at risk of TB following reinfection. The importance of reinfection remains controversial, but mathematical modeling shows that the decline of TB in Europe cannot easily be explained without reinfection (Dye and others 1998; Vynnycky and Fine 1997). In addition, molecular fingerprinting has produced direct evidence that TB commonly arises from infection and reinfection in endemic areas (de Viedma and others 2002; Richardson and others 2002; van Rie and others 1999; Verver and others 2004), especially where subjects are infected with HIV (Glynn and others 2004).

The low incidence of infection and the low probability of breakdown to disease explain why TB is relatively rare. Its importance among infectious diseases is attributable not so much to the number of cases as to the high case-fatality rate among untreated or improperly treated patients. About two-thirds of untreated smear-positive patients will die within five to eight years, the majority within the first 18 months (Styblo 1991). Most of those who are still alive after eight years will have quiescent TB (self-cures, susceptible to relapse), and a few will become chronic excretors of bacilli. The case-fatality rate for untreated smear-negative cases is lower, but still of the order of 10 to 15 percent (Krebs 1930; Rieder 1999). Even among smear-positive patients receiving antituberculosis drugs, the case-fatality rate can exceed 10 percent if adherence to treatment is low or if rates of HIV infection and drug resistance are high (WHO 2004c).

Online annex 1 contains more information about factors that affect the risk to individuals of contracting infection and developing disease and the distribution of TB in populations.

EPIDEMIOLOGICAL BURDEN AND TRENDS

Surveys of the prevalence of infection and disease, assessments of the performance of surveillance systems, and death registrations yield an estimated 8.8 million new cases of TB in 2003, fewer than half of which were reported to public health authorities and WHO (online annex 2). Approximately 3.9 million cases were sputum-smear positive, the most infectious form of the disease (Corbett and others 2003; Dye and others 1999; WHO 2005). The African region has the highest estimated incidence rate (345 per 100,000 population annually), but the most populous countries of Asia harbor the largest number of cases: Bangladesh, China, India, Indonesia, and Pakistan together account for half the new cases arising each year. In terms of the total estimated number of new TB cases arising annually, about 80 percent of new cases occur in the top-ranking 22 countries.

In most countries (but not all), more cases of TB are reported among men than women. This differential is partly because women have less access to diagnostic facilities in some settings (Hudelson 1996), but the broader pattern also reflects real epidemiological differences between men and women, both in exposure to infection and in susceptibility to disease (Borgdorff and others 2000; Hamid Salim and others 2004; Radhakrishna, Frieden, and Subramani 2003). Where the transmission of *M. tuberculosis* has been stable or increasing for many years, the incidence rate is highest among young adults, and most cases are caused by recent infection or reinfection. As transmission falls, the caseload shifts to older age groups, and a higher proportion of cases comes from the reactivation of latent infection.

Globally, the TB incidence rate per capita appears to be growing slowly (online annex 2). Case numbers have been declining more or less steadily for at least two decades in Western and Central Europe, the Americas, and the Middle East. Striking increases have occurred in countries of Eastern Europe (mainly the former Soviet republics) since 1990 and in Sub-Saharan Africa since the mid 1980s, although trends in case notifications suggest that the rate of increase in both regions has slowed significantly since the mid 1990s (WHO 2005).

TB has increased in Eastern European countries because of economic decline and the general failure of TB control and other health services since 1991 (Shilova and Dye 2001). Periodic surveys indicate that more than 10 percent of new TB cases in Estonia, Latvia, and some parts of the Russian Federation are multidrug-resistant—that is, resistant to at least isoniazid and rifampicin, the two most effective anti-TB drugs (Espinal and others 2001; WHO 2004a). Drug resistance is likely to be a by-product of the events that led to TB resurgence in these countries, not the primary cause of it, for three reasons. First, resistance is generated initially by inadequate treatment caused, for example, by interruption of the treatment schedule or use of low-quality drugs. Second, resistance tends to build up over many years, and yet TB incidence increased suddenly in Eastern European countries after 1991. Third, although formal calculations have not been done, resistance rates are probably too low to attribute all of the increase in caseload to excess transmission from treatment failures.

Globally, 12 percent of new adult TB cases were infected with HIV in 2003, but there was marked variation among regions—from an estimated 33 percent in Sub-Saharan Africa to 2 percent in East Asia and the Pacific (online annex 2). HIV infection rates in TB patients have so far remained below 1 percent in Bangladesh, China, and Indonesia. The increase in TB incidence in Africa is strongly associated with the prevalence of HIV infection (Corbett and others 2002), and in populations with higher rates of HIV infection, women 15–24 years old constitute a higher proportion of TB patients (Corbett and others 2002). The rise in the number of TB cases in Africa is slowing, almost certainly because HIV infection rates are also beginning to stabilize or fall (Asamoah-Odei, Garcia Calleja, and Boerma 2004). HIV has probably had a smaller effect on TB prevalence than on incidence because HIV significantly reduces the life expectancy of TB patients (Corbett and others 2004). Where HIV infection rates are high in the general population, they are also high among TB patients; estimates for 2003 suggested that more than 50 percent of TB patients infected with HIV in Botswana, South Africa, Zambia, and Zimbabwe, among other countries.

Approximately 1.7 million people died of TB in 2003 (Corbett and others 2003), including 229,000 patients who were also infected with HIV (online annex 2). Although these

are usually reported as AIDS deaths under the *International Statistical Classification of Diseases and Related Health Problems, 10th revision* (ICD-10), and by WHO, TB control programs need to know the total number of TB deaths, whatever the underlying cause.

INTERVENTIONS AGAINST TUBERCULOSIS

TB can be controlled by preventing infection, by stopping progression from infection to active disease, and by treating active disease. The principal intervention is the DOTS strategy and its variations, centered on the diagnosis and treatment of the most severe and most infectious (smear-positive) forms of TB but including treatment for smear-negative and extrapulmonary cases as well. Anti-TB drugs can also be used to treat latent *M. tuberculosis* infection and active TB in patients with HIV coinfection, and the widely used bacillus Calmette-Guérin (BCG) vaccine prevents (mainly) severe forms of TB in childhood. These biomedical interventions directed specifically against TB can be implemented in a variety of ways through medical services and public action and can be supported by other efforts to reduce environmental risk factors (online annex 1).

Vaccination

Currently, the only means of immunizing against TB is with the live attenuated vaccine BCG, although other vaccines are under development (Fruth and Young 2004; Goonetilleke and others 2003; Horwitz and others 2000; Letvin, Bloom, and Hoffman 2001; Reed and others 2003; Young and Stewart 2002). Randomized controlled trials and case-control studies have shown consistently high protective efficacy of BCG against serious forms of disease in children (73 percent [95 percent confidence limits 67–79 percent] for meningitis and 77 percent [95 percent confidence limits 58–87 percent] for miliary TB) but highly variable—and often very low—efficacy against pulmonary TB in adults (Bourdin Trunz, Fine, and Dye, forthcoming; Fine 2001; Rieder 2003). Thus, even with the high coverage now achieved, BCG is unlikely to have any substantial effect on transmission. In parts of Europe and North America that did and did not use BCG, TB declined at rates that were not measurably different (Styblo 1991). In areas of high incidence, BCG vaccination is recommended for children at birth or at first contact with health services. Vaccination is being discontinued in many low-incidence countries because the risk of infection is low and because the response to BCG confounds the interpretation of tuberculin skin tests used to track persons infected during occasional outbreaks. BCG may have substantial nonspecific effects on child mortality—that is, in reducing deaths from causes other than TB—but this possibility is still controversial (Kristensen, Aaby, and Jensen 2000).

Reported BCG vaccination coverage has increased throughout the world during the past 25 years, reaching about 100 million infants, or 86 percent of all infants, in 2002. An estimated 92 percent of children were vaccinated in Europe and 62 percent in Africa in 2002 (WHO 2001). During the past 15 years, coverage has generally been most variable among African countries and least variable in Europe and the Americas. The most complete analysis of the effect of BCG vaccination suggests that BCG given to children born in 2002 prevents about 29,700 cases of childhood meningitis and 11,500 cases of miliary TB during the first five years of life, or one case for every 3,400 and 9,300 vaccinations, respectively (Bourdin Trunz, Fine, and Dye, forthcoming).

Treatment of Latent Infection

Individuals at high risk of TB who have a positive tuberculin skin test but not active disease (for example, associates of active cases, especially children and immigrants to low-incidence countries) can be offered treatment for latent TB infection (TLTI), most commonly with the relatively safe and inexpensive drug isoniazid. Studies among those who have contacts with active cases have demonstrated that 12 months of daily isoniazid gives 30 to 100 percent protection against the development of active TB (Cohn and El-Sadr 2000; Comstock 2000). For patients who may be carrying a strain resistant to isoniazid, rifampicin daily for 4 months is an acceptable alternative (or rifabutin, if used with protease inhibitors for HIV-infected people; Cohn 2003; Menzies and others 2004). Nevertheless, TLTI is not widely used. The main reason is that compliance with long-term daily treatment tends to be poor among healthy people—a relatively high risk of TB among those who are latently infected is usually still a low risk in absolute terms. An additional reason is that the tuberculin skin test tends to be less specific when applied to individuals who have been vaccinated with BCG. Although it is sometimes possible to make separate estimates of the number of individuals in a population who have been infected and who have received BCG (Neuenschwander and others 2002), distinguishing the responses to BCG and infection is harder in any given individual.

The exceptionally high risk of TB among persons coinfecting with *M. tuberculosis* and HIV is a reason for encouraging wider use of TLTI, especially in Africa. However, there are significant barriers to making TLTI effective for coinfecting individuals living in areas of high transmission (in addition to those listed earlier). Although trials of TLTI with individuals infected with HIV whose tuberculin skin test was positive have averaged about 60 percent protection for up to three years (with a good deal of variability), the effects have been lost soon afterward, and little or no effect has been seen on mortality (Bucher and others 1999; Johnson and others 2001; Mwinga and others 1998; Quigley and others 2001; Whalen and others 1997; Wilkinson,

Squire, and Garner 1998). In addition, identifying *M. tuberculosis* infection is more difficult in HIV-positive individuals than in those who are HIV-negative because the former are often anergic and are, therefore, unresponsive to tuberculin. Early studies have also experienced problems with uptake and compliance. In a pilot project in Zambia, for example, only 35 percent of HIV-infected individuals identified through HIV testing and counseling services actually started TLTI, and, of those who started, only 23 percent completed at least six months of treatment (Terris-Prestholt and Kumaranayake 2003).

TLTI has been used as a component of intensive, local control campaigns, such as those carried out for North American and Greenland Eskimos, but probably had effects secondary to the prompt treatment of active disease (Comstock, Baum, and Snider 1979; Styblo 1991). At present, TLTI plays no more than an accessory role in TB control in any setting, although the number of recipients around the world has been neither directly quantified nor indirectly estimated.

Treatment of Active Disease: The DOTS Strategy

The cornerstone of TB control is the prompt treatment of active cases with SCC using first-line drugs, administered through the DOTS strategy (WHO 2002a) within targets framed by the MDGs. The DOTS strategy has five elements:

- political commitment
- diagnosis primarily by sputum-smear microscopy among patients attending health facilities
- SCC with effective case management (including direct observation of treatment)
- a regular drug supply
- systematic monitoring to evaluate the outcomes of every patient started on treatment.

Standard SCC can cure more than 90 percent of new, drug-susceptible TB cases, and high cure rates are a prerequisite for expanding case finding. Although the DOTS strategy aims primarily to provide free treatment for smear-positive patients, most DOTS programs also treat smear-negative patients, usually without a fee. DOTS can be used as the basis for more complex TB control strategies where rates of drug resistance or HIV infection are high.

Mathematical modeling and practical experience suggest that the incidence of TB will decline at 5 to 10 percent per year when 70 percent of infectious cases are detected through passive case finding and 85 percent of these cases are cured, even though that level represents a treatment success rate among all infectious cases of only 60 percent (Dye 2000; Dye and others 1998). In principle, TB incidence could be forced down more quickly, by as much as 30 percent per year, if new cases could be

found soon enough to eliminate transmission. In general, the decline will be faster where a larger fraction of cases arises from recent infection (that is, in areas where transmission rates have recently been high) and slower where there is a large backlog of asymptomatic infection. As TB transmission and incidence go down, a higher proportion of cases comes from the reactivation of latent infection and the rate of decline in incidence slows. These facts explain why it should be easier to control epidemic than endemic disease: during an outbreak in an area that previously had little TB, the reservoir of latent infection will be small, and most new cases will come from recent infection.

In the control of endemic TB, largely by chemotherapy, the best results have been achieved in communities of Alaskan, Canadian, and Greenland Eskimos, where incidence was reduced at 13 to 18 percent per year from the early 1950s (Styblo 1991). Over a much wider area in Western Europe, TB declined at 7 to 10 percent per year after drugs became widely available during the 1950s, although incidence was already falling at 4 to 5 percent per year before chemotherapy (Styblo 1991). More recently, between 1994 and 2000, the incidence of pulmonary TB among Moroccan children 0 to 4 years of age fell at more than 10 percent per year, suggesting that the risk of infection was falling at least as quickly (S. Ottmani, personal communication 2005). The overall reduction in pulmonary TB was only 4 percent per year, in part because of the large reservoir of infection in adults. DOTS was launched in Peru in 1991, and high rates of case detection and cure appear to have pushed down the incidence rate of pulmonary TB by 6 percent per year (Suarez and others 2001). For epidemic TB, as a result of aggressive intervention following an outbreak in New York City, the number of MDR-TB cases fell at a rate of more than 40 percent per year (Frieden and others 1995).

Although the long-term aim of TB control is to eliminate all new cases, cutting prevalence and death rates is arguably more important. About 86 percent of the burden of TB, as measured in terms of disability-adjusted life years (DALYs) lost, is attributable to premature death rather than illness, and prevalence and mortality can be reduced faster than incidence in chemotherapy programs. Thus, the TB death rate among Alaskan Eskimos dropped at an average of 30 percent per year in the period 1950–70 and at an average of 12 percent per year throughout the Netherlands from 1950 to 1990. Indirect assessments of the effect of DOTS suggest that 70 percent of the TB deaths expected in the absence of DOTS were averted in Peru between 1991 and 2000, and more than half the TB deaths expected in the absence of DOTS are prevented each year in DOTS provinces of China (Dye and others 2000; Suarez and others 2001). There have been few direct measures of the reduction in TB prevalence over time, but surveys done in China in 1990 and 2000 showed a 32 percent (95 percent confidence limits 9–51 percent) reduction in the prevalence rate of all forms of TB in DOTS areas, as compared with the change in the

prevalence rate in other parts of the country (China Tuberculosis Control Collaboration 2004; PRC Ministry of Health 2000). These findings imply that the targets of halving prevalence and death rates between 1990 and 2015 are technically feasible, at least in countries that are not burdened by high rates of HIV infection or drug resistance.

Many of the 182 national DOTS programs in existence by the end of 2003 have shown that they can achieve high cure rates: the average treatment success rate was 82 percent (that is, the percentage that were sputum-smear negative at the end of treatment plus the percentage that had completed treatment but for whom cure was not confirmed by sputum smear), not far below the 85 percent international target (WHO 2005). The outstanding deviations below that average were in Africa (73 percent) and some former Soviet republics (for example, 67 percent in Russia). Although the completion of treatment was almost a guarantee of cure before the spread of HIV and drug resistance, “completed” is an unsatisfactory way to report the outcome of treatment if cure is in doubt.

Although most TB patients probably receive some form of treatment, only 45 percent of all estimated new smear-positive cases were reported by DOTS programs to WHO in 2003. The case-detection rate in DOTS programs has been accelerating globally since 2000, but the annual increment must be still greater if the 70 percent target is to be reached by the end of 2005. Observations on the way DOTS is presently implemented suggest that a ceiling on case detection might be reached at about 50 to 60 percent (Dye and others 2003; WHO 2005). This fraction is about the same as the percentage of all cases reported annually to WHO from all sources (that is, from DOTS and non-DOTS programs). The problem is that, as DOTS programs have expanded geographically, they have not yet reached far beyond existing public health reporting systems.

ALTERNATIVE AND COMPLEMENTARY APPROACHES TO THE DIAGNOSIS AND TREATMENT OF ACTIVE DISEASE

The limitations of the DOTS strategy have stimulated numerous initiatives to improve program performance (including treatment protocols for patients carrying drug-resistant bacilli or who are infected with HIV), active case finding, collaborations within and between public and private sector health services, schemes for outpatient and community-based treatment, and integration of the management of TB and other illnesses.

Management of Drug-Resistant Disease

The higher the proportion of patients carrying drug-resistant bacilli is, the greater the need for accurate resistance testing and for the provision of alternative regimens that include at least

three drugs to which bacilli are fully susceptible. Of greatest importance is resistance to the two principal first-line drugs, isoniazid and rifampicin (that is, MDR-TB). The introduction of resistance testing, second-line drugs, longer treatment regimens (12 to 18 months), and rigorous bacteriological and clinical monitoring all increase program costs without necessarily ensuring high cure rates (equal to or greater than 85 percent). Indeed, achieving the same cure rates for MDR-TB patients as for patients carrying fully susceptible strains may not be possible. The cost-effectiveness of this component of a TB control program is therefore lower by an amount that depends on the nature of the resistance, the methods of testing and monitoring, and the choice of regimen. The higher costs and lower cure rates associated with treating drug-resistant TB are part of the argument for preventing the spread of resistance in the first place, as can be investigated with models of selection and transmission (Dye and Espinal 2001; Dye and others 2002; Dye and Williams 2000). Suarez and others (2002) have investigated the cost-effectiveness of managing drug-resistant TB in Peru, but because studies in other settings have yet to be published, an empirical overview is not yet possible. Further data will be available from studies in Estonia, the Philippines, and Russia in 2005.

Treatment of HIV Coinfection

Antiretroviral therapy for HIV-positive individuals is unlikely to prevent a large fraction of TB cases unless treatment can be given shortly after HIV infection is acquired (Sonnenberg and others 2005; Williams and Dye 2003). In general, antiretroviral therapy is likely to be most effective, not in reducing TB incidence, but in extending the life expectancy of HIV-positive patients successfully treated for TB (Friedland and others 2004). Antiretroviral therapy and DOTS are formally synergistic, because without undergoing both together, HIV-infected TB patients have a short life expectancy, typically less than five years.

Where the prevalence of HIV infection has been rising quickly, as in eastern and southern Africa, even the most energetic programs of TB chemotherapy may not be able to reverse the rise in TB incidence. However, mathematical modeling indicates that, even in the midst of a major HIV epidemic, early detection and cure are the most cost-effective ways of minimizing TB cases and deaths (Currie and others, 2005). One reason is that DOTS programs treat all TB cases, not just those linked with HIV. The alternatives—the prevention of HIV infection, TLT, and antiretroviral therapy—are less promising strategies to control TB, at least for the coming decade, although they could be used in combination with DOTS.

Active Case Finding

The DOTS strategy is based on passive case detection for three reasons: (a) the majority of incipient TB cases develop active

smear-positive, infectious disease more quickly than any reasonable interval between successive rounds of mass screening for TB symptoms or x-ray abnormalities; (b) the majority of patients severely ill with a life-threatening disease are likely to seek help quickly (Toman 1979); and (c) countries that have not yet implemented effective systems for passive case detection are not in a position to pursue cases more actively. The drawback of passive case finding is that the delays to diagnosis among symptomatic patients are often long, and health services never see some patients. To shorten delays and increase the proportion of cases detected, studies of risk can identify subpopulations in which TB tends to be relatively common. Systematic surveys of these subpopulations for active TB may be logistically feasible and affordable. The target populations include individuals infected with HIV, refugees (Marks and others 2001), contacts of active cases (Claessens and others 2002; Noertjojo and others 2002), health workers (Cuhadaroglu and others 2002), and drug users and prisoners (Nyangulu and others 1997). Despite the practical possibilities and the potential effect on transmission (Murray and Salomon 1998), active case finding is rarely done in high-burden countries, where the emphasis is still on implementing the basic DOTS strategy.

Case Finding and Treatment in the Private Sector

It is well known that many TB patients first seek treatment from private practitioners and that diagnosis and treatment in the private sector often do not meet internationally accepted standards (Uplekar, Pathania, and Raviglione 2001). A new scheme to deliver DOTS through the private sector (Public-Private Mix DOTS) operates through the provision of free drugs, by information exchange and patient referral, and with some financial support from participating governments. Two pilot projects in Hyderabad and Delhi, India, improved case-detection rates by 26 percent and 47 percent, respectively, and maintained treatment success close to the target of 85 percent (WHO 2004b). Other such projects are under way elsewhere in India as well as in Bangladesh, Indonesia, Nepal, the Philippines, and Vietnam (WHO 2004d).

Outpatient and Community-Based Treatment

Early studies of the cost-effectiveness of TB control found that full ambulatory treatment, eliminating hospitalization during the first two months (intensive phase), was cheaper and did not compromise cure rates (de Jonghe and others 1994; Murray and others 1991). Partly as a result, ambulatory treatment has become the standard of care in many high-burden countries. The natural extension, to home- and community-based treatment, has proved to be just as effective in several African settings, and even lower in cost (Adatu and others 2003; Dudley

and others 2003; Floyd and others 2003; Floyd, Wilkinson, and Gilks 1997; Moalosi and others 2003; Okello and others 2003; Sinanovic and others 2003; Vassall and others 2002; Wilkinson, Floyd, and Gilks 1997). Various schemes have been used to provide TB care in the community, in which nongovernmental organizations, volunteers (Okello and others 2003), or appointed “guardians” (Floyd and others 2003) supervise treatment, sometimes with financial incentives (Sinanovic and others 2003). Consequently, community-based care is being adopted in some countries (for example, Uganda) as standard procedure.

Integrated Management of Tuberculosis and Other Respiratory Illnesses

Surveys in nine countries found that up to one-third of patients over five years of age attending primary health centers had respiratory symptoms, of whom 5 to 10 percent were TB suspects, but only 1 to 2 percent had TB (WHO 2004e). Because TB is rare among respiratory diseases, comanaging TB with other conditions has clear advantages. The purpose of the WHO’s Practical Approach to Lung Health (PAL) project is to encourage a syndromic approach to management of patients, to standardize health service delivery through the development and implementation of clinical guidelines, and to promote the necessary coordination within national health services. Preliminary investigations in the Kyrgyz Republic and Morocco suggest that PAL projects can improve the accuracy of diagnosis, encourage better practice in prescribing drugs, and strengthen primary care. However, a full analysis of costs and effects in the nine-country study remains to be done.

COST-EFFECTIVENESS OF INTERVENTIONS AGAINST TUBERCULOSIS

Some questions about investing in TB control are broad and strategic (for example, should money be spent on the control of TB rather than on the control of some other condition?); others are specific and technical (for example, which laboratory diagnostic procedures should be used?). On whatever level the question is posed, cost-effectiveness analysis (CEA) has become a prominent method for evaluating and choosing among different health interventions.

Background

Between 1980 and 2004, 32 studies of the cost-effectiveness of TB control were published from the low- and middle-income countries considered by the Disease Control Priorities Project (table 16.1; online annex 3 summarizes the 32 studies that have been published according to the country and year of publication, the question being addressed, the strategies compared, the

Source: Authors.

subjects and costs considered, the effectiveness of measures used, whether or not transmission is considered, and the main results and conclusions). Almost all of these studies (28, or 88 percent) have concerned ways of finding, diagnosing, and treating patients with active TB, and most (18, or 56 percent) have been done in eight countries in Sub-Saharan Africa (Floyd 2003). Three studies (all in Sub-Saharan Africa) have investigated TLTI, and one study in Indonesia has examined BCG vaccination. The principal findings are that short-course chemotherapy for active TB is a comparatively cost-effective intervention and one of the most cost-effective of all health interventions. TB patients can be treated more cheaply and conveniently outside hospitals on an ambulatory basis, by health staff or with the help of family and community members, without compromising the success of treatment. Supplementary methods, such as standardized second-line drug treatment for MDR-TB, appear to be affordable and cost-effective in some settings.

What does not emerge from this compilation of data is a comprehensive overview of the value for money provided by current and potential interventions against TB in all major regions of the world, expressed using a common measure of effectiveness and based on a consistent approach to the evaluation of transmission. (The returns on investment in infectious disease control include the immediate benefits to individuals treated—for example, those vaccinated or given drug therapy—plus the longer-term benefits gained by preventing secondary

cases through reduced transmission.) Little work has been done in China, India, and other large countries in Asia, even though Asia carries the largest burden of TB, and only limited information is available for Europe and Central Asia, Latin America and the Caribbean, and the Middle East and North Africa. Of the 32 studies, only 10 used a measure of effectiveness that allows comparison with other diseases (table 16.2), and only 9 attempted to include an estimate of the benefits gained from reduced transmission (table 16.1). The benefits from reduced transmission are usually assessed through mathematical modeling (using computer simulations) for a given epidemiological situation, an approach that produces specific solutions for each setting rather than results that are generally applicable. In addition, although the benefits from prevented transmission are lower when TB is endemic, existing studies do not make a clear distinction between the cost-effectiveness of interventions in epidemic (outbreak) and endemic situations.

Methods

In this study, a general analytical framework was used to evaluate the total costs and total effects (defined as cases prevented, deaths averted, and DALYs gained) of the principal interventions against TB across six regions of the world (see online annexes 4–7 for further details). A dynamic infectious disease model (online annex 4) was used to derive general formulas for calculating the cost-effectiveness of interventions

Table 16.2 Number of Studies on the Cost-Effectiveness of TB Control by Effectiveness Measure and Intervention, 1980–2004

Intervention	Cases detected or cases diagnosed	Cases prevented	Cure or successful treatment rate	Deaths prevented	Years of life saved	QALYs gained	DALYs gained
BCG vaccination	0	1	0	1	0	0	0
TLTI	0	3	0	0	0	1	0

QALY = quality-adjusted life year.

Note: The total for all interventions is greater than the number of studies because some studies use more than one measure of effectiveness.

to control endemic (online annex 5) and epidemic (online annex 6) TB in a wide variety of settings. The formulas are approximate, but they are simple and able to provide insights into the strategies that give value for money under a wide variety of epidemiological circumstances. The model was then supplied with cost and efficacy data (online annex 7) for each of the six World Bank regions for four main groups of interventions:

- immunization with BCG (proportion of infants, m , assumed to be protected against severe, noninfectious childhood TB only), or a new vaccine that prevents infection and progression to pulmonary and extrapulmonary TB in children and adults
- isoniazid treatment of latent TB infection (TLTI, given at per capita rate ρ), for people infected with *M. tuberculosis*, with or without HIV coinfection and with or without the use of radiography to exclude patients with active disease
- short-course chemotherapy, delivered as a component of the DOTS strategy, for smear-positive or smear-negative pulmonary disease and extrapulmonary disease (with a combination of drugs given at per capita rate τ), and for patients infected with HIV, with or without supporting anti-retroviral therapy
- treatment for MDR-TB using a standardized regimen including first- and second-line drugs or using individualized regimens of first- and second-line drugs that are tailored to each patient's drug susceptibility pattern.

Costs were considered from a health system or provider perspective. They were calculated by combining estimates of the quantities of resources required for each intervention (per patient or per person treated) with the unit prices of those resources (in 2001 U.S. dollars) using the cost categories and unit prices defined in the Disease Control Priorities costing guidelines.

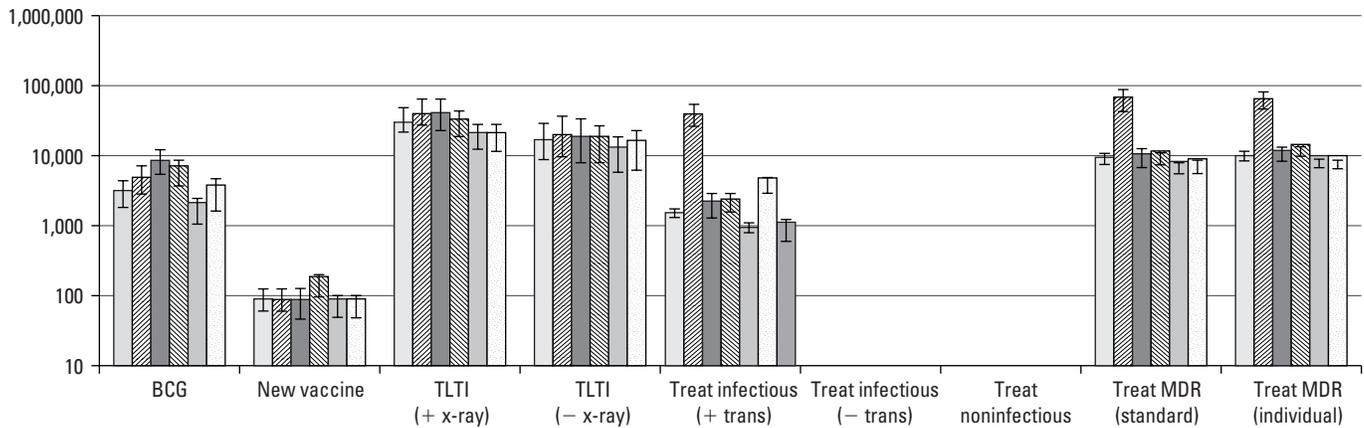

COST-EFFECTIVENESS OF MANAGING ENDEMIC TUBERCULOSIS

The primary problem in global TB control is the management of disease in countries where incidence has been roughly stable for many years (that is, where TB is endemic).

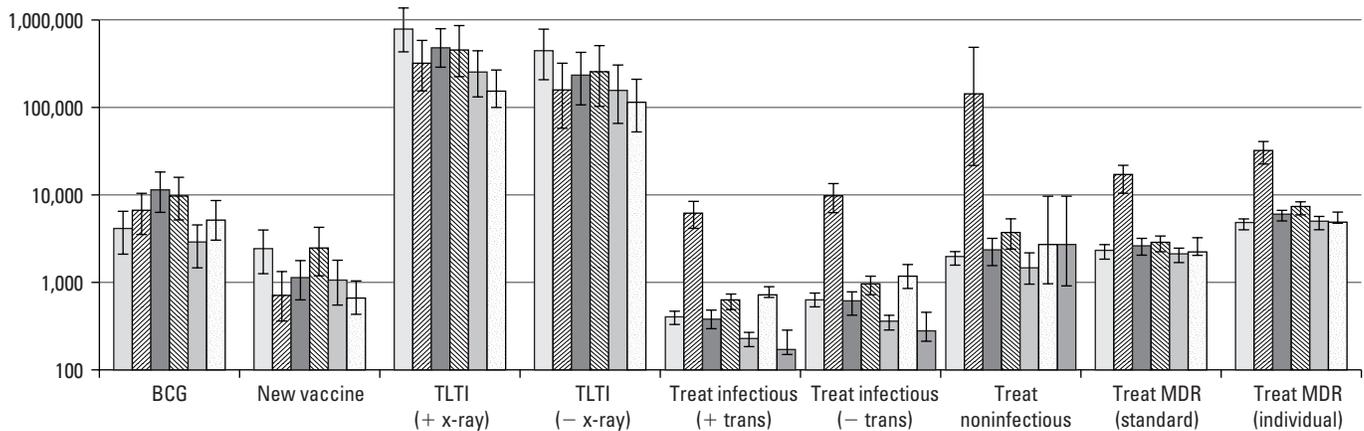

Cost per Case Prevented

In monetary terms, the cost-effectiveness (C/E) of a new program of treatment for active infectious disease (here defined as sputum-smear positive), per case prevented, can be calculated from $C/E \approx P/\epsilon kT$, where P is the cost of treatment, ϵ is the efficacy of treatment, k is a constant determined by the mode of action of the intervention, and T is the duration of the intervention in years (online annex 5). The cost per case prevented is mostly in the range of US\$1,000 to US\$10,000, depending on the region of the world (figure 16.1). The exception is Europe and Central Asia, where costs are high because patients are currently treated for long periods in hospitals rather than on an

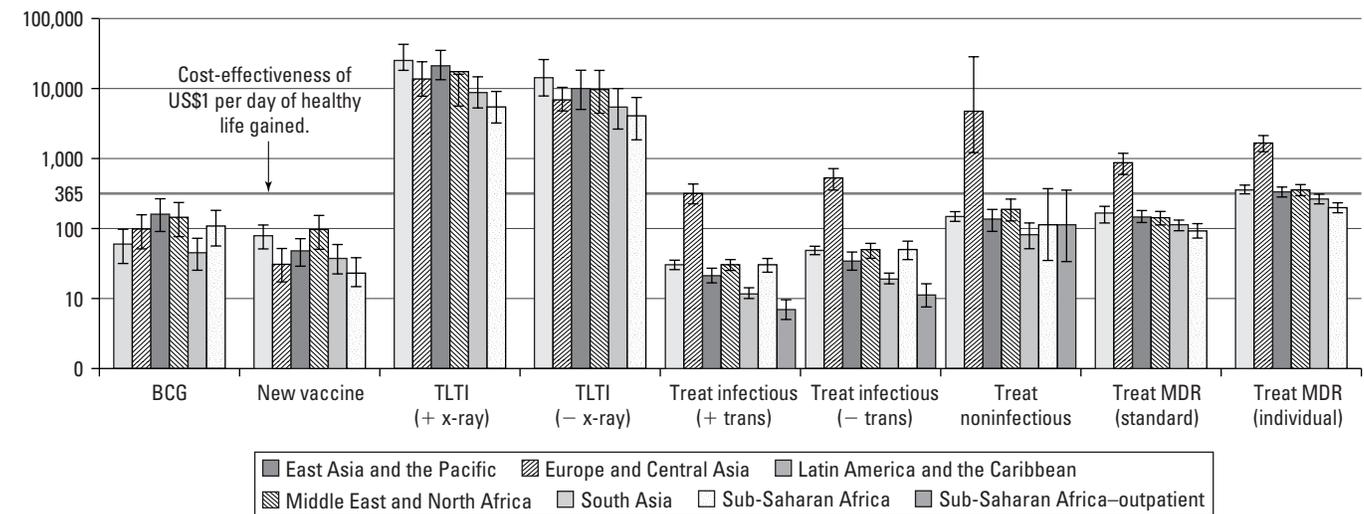

Cost per case prevented (US\$)

Cost per death prevented (US\$)

Cost per DALY gained (US\$)

Source: Authors.

Note: Where shown, bar 7 is for ambulatory (outpatient) treatment in Sub-Saharan Africa. The treatment of active disease saves no additional cases of TB when the effects of reducing transmission are excluded, so the cost per case prevented cannot be calculated. Cost-effectiveness of vaccination and TLTI is calculated for an initial incidence rate of 100 per 100,000 population per year. Cost-effectiveness ratios are plotted on a logarithmic scale. Error bars are 90 percent confidence limits. The horizontal gray line in the third chart marks a cost-effectiveness of US\$1 per day of healthy life gained.

Figure 16.1 Cost-Effectiveness of Different Interventions against Endemic TB

ambulatory basis. These cost-effectiveness ratios (CERs) are computed from the total costs and total effects of treatment. Costs are therefore the same as the incremental costs for new programs. If costs and effects are compared with those of a previous treatment program, CERs for the treatment of active disease are often negative; that is, the program sooner or later saves money, as well as preventing TB cases. The positive CERs reported here for new treatment programs are, in this sense, upper estimates.

The cost of TLTI per active case prevented also depends on the initial incidence rate (I) and is calculated from $C/E \approx P/\epsilon kIT$ (online annex 5). The cost is substantially higher than that for the treatment of active TB: US\$20,000 to US\$40,000 when radiography is used to exclude patients with active disease, but it is less (US\$13,000 to US\$20,000) if active TB can be ruled out on the basis of symptoms and clinical examination (figure 16.1). TLTI is less cost effective than the treatment of active TB because preventive treatment would be given to latently infected individuals, most of whom were not recently infected and who are at small risk of developing active disease. In an endemic setting, there is no feasible method of identifying individuals who have recently acquired infection and who will proceed rapidly to active TB.

A new vaccine that prevents infection and, hence, the progression to pulmonary TB among people who were previously uninfected would be extremely competitive (US\$90 to US\$200) per case prevented if the costs were the same as those for BCG. BCG is cheap to manufacture and administer (US\$1 to US\$3 per dose) but less cost-effective (US\$2,000 to US\$8,500 per case prevented) than the treatment of active disease because it is assumed to protect against severe forms of childhood TB only and because it does not affect transmission (figure 16.1).

Cost per Death Prevented and DALY Gained

The wider benefits of treating active TB are revealed when allowing for the additional reduction in case fatality. For a 10-year program of treatment for infectious TB, the cost per death prevented is typically US\$150 to US\$750, and the cost per DALY gained is US\$5 to US\$50 for all regions except Europe and Central Asia (figure 16.1). When TB is close to the endemic equilibrium, the extra benefits gained from reducing transmission under DOTS are small: the cost per DALY gained is only 60 percent higher when transmission benefits are excluded. The treatment of noninfectious TB is less cost-effective (US\$60 to US\$200 per DALY gained), not primarily because transmission is unaffected, but because the case fatality of untreated smear-negative and extrapulmonary disease is relatively low. Treating infectious MDR-TB is between two and ten times more costly than treating drug-susceptible TB per death prevented (greater than US\$2,000), or per DALY gained

(greater than US\$90), assuming resistant bacilli are as transmissible and pathogenic as susceptible bacilli.

BCG vaccination is not much less cost-effective than the treatment of active disease (US\$40 to US\$170 per DALY gained; higher where the risk of infection is lower). If a new vaccine with 75 percent efficacy against pulmonary disease and other forms of TB costs the same as BCG, it would be almost as cost-effective (US\$20 to US\$100 per DALY gained) as the ambulatory treatment of active TB. As expected from the preceding analysis, TLTI is much more expensive than all other options (US\$5,500 to US\$26,000 per DALY gained) and most costly where the death rate from TB among adults is already relatively low—for example, because an effective DOTS program already exists. Although the cost-effectiveness of each intervention varies among regions, the variation among strategies is much greater, whatever the outcome measure (figure 16.1).

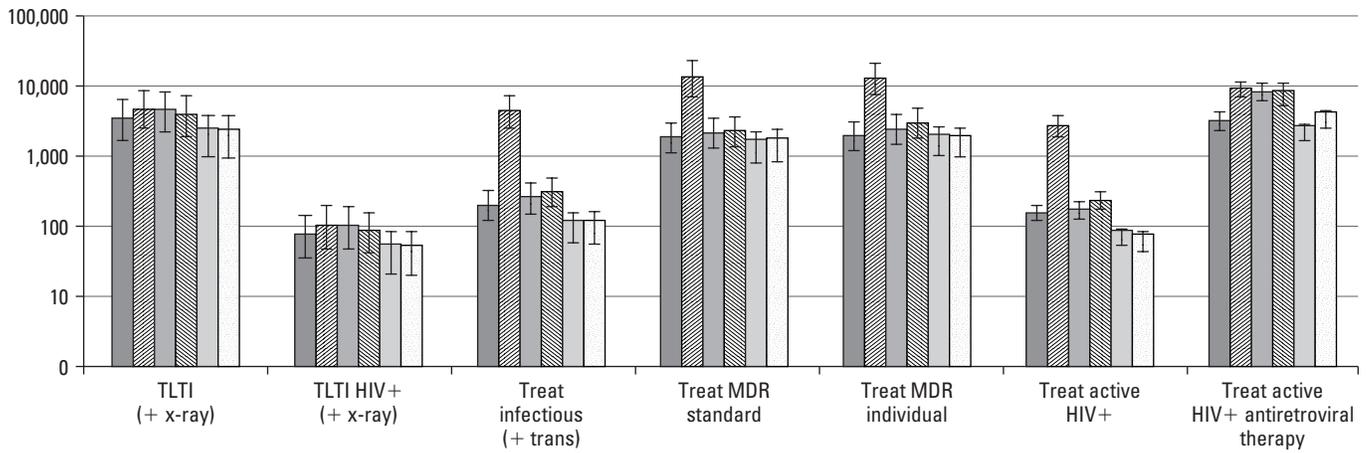

COST-EFFECTIVENESS OF MANAGING TUBERCULOSIS OUTBREAKS

The basic case reproduction number, R_0 , is a ready-made epidemiological tool for relating effort and reward in the management of outbreaks. R_0 is the average number of secondary cases generated by a primary case introduced into a previously uninfected population (Anderson and May 1991). No country is presently free of TB, but some countries have recently suffered “epidemic” increases in incidence from previously low levels. The algebraic expression of R_0 for TB reveals how the various components of a disease’s natural history and the different kinds of intervention interact with each other to influence transmission and the generation of new cases (online annex 4). For example, the cost-effectiveness of chemotherapy per *M. tuberculosis* generation is $C/E = P\sigma\tau/\epsilon R_0$, where τ is the number of TB patients treated per prevalent case per unit time, and σ is the proportion of new cases that is infectious.

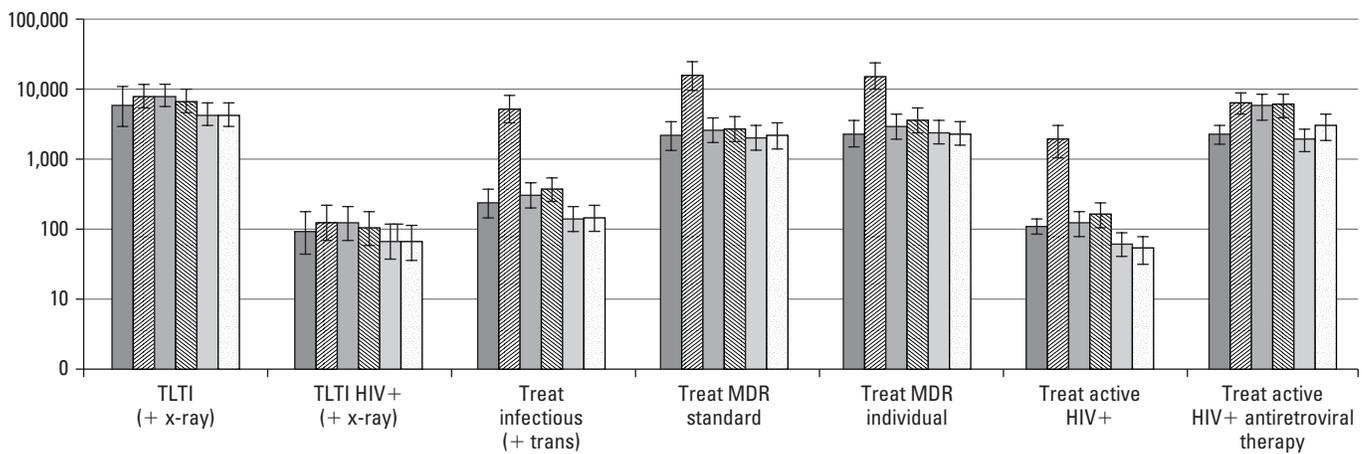

The biggest resurgences of TB in recent history have been driven by the spread of HIV in Africa and are linked to the rise of drug resistance in former Soviet republics; this analysis is confined to interventions associated with these two phenomena (figure 16.2; online annex 6). Indeed, in this study, interventions related to TB with HIV are considered only in the epidemic context.

If multidrug-resistant strains of *M. tuberculosis* are assumed to have the same intrinsic transmissibility and pathogenicity as drug-susceptible strains, and given the spread of MDR-TB as an independent epidemic (Dye and Williams 2000), then treatment of MDR-TB with a standard regimen including second-line drugs is more costly per DALY gained than treatment of fully susceptible disease in Sub-Saharan Africa, but it is marginally less costly than TLTI (with an x-ray screen) over most rates of case detection and treatment (online annex 6).

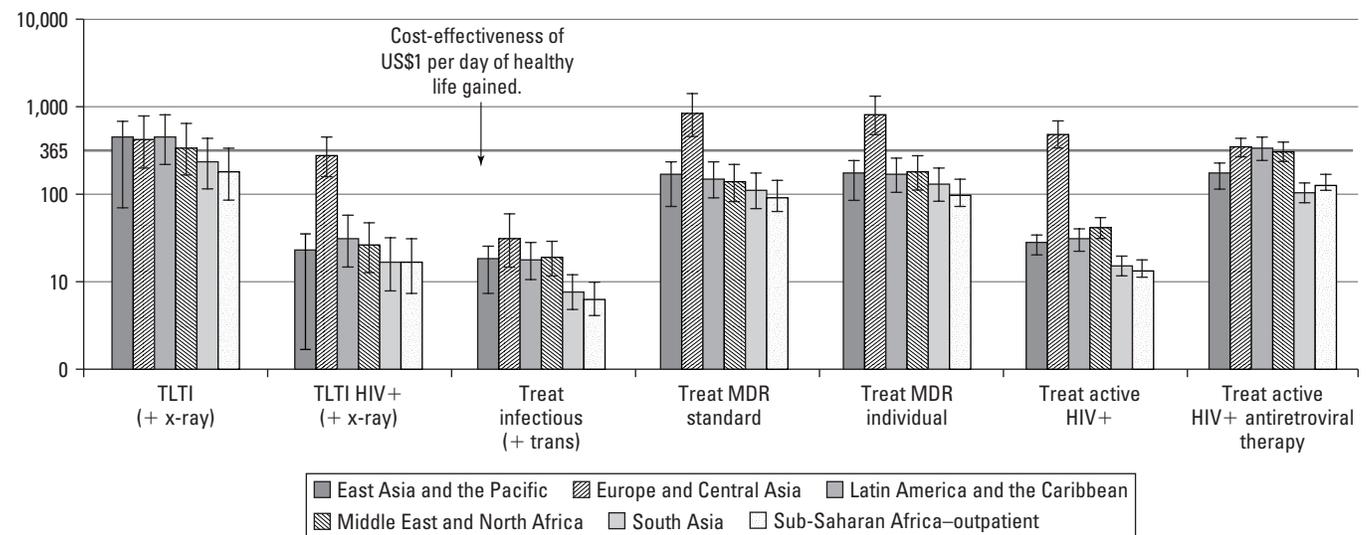

Cost per case prevented (US\$)

Cost per death prevented (US\$)

Cost per DALY gained (US\$)

Source: Authors.

Note: Five interventions used in the management of TB epidemics that are linked with HIV and MDR-TB (TLTI for people coinfecting with TB and HIV, treatment of infectious MDR-TB with a standard or individual regimen, treatment of HIV-infected TB patients with TB drugs, treatment of HIV-infected TB patients with TB and antiretroviral drugs) are compared with two standard methods (TLTI, with active disease excluded by x-ray screen, and treatment of active infectious disease, allowing for transmission). Cost-effectiveness ratios (plotted on a logarithmic scale) vary with the treatment rate (online annex 6); for illustration here, 20 percent of eligible people are treated annually with each intervention. The horizontal gray line in the third figure marks a cost-effectiveness of US\$1 per day of healthy life gained. Error bars are 90 percent confidence limits.

Figure 16.2 Cost-Effectiveness of Managing Epidemic TB

For example, at the fixed rate of treatment used to generate figure 16.2, treatment of MDR-TB with a standard regimen costs US\$91 to US\$846 per DALY gained, depending on the region, as compared with US\$6 to US\$31 for the treatment of drug-susceptible TB. The treatment of MDR-TB with regimens tailored to the resistance patterns of individual patients is more costly but also more efficacious than standardized treatment for MDR-TB and, therefore, almost equally cost-effective under this set of assumptions.

TB patients infected with HIV are more costly to treat per DALY gained than HIV-negative patients, either without antiretroviral therapy (low cost, short life expectancy) or with such therapy (high cost, long life expectancy). TLTI is a more attractive option for the management of epidemic TB than for endemic TB (compare figures 16.1 and 16.2), because during an outbreak, TLTI is directed at recent rather than remote infection. TLTI is even more cost-effective in the control of TB and HIV coinfection, because it prevents the rapid breakdown to active disease caused by immunodeficiency.

These results are indicative rather than definitive, because the calculations assume, among other things, that HIV-infected populations exist in isolation; in reality, HIV-infected people also acquire TB infection from TB patients who are not infected

with HIV. Neither does this analysis address all the important questions about managing outbreaks of drug-resistant or HIV-related TB. Fuller investigations should assess, for example, the benefits to whole populations of giving antiretroviral therapy to HIV-infected individuals before they develop TB and of investing in DOTS to prevent multidrug-resistant epidemics from arising in the first place.

SUMMARY OF COST-EFFECTIVENESS ANALYSES

Box 16.1 summarizes the results of these calculations of the cost-effectiveness of managing epidemic and endemic TB. The findings are one justification for maintaining and expanding DOTS programs, on the basis of SCC for patients with active disease, as the dominant mode of TB control around the world. BCG vaccination and the treatment of MDR-TB (standard or individualized regimens) or HIV-infected TB patients (with or without supporting antiretroviral therapy) are more costly in absolute terms, but they typically cost less than US\$1 per day of healthy life gained, which is less than the average economic productivity of workers in the least developed countries. TLTI appears to be relatively poor value for money, even though this analysis assumes that one course of treatment prevents active

Box 16.1

Cost-Effectiveness of TB Interventions: Main Findings

- The cost effectiveness of TB control depends not only on local costs but also on the local characteristics of TB epidemiology (for example, epidemic or endemic, low or high rates of HIV infection and drug resistance) and on the rate of application of any chosen intervention.
- Short-course chemotherapy for the treatment of infectious and noninfectious TB patients through the DOTS strategy is highly cost-effective for the control of either epidemic or endemic TB (US\$5 to US\$50 per DALY gained, for regions excluding Eastern and Central Europe). When a new treatment program is compared with a previous program, DOTS often saves money as well as preventing cases and deaths.
- Some variations on DOTS are less cost-effective but still good value for money, including the treatment of patients with MDR-TB (standard or individualized drug regimens) and with HIV infection (with or without supporting antiretroviral therapy). For these additional interventions, the cost per DALY gained is less than the annual average economic productivity per capita in the least developed countries.
- Even with relatively favorable assumptions, the treatment of latent TB infection where TB is endemic and populations are unaffected by HIV is the least cost-effective of the interventions examined here (US\$5,500 to US\$26,000 per DALY gained). TLTI is more cost-effective during outbreaks (US\$150 to US\$500 per DALY gained) and for people who are coinfecting with TB and HIV (US\$15 to US\$300 per DALY gained).
- BCG vaccination to prevent severe forms of childhood TB is much less effective than SCC but nearly as cost-effective (US\$40 to US\$170 per DALY gained).
- A new vaccine that prevents pulmonary TB with high efficacy (equal to or greater than 75 percent) would be more cost-effective than BCG if the cost of immunization were the same as BCG (US\$20 to US\$100 per DALY gained).
- For any intervention with the potential to cut transmission (that is, excluding BCG vaccination), control of epidemic disease produces more favorable cost-effectiveness ratios than control of endemic disease, because the benefits gained from reduced transmission are greater during outbreaks.

Source: Authors.

TB for life. TLTI is more cost-effective in epidemic than in endemic settings, and it is more cost-effective when it is used to treat individuals coinfecting with TB and HIV. A new, high-efficacy vaccine that prevents infection and the progression to pulmonary TB in adults, to be directed at the control of endemic TB, would be more cost-effective than BCG at the same price and almost as cost-effective as SCC.

Averted and Avertable Burden of Tuberculosis

Trends in case notifications can be used, judiciously, to assess regional and global trends in TB incidence, but no satisfactory large-scale analysis has been done of the number of cases prevented by chemotherapy (as distinct from the reductions in transmission and susceptibility associated with improved living standards). One approach to evaluating the averted and avertable burden of TB begins with the observation that 86 percent of the years of healthy life lost that are attributable to TB are from premature death, and only 14 percent are from illness. Because DALYs lost are dominated by premature death, a conservative estimate of the burden of TB alleviated can be obtained in terms of the number of deaths and associated DALYs gained, regionally and globally, since the introduction of the DOTS strategy in 1991.

Figure 16.3 is derived from recent estimates of cases and deaths and their trends by region, including those attributable to HIV coinfection (Corbett and others 2003; WHO 2004c). In the MDG baseline year, 1990, approximately 1.5 million TB deaths (28 per 100,000) occurred. BCG vaccination saved roughly 650,000 deaths from extrapulmonary TB among

children between 1990 and 2003. If chemotherapy is assumed to reduce only the case-fatality rate and to have no effect on transmission and incidence, 23 million deaths (44 percent) would have been saved in non-DOTS treatment programs. The expansion to 45 percent case-detection rate under DOTS during the same period saved an estimated 2.3 million (≈5 percent) additional deaths, the largest numbers in Sub-Saharan Africa (1.1 million), East Asia and the Pacific (558,000), and South Asia (408,000). Further analysis shows that, if 70 percent of TB cases (smear positive and smear negative) can be treated under DOTS before MDG target year 2015, an estimated 1.9 million TB deaths (26 per 100,000) will occur in that year, a greater number than in 1990, but a 7 percent lower death rate per capita (Dye and others 2005).

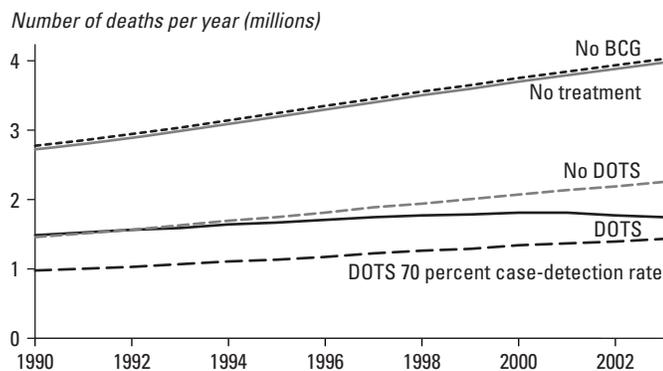

The calculations for Africa assume that treatment cures TB in the majority of HIV-infected patients even though, without antiretroviral therapy, many of these patients will die anyway. Despite these favorable assumptions, the number of TB deaths was evidently still rising in Africa in 2003, whereas it was falling in Asia, aided by the large programs of DOTS expansion in China (1991–97) and India (from 1998).

Reducing the TB death rate sufficiently to meet the MDG target requires a significant cut in incidence, as well as in case fatality. An extension of this assessment suggests that case detection must reach at least 70 percent and the TB incidence rate must fall by 5 to 6 percent annually between 2003 and 2015 (Dye and others 2005). For the world, excluding Sub-Saharan Africa and former Soviet republics, the incidence rate would have to fall at a more modest 2 percent per year.

New diagnostics, drugs, and vaccines would also help reduce the global TB burden more quickly. The most desirable of these is a vaccine that prevents pulmonary disease, whether or not vaccination subjects are already infected (a pre- or postexposure vaccine), and that confers lifetime immunity (Andersen 2001; Fordham von Reyn and Vuola 2002; McMurray 2003; Young and Stewart 2002). A new vaccine with high efficacy against pulmonary TB would almost certainly change immunization practice: mass vaccination campaigns among adults (rather than infants) would have dramatic effects, going far beyond the expectations of DOTS programs (figure 16.4; Dye 2000). A postexposure vaccine that stops progression to disease among those already infected, as well as preventing infection in others, would have greater effect than a preexposure vaccine that only prevents infection (Lietman and Blower 2000). However, such calculations are at present highly speculative, because the mode of action and efficacy of any new vaccine is unknown.

Economic Benefits of Tuberculosis Control

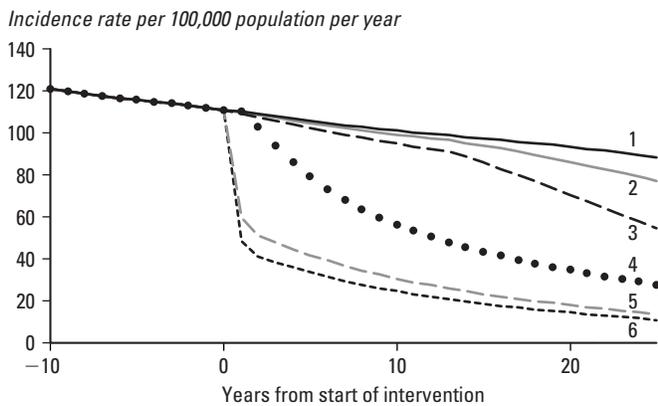

Preventing TB deaths brings no savings in the costs of TB control unless it is accompanied by a reduction in incidence so that fewer patients require treatment. The prompt and effective

Source: Authors.

Note: Broken and gray lines represent various hypothetical scenarios; the solid black line represents DOTS programs. The interventions are, from top to bottom: no BCG vaccination and no anti-TB treatment, no treatment, no DOTS programs, DOTS expansion from zero to 45 percent case detection over the period 1990–2003, and DOTS with 70 percent case-detection rate throughout the period 1990–2003. To make a conservative assessment of effect, the treatment of active TB is assumed to change the case-fatality rate without affecting the TB incidence rate.

Figure 16.3 Estimated Number of TB Deaths Worldwide under Various Hypothetical Scenarios and the Estimated Effect of DOTS Programs, 1990–2003

Source: Dye 2000.

Note: Lines and points show: (1) no intervention in a population where TB is already in slow decline, as in many countries in Asia and Latin America; (2) a postexposure vaccine given annually to infected infants so that 20 percent are immunized; (3) a postexposure vaccine given annually to infected infants so that 70 percent are immunized; (4) DOTS reaching 70 percent case detection and 85 percent cure by year 5 and maintained at these levels thereafter; (5) one-time mass immunization with a preexposure vaccine giving 70 percent protection to uninfected people, followed by annual vaccination of infants with the same fraction protected; and (6) one-time mass immunization with a postexposure vaccine giving 70 percent protection to uninfected people, followed by annual vaccination of infants with the same fraction protected.

Figure 16.4 Hypothetical Effect of New Vaccines on TB Incidence Rate

treatment of active disease is almost certainly reducing transmission around the world, but because the effect on incidence is necessarily slow, it has been hard to quantify in all but a few countries, notably Peru (Suarez and others 2001).

The monetary savings implied by a reduction in incidence of one-quarter (26 percent) between 2000 and 2015—which may be enough to achieve the MDG targets—could be magnified or diminished by adjustments to the DOTS strategy. On the one hand, without compromising cure rates, chemotherapy can be delivered more cheaply to outpatients than inpatients and with less reliance on x-ray diagnosis and surgical procedures. On the other hand, various additions to DOTS—contact tracing, active case finding, antiretroviral therapy for HIV-infected patients, second-line drugs for patients carrying resistant bacilli, or joint public-private schemes for the management of TB—might be desirable but more costly per year of healthy life gained. Whether the savings made by reducing incidence and improving efficiency offset the costs of DOTS add-ons will, therefore, depend on the setting.

Besides the possibility of reducing diagnostic and treatment costs, improved health and longevity yield other economic benefits, but the quantification of those benefits is always controversial. This difficulty is reflected in the limited number of cost-benefit analyses of TB control; among the few examples, one detailed study in India estimated the potential societal benefits of DOTS to be worth US\$8.3 billion in 1993–94, or 4 percent of the gross domestic product (Dholakia 1996). Without attempting to extend such analyses here, we note that the preceding results also imply that large-scale treatment programs

for TB are likely to give net returns on investment or at least to appear to be good value for money in ways that go beyond the arguments from cost-effectiveness (Jack 2001).

The analysis earlier in this chapter showed that SCC typically costs up to US\$30 per DALY gained for the treatment of infectious TB and up to US\$200 per DALY gained for the treatment of noninfectious TB (excluding Europe and Central Asia). These figures can be compared with a recent estimate of US\$1.5 billion as the annual global cost of treating 70 percent of cases with 85 percent cure (WHO 2004c). Reaching these targets would prevent approximately 2.1 million of all the TB deaths expected if no treatment were available in 2003, including 391,000 deaths prevented by DOTS (figure 16.3). Because each TB death prevented gains approximately 20 DALYs (WHO 2002b), the total cost per DALY gained would be about US\$36. This rough calculation excludes any benefits in reduced transmission but includes the costs of treating smear-negative and extrapulmonary TB and is of the same order of magnitude as the results from CEA.

However the calculation is done, the cost of gaining a year of healthy life under DOTS is substantially less than the annual average productivity per capita in the low-income (gross national income [GNI] less than or equal to US\$735) or least developed (GNI average US\$290, <http://www.worldbank.org>) countries, and it is probably less than the marginal productivity of labor in the poorest communities. It is also less than twice the average annual income per capita, which has also been proposed as a benchmark for assessing whether an intervention is cost-effective (Garber and Phelps 1997). Moreover, it is less than the World Bank's definition of *absolute poverty* (living on US\$1 per day or less, close to average GNI per capita for the least developed countries) and is certainly less than the monetary values that are typically placed on the value of a human life year (for example, a life was valued at US\$100,000 by the 2004 Copenhagen Consensus panel, <http://www.copenhagenconsensus.com>). All these comparisons suggest not only that the basic DOTS strategy, and perhaps even an enhanced DOTS strategy, are cost-effective but that they also have very favorable cost-benefit ratios.

RESEARCH AND DEVELOPMENT

The preceding review and analysis suggest at least six areas for economic and epidemiological research and development:

1. *DOTS expansion.* Refinement of existing cost estimates of scaling up DOTS programs to reach and move beyond targets for case detection (70 percent) and cure (85 percent) in the poorest countries—notably in Africa—through more comprehensive planning and budgeting exercises. The analyses should include the costs of developing fully staffed

health services, with expanded and renovated infrastructure and improved management capacity where necessary, and the costs of the new initiatives that will be required to improve case detection and cure rates.

2. *Service delivery.* Assessment of the potential for health service restructuring to detect, diagnose, and treat TB patients more efficiently through syndromic management of respiratory diseases at primary health centers and through collaborations between public and private health services, between different parts of the public sector health service, and between TB and HIV/AIDS control programs.
3. *Complementary strategies.* Further investigation of the costs and effectiveness of strategies that are potentially complementary to DOTS, including active case finding and TLTI in high-risk populations, and the management of drug resistance and of patients infected with HIV.
4. *Impact and targets.* Evaluation of the actual and potential effects of the tools (mostly drugs) now being used for TB control. This research requires a better understanding of the ways human population density, age structure, migration, HIV coinfection, and drug resistance affect TB epidemiology. The analyses should check the internal consistency of international targets for the implementation and effect of chemotherapy programs, as defined by the MDGs. The analyses should also make better use of the rich body of routine surveillance data collected by all national TB control programs around the world.
5. *Risk factors.* Assessment of the reductions in TB cases and deaths that could be made by reducing exposure to environmental risk factors, notably indoor and outdoor air pollution, tobacco smoking, and malnutrition. These risk factors affect the establishment of infection, the progression to active disease, and the outcome of treatment.
6. *New diagnostics, drugs, and vaccines.* A sensitive and specific test for active TB that is cheap and simple to use at the first point of contact between patients and health services would be a major advance in diagnosis. Mycobacterial culture, which detects a higher proportion of active TB patients than sputum-smear microscopy, is a prerequisite for screening for drug resistance. However, present culture methods are slow, taking four to six weeks to obtain a result. Technology based on phage amplification and nucleic acid amplification can establish whether cultures are positive in days or hours, but this technology needs to be packaged for use in developing countries (Albert and others 2002, 2004; Johansen and others 2003; Woods 2001). The tuberculin skin test is being superseded in many developed countries by more specific methods for detecting infection (Doherty and others 2002; Pai, Riley, and Colford 2004). A test that can predict who will progress from latent to active disease, as yet hypothetical, would greatly increase the feasibility of treating latent infection.

Among a growing list of new vaccine antigens (Fruth and Young 2004), three of the most promising are now undergoing phase 1 safety trials in humans. One trial has evaluated mycobacterial antigen 85, delivered as a recombinant smallpox vaccine (Goonetilleke and others 2003). Another is testing a live attenuated BCG bacterium (rBCG30) that overexpresses antigen 85B protein and that provides guinea pigs with greater protection than BCG alone (Horwitz and others 2000). A third trial is assessing a fusion protein of two different antigens in adjuvant, referred to as Mtb72f, that is likely to be used as a booster to either BCG or rBCG30 (Reed and others 2003). Compounds that could form the basis of new drugs and new drug regimens include the nitroimidazopyran PA-824. Experiments with a mouse model of TB have shown that PA-824 has bactericidal activity similar to that of isoniazid and sterilizing activity that may rival that of rifampicin and that it is particularly active against dormant bacilli.

Among the most important recent discoveries is a diarylquinoline with a novel mode of action on the ATP synthase of *M. tuberculosis* that powerfully inhibits both drug-sensitive and drug-resistant strains of bacilli (Andries and others 2004). Alongside these laboratory studies, analytical and operational research are needed to find out what kinds of new tools will give the best returns on investment. Investigations of this kind will contribute to the introduction of new vaccines, drugs, and diagnostics and will inform the work of the Foundation for Innovative New Diagnostics (<http://www.finddiagnostics.org>), the Global Alliance for TB Drug Development (<http://www.tballiance.org>), and the AerasGlobal TB Vaccine Foundation (<http://www.aeras.org>).

CONCLUSIONS

After more than a decade of climbing incidence rates in Africa and former Soviet republics, the global TB epidemic appears once again to be on the threshold of decline. The spread of HIV and drug resistance, respectively, in those two regions has exacerbated the problems of TB control, but at the same time it has helped keep TB on the international public health agenda. The global incidence rate was still rising in 2003, but more slowly each year. This slowdown is not only (or even mainly) because of direct intervention through DOTS programs but because HIV epidemics are approaching peak levels in Africa and because incidence is now starting to fall again in some former Soviet republics, including Russia. Where TB incidence is already falling, prevalence and death rates should be dropping more quickly, although little evidence demonstrates this decrease yet.

The prompt diagnosis and treatment of active TB has been the mainstay of TB control and will continue to be so for the foreseeable future. Short-course chemotherapy, delivered

through the DOTS strategy, is, at typically US\$5 to US\$350 per DALY gained, the most cost-effective among current methods for the management of TB, and in most high-burden countries, the cost is toward the lower end of this range. A comparison of the costs of treating active TB with the costs of running a previous program suggests that DOTS could actually save money in the long run. In addition, DOTS provides an operational framework for the introduction of more specialized methods in certain risk groups. The extensions to DOTS investigated here include the treatment of MDR-TB with second-line drugs, preventive therapy (TLTI) during outbreaks and for people coinfecting with *M. tuberculosis* and HIV, and antiretroviral therapy for HIV-infected TB patients. Those interventions cost more than the basic DOTS strategy but are still less than a dollar for each day of healthy life gained, which provides an economic argument for their integration into enhanced DOTS programs.

Although the analyses in this chapter show that DOTS and its extensions are good value for money, they conceal various features of health systems, as yet poorly defined, that may facilitate the implementation of treatment programs. For example, if broader investment in the health sector is needed before TB control programs can work in some parts of some countries, then the full cost of DOTS could be greater. By contrast, a more integrated approach to the management of TB and other respiratory diseases in primary health facilities could lead to cost savings. Those possibilities have not yet been investigated.

The only development that could radically alter the current approach to TB control—shifting the emphasis from cure to prevention—is the discovery of a new vaccine that protects adults against infectious pulmonary disease. Whether such a vaccine would be more or less cost-effective than BCG (US\$40 to US\$1,600 per DALY gained) depends on price and efficacy, but the potential epidemiological effect would be far greater than that of BCG, perhaps justifying mass adult vaccination. If research and development proceed according to plan, a new vaccine of some kind could be licensed between 2010 and 2015. New drugs and diagnostics should be available earlier, shortening the delay to, and duration of, treatment.

Although cost-effectiveness studies show that DOTS is a good investment, they do not formally show that the strategy is affordable. The analytical difficulty is that CEA does not solve the practical problem of how to allocate money to TB control in combination with other interventions, or even how to combine different approaches to TB control (Tan-Torres Edejer and others 2004). Interpreted literally, CEA says that the best return on total investment is obtained by ranking interventions according to CER and then fully implementing each intervention, from smallest to largest CER, allowing for diminishing returns, until the total budget is spent. This method is unlikely to lead to a balanced health care portfolio in the poorest countries. Besides, the evidence is rarely available to carry out

such a complete analysis. The results of CEA are therefore typically used more informally, along with other evidence and constraints, when a mix of health interventions is chosen.

Although this problem will recur in discussions about allocating health budgets, the case for large-scale programs of TB treatment has now been accepted in many parts of the world. That is the fruit of more than 10 years' work on burden, cost, efficacy, effectiveness, and cost-effectiveness. The governments of the less poor members of the group of 22 high-burden countries have demonstrated that they can budget for, and provide, most of the funds needed to reach target levels of case detection and cure (WHO 2004c, 2005). Some of the poorer countries among the 22 are now receiving sufficient external assistance to fill the gaps in their budgets for TB control, principally from the Global Fund to Fight AIDS, Tuberculosis, and Malaria. Consequently, the total reported budget deficit for the high-burden countries in 2005 was remarkably small—just US\$119 million—and concentrated in the poorest countries (WHO 2005).

From those findings and observations arise two key questions for global TB control: If the estimated budget gap is filled, would the money be enough to ensure that enhanced DOTS programs reach 70 percent case detection and 85 percent cure—and by when? And if those targets are reached, will the effort be sufficient to achieve the MDG objectives of halving prevalence and death rates by 2015?

As yet, there are only partial answers. On the costs, it is clear that, by moving treatment out of hospitals and into the community, DOTS can often be made cheaper and more convenient for patients and health services without compromising treatment outcome. However, planning for TB control in the poorest countries is still inadequate, and budgets commonly understate the real costs of scaling up national TB control programs (WHO 2004c, 2005). Despite those weaknesses in the budgeting and funding process, the overall expenditure on TB control in high-burden countries has increased since 2000, and the injection of extra effort and money has led to a small acceleration in case finding globally. As a result, case detection under DOTS could reach 50 to 60 percent by 2005, and treatment success should be close to the target level of 85 percent.

A case-detection rate of 50 to 60 percent may not be enough. The analysis in this chapter suggests that the MDG objective of halving the death rate can be reached with 70 percent case detection globally, provided this case detection also generates a 5 to 6 percent annual reduction in the incidence rate between 2003 and 2015. The DOTS program in Peru generated a 6 to 7 percent annual reduction in the incidence rate of pulmonary TB, but that result has not yet been repeated in other high-burden countries with good control programs (for example, India, Morocco, and Vietnam). It is unlikely to be achieved in African countries that currently have high rates of HIV infection.

Although others have emphasized that the costs of infectious disease control can be related to the benefits in complex ways (Brandeau, Zaric, and Richter 2003), we advocate the use of a powerful new method of carrying out CEA, which is based on the observation that mathematical models can be used to generate simple (albeit approximate) and general formulas that relate reward to effort in the management of both epidemic (based on R_0) and endemic (based on dynamics in the vicinity of equilibrium) TB. The results are similar to those obtained by using more complex simulations in specific settings, and they are accurate enough to offer a choice between interventions (Currie and others, 2005). The generality of the method exposes more clearly the reasons some interventions are comparatively cost-effective and indicates the range of conditions under which specific cost-effectiveness results apply. The scope for using this approach for other infectious diseases remains to be explored, but it should be readily applicable in the evaluation of new approaches to TB control, whether through vaccination, drug treatment, the reduction of environmental risks, or improved service delivery.

ACKNOWLEDGMENTS

The authors wish to thank Uli Fruth, Kreena Govender, Ulla Griffiths, Mehran Hosseini, Anne Mills, Mark Perkins, Catherine Watt, Diana Weil, and Brian Williams for help of various kinds during the preparation of this chapter.

Sexually Transmitted Infections

Sevgi O. Aral and Mead Over, with Lisa Manhart and King K. Holmes

Sexually transmitted infections (STIs) are responsible for an enormous burden of morbidity and mortality in many developing countries because of their effects on reproductive and child health (Wasserheit 1989) and their role in facilitating the transmission of HIV infection (Laga, Diallo, and Buvé 1994).

INTRODUCTION

Largely because of the HIV epidemic, interest in STIs has increased over the past two decades. During that time, the epidemiology of STIs has changed in developing countries, partly as a result of modifications in STI case management approaches and partly because of behavioral changes in response to the HIV epidemic. At the same time, advances in STI prevention have enhanced understanding of the intricacies of STI transmission dynamics and the role of interventions in the control of STIs. However, what has not changed is as significant as what has changed: the epidemiology of STIs still differs substantially in the industrial countries and the developing world. The sociocultural and economic contexts in developing countries influence the epidemiology of STIs and help make them an important public health priority.

Incidence and prevalence rates of STIs are generally high in both urban and rural populations and vary considerably across areas. Because diagnosis and treatment of STIs are often delayed, inadequate, or both, rates of STI complications are also high in developing countries. Those complications include pelvic inflammatory disease, ectopic pregnancy, and chronic abdominal pain in women; adverse pregnancy outcomes, including abortion, intrauterine death, and premature delivery;

neonatal and infant infections and blindness in infants; infertility in both men and women; urethral strictures in men; genital malignancies, such as cancer of the cervix uteri, vulva, vagina, penis, and anus; arthritis secondary to gonorrhea and chlamydia; liver failure and liver cancer secondary to hepatitis B or human T cell lymphotropic virus type I; and central nervous system disease secondary to syphilis (Holmes and Aral 1991; Meheus, Schulz, and Cates 1990; van Dam, Dallabetta, and Piot 1999). Thus, STI sequelae affect mostly women and children.

In developing countries, high levels of STIs and high rates of complications and sequelae result largely from inadequacies in health service provision and health care seeking (Aral and Wasserheit 1999). STI care is provided by a large variety of health care providers, many of whom are poorly trained in STI case management, and the quality of care they provide is often less than desirable (Moses and others 1994; WHO 1991). Health care seeking for STIs is frequently inadequate, particularly among women (van Dam 1995), because of the low levels of awareness regarding sexual health, the stigmatization associated with genital symptoms, and the asymptomatic nature of many STIs. A study in Nairobi, Kenya, found that 42 percent of patients had been symptomatic for more than a week before coming to a clinic and that 23 percent had been symptomatic for more than two weeks (Moses and others 1994).

Setting up good-quality STI services is considerably more difficult in resource-poor settings than elsewhere. Variables that affect the duration of infectiousness include adequacy of health workers' training, attitudes of health workers toward such marginalized groups as sex workers, patient loads at health centers, availability of drugs and clinic supplies, and

costs of care (Moses and others 2002). Thus, improvements pertaining to all these factors would greatly improve STI-related services, help reduce the duration of infectiousness, and decrease the incidence of STIs (Aral 2002a). However, in many countries in the developing world, worsened economic conditions and the increasing burden of HIV/AIDS have negatively affected these variables. For example, in South Africa, the ratio of hospital beds to population declined from 6.5 per 1,000 in 1976 to 2.3 in 1996; during 1999, approximately 300 professionally trained nurses left the country each month; and student enrollments in nursing school declined from 12,282 in 1996 to 10,398 in 1999 (Aral 2002a).

Sexual behaviors also contribute to the STI burden in developing countries. These behaviors are heavily influenced by the sociocultural, economic, and political contexts, which in the past two decades have deteriorated at an accelerated rate in many areas. Societal change has included rising levels of inequality within countries, growing inequality between countries, increased levels of globalization, increased proportions of people who live in cultures they were not born in, and a larger proportion of the world's population living in postconflict societies (Aral 2002a). One effect of these changes is an increase in multipartner sexual activity, which in turn increases the rate at which infected and susceptible individuals are sexually exposed to each other and consequently the rate at which STIs spread.

Changes in STI Epidemiology, Management, and Prevention since 1993

Since 1993, STI epidemiology and management have evolved interactively, particularly in developing countries. Technological advances in diagnosis, screening, and treatment; evaluation and widespread implementation of new case-management algorithms; and changes in risk behaviors in response to the AIDS epidemic have all influenced the dynamic typology of STIs (Wasserheit and Aral 1996).

The introduction of nucleic acid amplification tests, which have improved the sensitivity and expanded the repertoire of usable specimens, has heralded a new era in STI diagnosis. The use of urine and vaginal swabs in diagnosis has enabled providers to supply diagnostic and screening services outside traditional clinical facilities and has greatly enhanced the coverage of outreach activities (Schachter 2001). Unfortunately, many of these tests are currently too expensive for routine use in developing countries. Single-dose oral azithromycin has improved the treatment of several bacterial STIs (Lau and Qureshi 2002), but quinolones are apparently becoming ineffective for gonorrhea in some locations (Donovan 2004).

A major recent advance in STI prevention is the early success of a prophylactic, monovalent human papillomavirus (HPV) type 16 vaccine (Koutsky and others 2002); HPV

vaccines may be able to help prevent genital and anal cancers in the foreseeable future. Researchers are evaluating multivalent vaccines for preventing moderate to severe cervical dysplasia as well. Other advances include easier episodic treatment of genital herpes (Strand and others 2002) and the use of suppressive therapy to reduce the transmission of genital herpes to regular partners (Corey and others 2004). In a related development, a prophylactic vaccine against herpes simplex virus type 2 (HSV-2) has shown limited efficacy in that it has proved partly effective for HSV-seronegative women, but not for men or herpes simplex virus type 1 (HSV-1) seropositive women (Stanberry and others 2002). Prevention successes of the recent past include STI sequelae, such as pelvic inflammatory disease and cervical cancer. A randomized controlled trial showed that selective screening of women for *Chlamydia trachomatis* significantly reduced the incidence of pelvic inflammatory disease (Scholes and others 1996).

Widespread implementation of syndromic management as an approach to STI case management has apparently had a considerable effect on the epidemiology of STIs, particularly in resource-poor settings (King Holmes and Michael Alary, personal communication, May 15, 2003).

In some developing countries, including Cambodia, the Dominican Republic, and Thailand, sexual risk behaviors have been changing over the past decade. In Uganda, for example, the age of sexual debut has increased, the frequency of sex with casual partners has decreased, and the use of condoms has increased (Stoneburner and Low-Beer 2004). During the 1990s, demographic and health surveys in 29 developing countries asked individuals if they had done anything to avoid AIDS (Low-Beer and Stoneburner 2003): almost 80 percent of men and 50 percent of women surveyed reported that they had. Specific behavior changes reported included increased monogamy, reduced number of partners, avoidance of sex workers, and increased condom use.

By contrast, in developed countries, recent years have seen behavior changes in the opposite direction; for example, in many European countries and in the United States, risk behaviors among men who have sex with men have increased significantly (CDC 2004; L. Doherty and others 2002). In addition, Grémy and Beltzer (2004) report declines in condom use among heterosexual adult populations in Europe. Investigators attribute increases in risk behaviors to the introduction and availability of antiretroviral therapy for HIV infection and the difficulties in sustaining preventive behaviors in the long term, referred to as *prevention fatigue*. Some researchers speculate that the widespread introduction of antiretroviral therapy in developing countries may have a similar disinhibitory effect on sexual behaviors and that changes in sexual behavior may offset the beneficial effect of antiretroviral therapy (Blower and others 2001; Blower and Farmer 2003; Blower and Volberding 2002; Over and others 2004).

Advances in STI prevention in recent decades have enhanced understanding of transmission dynamics and the role of interventions. Investigators have articulated the following five emergent insights about STI epidemiology and prevention over the past two decades:

- Populations consist of many diverse subpopulations, and each population-level epidemic trajectory consists of many distinct subpopulation epidemic trajectories (Pisani and others 2003). The epidemic trajectories of specific STIs differ depending on when and where the infection was introduced; the natural history and transmissibility of the infection; the structure of sexual networks; the demographic, economic, social, and epidemiological context; and the state of the health system (Aral and others 2005).
- Temporal dimensions are important in relation to STI epidemiology (Aral and Blanchard 2002). At the individual level, concurrency of partnerships and gaps between partnerships are risk factors for the acquisition and transmission of STIs (Adimora and others 2002; Agrawal, Gillespie, and Foxman 2001; Kraut and Aral 2001). At the population level, investigators have described the evolution of STI epidemics through sometimes predictable phases, characterized by changing patterns in the distribution and transmission of STI pathogens within and between subpopulations (UNAIDS and WHO 2000; Wasserheit and Aral 1996).
- Sexual networks are important in the transmission dynamics of STIs at the population level, and position in a sexual network is important in the transmission and acquisition of STIs at the individual level (Morris 2004).
- Trajectories whereby STI epidemics evolve differ for different types of population-pathogen interactions (Aral 2002a; Blanchard 2002; Garnett 2002). Whereas highly infectious, short-duration bacterial STIs—for instance, gonorrhea—depend on the presence of core groups marked by multiple sex partnerships of short duration for their spread, less infectious, long-duration viral STIs—for example, HSV—depend on the presence of multiple partnerships of longer duration.
- Interactions among sexually transmitted pathogens affect STI epidemic trajectories at the population level (Wasserheit 1991). The inconsistent findings of three landmark randomized community trials evaluating the effect of STI treatment on HIV transmission (Grosskurth and others 1995; Kamali and others 2003; Wawer and others 1999) can be accounted for by the complex, multifactorial, multilevel, and phase-specific nature of STI epidemics (Orroth 2003).

Epidemiology and Control

The epidemiology of STI pathogens, the local prevention and care infrastructure, and the cultural and sociopolitical context

vary considerably within and across developing countries. At the same time, health care delivery for STIs varies by type of institution and location, although inadequate resources are universal in the developing world, as are recordkeeping, data management, and data analysis. The limited data that are available suggest that STIs are a major public health burden in the developing world. Although the prevalence and incidence of bacterial STIs have apparently declined because of expanded syndromic management, changes in sexual behavior, and death of high-risk populations, the prevalence and incidence of viral STIs seem to have increased over the past decade.

Syndromic Management. Health systems can use three different approaches to manage patients presenting with symptoms suggestive of an STI. First, etiology-based management relies on identifying causative micro-organisms or detecting specific antibodies. It requires costly and often technically complex laboratory diagnosis, trained personnel, quality assurance programs, and infrastructure. Second, clinical diagnosis-based management is rapid, inexpensive, and requires less infrastructure than etiology-based management; however, clinical diagnosis is often inaccurate, may miss multiple infections, and may result in undertreatment or overtreatment. Third, syndromic management, which is based on the recognition of a constellation of clinical signs and symptoms, is inexpensive, can be standardized, and can be used by both physicians and paramedical personnel, though it often results in some overtreatment. Nevertheless, syndromic management has been recommended as a realistic approach for managing symptomatic patients in developing countries (Over and Piot 1993). Implementation issues associated with the syndromic management approach involve inadequate local evaluation of treatment algorithms because of a lack of local data, inconsistencies in implementation, and inadequate monitoring (Dallabetta, Gerbase, and Holmes 1998; Hawkes and Santhya 2002; WHO 2001b).

Limitations of the syndromic management approach include the inability to directly target the subclinical STI pool, the variability of STI symptoms and signs, the potential for wasting antibiotics, the risk of promoting drug resistance, and the unintended consequence of decreasing the skill levels of health care providers (Dallabetta Gerbase, and Holmes 1998; Donovan 2004). Moreover, syndromic management tends to undermine STI surveillance efforts because cases are managed and treated in the absence of a specific clinical or laboratory diagnosis (O'Farrell 2002).

Role of Core Groups and Bridge Populations. Core groups—that is, groups of individuals who have large numbers of sex partners who themselves have large numbers of sex partners—play an important role in the spread and persistence of STIs and are characterized by a high prevalence of STIs. Examples of

core groups include sex workers, drug users, truck drivers, and bar girls. Because a case treated or prevented in a core group member tends to prevent that person from infecting several others, interventions that target core groups tend to be more effective and more cost-effective than interventions that target the general population (Ainsworth and Over 1997; Over 1999; Over and Piot 1993). In situations in which a high prevalence of STIs is concentrated in core groups, so-called bridge populations (individuals who have sexual links with members of both high- and low-prevalence subpopulations) may play an important role in disseminating infection from core groups to the general population (Aral 2000; Aral and others 1999; Gorbach and others 2000; Morris and others 1996).

Several variables influence the relative importance of core groups in the spread of STIs, including the characteristics of the specific pathogen, such as its transmissibility and duration of infectiousness; the phase of a particular epidemic; and the duration of sexual partnerships among those involved in multipartner sexual activity (Aral 2002a, 2002b; Blanchard 2002; Garnett 2002; Wasserheit and Aral 1996). The role of core groups in STI dissemination tends to be greater during the initial and later phases of epidemics, when infection is highly concentrated in small, high-risk subpopulations, than during the middle phases of epidemics, when infection tends to be widely spread across subpopulations. The importance of core groups appears to be greater in populations in which most people are involved in sexual activity with a single partner and only a small minority of people engage in short-term sexual partnerships with a large number of sex partners (Laumann and Youm 1999).

Antibiotic Use and Drug Resistance. Antibiotic use is unregulated in many developing countries, and antibiotics are frequently misused and overused, which results in drug resistance. Resistance to antimicrobial drugs is increasing mortality and morbidity from infectious diseases (Hart and Kariuki 1998). STIs are among the most frequently occurring infections worldwide, with more than 76 percent estimated to occur in the developing world (WHO 2001a). *Neisseria gonorrhoeae* has shown great versatility in developing resistance to antimicrobial drugs, including sulfonamides, penicillins, and tetracycline. Fluoroquinolones such as ciprofloxacin and ofloxacin have proved highly effective in treating gonorrhea, but after widespread and often inappropriate use of fluoroquinolones, resistant *N. gonorrhoeae* has emerged. In some areas, such resistance leaves third-generation cephalosporins as the only predictably effective antibiotic treatment for gonorrhea.

STIs and HIV/AIDS. Because HIV is a sexually transmitted infection, people who are infected with another STI also tend to be at increased risk of HIV infection and vice versa. However, beyond this correlation resulting from common risk

behaviors, STIs and HIV may facilitate each other's transmission.

BACTERIAL AND VIRAL STIs AND THEIR SEQUELAE

Both bacterial and viral STIs are widespread in developing countries; recently, incidence of bacterial STIs has declined while that of viral STIs has been increasing.

Natural History of Bacterial STIs and Their Sequelae

Chancroid is a genital ulcer disease caused by *Haemophilus ducreyi*. Its incidence has declined greatly in both developed and developing countries. This decline has been associated with the provision of STI diagnostic and therapeutic services to sex workers (Steen 2001) and with improved syndromic management of genital ulcers. Like other genital ulcer diseases, chancroid is associated with increased acquisition and transmission of HIV (Donovan 2004).

Syphilis is a genital ulcer disease caused by *Treponema pallidum*. In 1999, the World Health Organization (WHO) estimated the global prevalence of syphilis at 12 million (WHO 2001a), with high prevalence rates in South and Southeast Asia and Sub-Saharan Africa. Those most likely to be affected are populations in developing countries and disadvantaged subpopulations in developed countries. Since 1999, syphilis outbreaks have reemerged in many developed countries among men who have sex with men (CDC 2004; L. Doherty and others 2002). Among heterosexuals, sexual contact with sex workers is an important risk factor. If untreated, syphilis during pregnancy may lead to stillbirth and congenital syphilis (Genc and Ledger 2000).

Gonorrhea is a discharge disease caused by *N. gonorrhoeae*. In 1999, WHO estimated its global prevalence at 62.4 million (WHO 2001a). Like syphilis, its prevalence is high in South and Southeast Asia and Sub-Saharan Africa, in many developing countries elsewhere, and among high-risk groups and disadvantaged subpopulations in developed countries. Community surveys reveal a substantial pool of asymptomatic gonococcal infections (Chandeying and others 2000; Turner and others 2002). Following the emergence of AIDS, gonorrhea cases declined among men having sex with men, sex workers, and the general population in the developed world and among sex workers in many developing countries (Donovan 2004).

In most populations tested, infection with *Chlamydia trachomatis* is the most common bacterial STI. In 1999, WHO estimated the global prevalence of chlamydial infection to be 92 million (WHO 2001a). Chlamydial infection is common in most countries, especially among young people. Key risk

factors are being younger than 25 and having a new sex partner. Many women with uncomplicated infection are asymptomatic or have mild symptoms. Like untreated gonococcal infection, untreated chlamydial infection can cause pelvic inflammatory disease, chronic pelvic pain, and ectopic pregnancy. Chlamydial infection is an important acquired cause of infertility in women (Simms and Stephenson 2000). Roughly half of men with urethral chlamydial infection develop symptomatic urethritis, chlamydial infection is the most common cause of epididymitis in young men, and both men and women may develop chlamydial conjunctivitis or reactive arthritis (Stamm 1999). Research also suggests that chlamydial infection in men may be associated with reduced fecundity among couples (Idahl and others 2004). In addition, chlamydial infection can affect neonates: many delivered vaginally become infected, developing conjunctivitis or, less often, chlamydia pneumonia (Donovan 2004). The role of *C. trachomatis* in preterm births and in cervical cancer awaits further clarification through research (Samoff and others 2004; Wallin and others 2002).

In the absence of control programs, the prevalence of *Trichomonas vaginalis* varies greatly across countries, ranging from less than 1 percent among urban women to more than 20 percent in underserved populations in the same country (Brown and Brown 2000), and may increase with age. WHO estimated the global prevalence of *T. vaginalis* at 174 million in 1999. The introduction of nucleic acid amplification tests highlighted the poor sensitivity of microscopy in the detection of *T. vaginalis*. Even though most infected people are asymptomatic, *T. vaginalis* can cause vaginitis with vaginal discharge in women and urethritis in men. *T. vaginalis* has been associated with preterm birth and may promote the sexual transmission of HIV (Laga and others 1993). However, a randomized controlled trial did not show that screening and treatment for *T. vaginalis* to prevent preterm birth were effective (Klebanoff and others 2001).

Like *T. vaginalis*, bacterial vaginosis and vulvovaginal candidiasis cause vaginal symptoms in women, are extremely prevalent in developing countries, and in one or more studies have been associated with HIV acquisition or HIV genital shedding by women (Donovan 2004). Although often referred to as reproductive tract infections rather than STIs, they are managed in conjunction with STIs, and bacterial vaginosis is associated with some of the same risk factors as other STIs.

Viral STIs and Their Sequelae

Both HSV-1 and HSV-2 infect the genital and anal areas, but HSV-2 causes the most clinical recurrences in the genital tract. Symptoms are mild in most of those infected and tend to go unrecognized and undiagnosed (Corey 2000; Scoular 2002). Genital herpes establishes a lifelong infection that in some people is associated with significant morbidity. Complications of

HSV-2 include severe primary disease, meningitis, hepatitis, erythema multiforme, and neonatal herpes (Donovan 2004). Infected neonates may die or develop severe neurological sequelae despite antiviral therapy. In contrast to bacterial STIs, HSV-2 may be transmitted to sex partners many years after initial infection and during periods when the infected individual may be asymptomatic. Infection with HSV-2 is now one of the most common STIs worldwide and is the most frequent cause of genital ulcers in almost all areas; however, this observation may be related to better diagnostic technologies rather than a genuine alteration in the spectrum of genital ulcer disease (Corey and Handsfield 2000). Improved control of chancroid and syphilis as well as actual increases in the sexual transmission of HSV-2 in areas with advanced HIV epidemics, where HIV-related immunosuppression causes more frequent and more severe HSV-2 disease, may also play a role. Estimates indicate that 10 to 30 percent of adults worldwide are infected with HSV-2 (Brugha and others 1997). Prevalence increases with age and is higher in women and high-risk populations.

HPV types are grouped into low-risk (nononcogenic) and high-risk (oncogenic) types. Low-risk types, including types 6 and 11, cause benign anogenital warts, whereas high-risk types, including HPV 16, 18, 31, and 45, occasionally lead to genital and anal squamous cell cancers. The introduction of nucleic acid amplification tests revealed that genital and anal HPV infection is common even among relatively sexually inexperienced individuals (Giuliano and others 2002; Stone and others 2002). Investigators believe that most adults become infected with HPV but that only a few develop warts or genital or anal cancer. Infection with a high-risk HPV type is implicated in nearly all cases of invasive cervical cancer (Walboomers and others 1999) and with vaginal, vulvar, and anal cancers.

In developed countries, hepatitis B virus is spread predominantly by sexual and injecting drug-use transmission. Indeed, the first three trials of hepatitis B vaccine successfully demonstrated prevention of sexual transmission of hepatitis B virus in men who have sex with men (Manhart and Holmes 2005). In developing countries, hepatitis B is more often acquired perinatally or during childhood, but a rise in seroincidence in adolescence and young adulthood in some countries probably reflects sexual or injecting drug-use transmission. Hepatitis B virus causes acute hepatitis and in some people causes chronic hepatitis that can lead to cirrhosis and liver cancer.

Human T cell lymphotropic virus type I (and perhaps in more cases type II) is, like hepatitis B virus, transmitted perinatally and sexually. In some high-risk populations, for example, female sex workers in Latin America, human T cell lymphotropic virus type I infection is substantially more common than HIV infection. This infection causes a serious form of spastic paralysis or human T cell lymphotropic-associated myelopathy, as well as T cell lymphoma or leukemia.

Coinfection with Sexually Transmitted Pathogens

The epidemiology and natural history of coinfection with more than one sexually transmitted pathogen may have important intervention and economic implications. Coverage by clinical services, outreach, access, partner management, and treatment may be different with coinfection than with independent infections. Although coinfections with HIV and other STIs have received a great deal of attention in recent years, researchers have not focused on overlaps among non-HIV STIs in a similar systematic manner. A number of biological mechanisms may lead to coinfection with STIs: infection with one pathogen may increase the probability of acquiring or transmitting another pathogen; infection with one pathogen may increase or decrease the frequency, the severity, or both of symptoms associated with another sexually transmitted pathogen; and presence of one STI may affect the natural history of another STI. High-risk behaviors and networks often lead to coinfection.

Empirical data on coinfection are limited. Most studies have been conducted in developed countries and have focused on co-occurrences of chlamydial and gonococcal infection. Earlier studies of coinfection assessed the proportion of gonorrhea cases with concurrent chlamydial infection in a variety of clinical settings. Reported levels of coinfection were 4 to 64 percent among attendees at STI clinics, 46 percent among prenatal clinic attendees, and 4 to 25 percent at primary health care facilities (Creighton and others 2003). The proportion of those with chlamydia who also have gonorrhea has been assessed less well, and estimates have ranged between 3 and 4 percent (Creighton and others 2003).

Sexual Behavior and Sexual Health Care

Unprotected sex with an infected partner is the most important risk factor for acquiring an STI. This risk is influenced by the behaviors of the individual and the probability that the partner is infected, which is determined by the prevalence and distribution of infection in the population as well as the partner's behaviors. Current approaches to STI epidemiology recognize at least three distinct components of transmission dynamics at the population level: likelihood of sexual exposure between infected and uninfected individuals, transmissibility of infection upon exposure between an infected and an uninfected person, and duration of infection among those infected (Aral and Holmes 1999; Over and Piot 1993). The first of these components is entirely behavioral, and behavior plays an important role in the last two—for example, condom use, sexual practices, and health care-seeking behaviors.

Demographic and Social Risk Markers. The prevalence and incidence of STIs vary across societies and subpopulations defined by age, gender, race and ethnicity, and socioeconomic

status (Fenton, Johnson, and Nicoll 1997). In all societies, adolescents and young people are at greater risk for acquiring most STIs. Women tend to have a higher prevalence and incidence of all STIs (except for men who have sex with men) and suffer more of the serious complications, such as pelvic inflammatory disease, ectopic pregnancy, infertility, and chronic abdominal pain. For many STIs, the probability of transmission from an infected man to a susceptible woman is higher than from an infected woman to a susceptible man. Social and behavioral patterns also increase women's vulnerability to STIs; for instance, many men have concurrent sex partnerships, which increase their risk for transmitting infection to their female sex partners. In addition, many young women have sex with older male partners, who expose them to the higher STI prevalence rates in older age groups.

In most societies, minority racial ethnic groups have higher STI rates than other groups. Both in the United Kingdom (Fenton, Johnson, and Nicoll 1997) and in the United States (Laumann and Youm 1999), assortative sexual mixing and higher rates of sexual mixing with members of core groups emerge as determinants of ethnicity differentials in STI rates. The prevalence of concurrent partnerships is also higher among racial ethnic minorities (Kraut-Becher and Aral 2003). The relative inadequacy of STI health services and of health care-seeking behaviors among minority racial ethnic groups may also contribute to their higher prevalence of STIs (Aral and Wasserheit 1999).

Socioeconomic status differentials in STI prevalence and incidence are similar to ethnicity differentials. However, the multicollinearity between the two factors makes delineating the independent contributions of either variable to differentials in STI prevalence and incidence difficult.

Behavioral Risk Factors for Exposure to Infected Sex Partners. Most sexual behaviors of individuals are associated with exposure to sex partners infected with sexually transmitted pathogens and, consequently, with acquisition of STI. These behavioral factors include number of sex partners over the individual's lifetime, over the past year, and over a short term (Fenton and others 2001; Laumann and Youm 1999); frequency or number of sexual encounters (Garnett and Rottingen 2001); having sex with members of groups with high STI prevalence, such as core groups and sex workers (Fenton and others 2001; Laumann and Youm 1999) or older age groups (Service and Blower 1996); and position in a sexual network (I. A. Doherty and others 2005). Some sexual behaviors of individuals are associated with transmission of STIs, and for those infected the behaviors increase the probability that people will transmit their infections to susceptible sex partners. These behaviors include having concurrent partnerships (Koumans and others 2001; Kraut-Becher and Aral 2003; Morris and Kretzchmar 1995) and having short

gaps between sex partners in serial monogamous partnerships (Kraut-Becher and Aral 2003).

Sex partners' behaviors are also critical determinants of exposure to infection. Investigators use many behavioral and epidemiological indicators to assess partners' risk of having infection, including existence and number of new sex partners; presence of concurrent partnerships; gap between sex partners; partners' number of partners; and risk status of partners' partners—for example, if they have sex with sex workers or men who have sex with men (Aral 2002b).

Behavioral Risk Factors Associated with STI Acquisition and Transmission on Exposure to Infected Partners. Certain behaviors influence the likelihood of an infected person's transmitting infection to a susceptible partner, including condom use, sexual practices such as anal intercourse, vaginal douching, and use of drying agents in the vagina (Bailey, Plummer, and Moses 2001; Donovan 2000a, 2000b). The probability of transmission varies depending on the pathogen and is much higher for bacterial STIs, such as gonorrhea, syphilis, and chlamydia, than for other STIs, such as HIV infection. Thus, preventive behaviors such as condom use may be more effective in preventing the latter than the former (National Institute for Allergy and Infectious Diseases 2001). In addition, the probability of both acquisition and transmission is significantly affected by such nonbehavioral cofactors as circumcision status (Aral and Holmes 1999).

Overall, oral sex and anal sex tend to be practiced less often in the developing world than in the developed world (Vos 1994). Insertion of herbs to tighten or dry the vagina and other practices of vaginal clearing and wiping are widespread (Brown and Brown 2000). Condom use is increasing in some countries—for example, India, Thailand, and Uganda—especially during high-risk encounters.

Behaviors Associated with the Duration of Infectiousness. The duration of infectiousness is an important component of transmission dynamics. Because effective treatment curtails the duration of curable STIs, the speed with which infected individuals seek treatment and the speed and effectiveness with which health care providers supply effective treatment together determine duration. To the extent that suppressive therapies truncate the period of infectiousness of viral STIs, as they do for HSV-2 and HIV infection, duration is also important in the transmission dynamics of incurable viral STIs.

Behaviors that can reduce the average duration of infectiousness include timely and appropriate health care seeking, effective participation in risk assessment, and compliance with therapy and prevention recommendations on the part of those infected and at risk (Aral and Wasserheit 1999). Health care seeking depends on perceived seriousness and causality of symptoms, availability and accessibility of health care, costs

(including opportunity costs) of treatment, perceived and actual quality of care, and beliefs about the appropriate provider to consult. The proportion of those infected seeking care is highly variable, and delays in seeking treatment can be substantial. In many places, the proportion of people seeking timely care from appropriately trained providers is limited (Hawkes and Santhya 2002; Moses and others 2002; Rekart 2002).

Behaviors on the part of health care providers that ensure timely and accurate diagnosis, appropriate treatment, and non-judgmental attitudes toward those infected would also help reduce the duration of infectiousness of STIs. However, establishing effective, accessible, affordable, and decentralized services is difficult (Over 2004; World Bank 2003). The major barriers Moses and others (2002) identified in Nairobi reflect the situation in many developing countries. Those barriers include inadequate basic training and inefficient deployment of health workers; attitudes of health workers toward marginalized groups (for instance, female sex workers); high patient loads at health centers; lack of supportive supervision; inadequate referral systems; chronic shortages of supplies and drugs; and inadequate recording of health information. User fees can be a substantial additional barrier, though they may contribute to the sustainability of the treatment program and improve the provider's incentives.

Behavioral Interactions. Both at the individual and the population levels, people's risk behaviors respond to changing circumstances. In many developing countries where HIV incidence has been high, people have adopted compensatory behavior changes, such as delayed age of sexual debut, reduced number of sex partners, and increased use of condoms (Shelton and others 2004; Stoneburner and Low-Beer 2004), especially with high-risk partners (Peterman and others 2000). Some people now seek health care when they suspect they have been exposed to an STI.

At the same time, risk behaviors can overlap: people who initiate sexual activity early in life tend to have many partners, and people who engage in risky sex tend to also use drugs and alcohol. A history of sexual abuse or of being an abuser is also positively associated with high-risk sexual behaviors and drug use (Aral 2004). The adoption of preventive behaviors raises the possibility that people will compensate by changing other behaviors in response; for example, many believe that the widespread adoption of antiviral therapy or condom use may lead to increases in the numbers of sex partners (Blower and others 2001; Blower and Farmer 2003; Over and others 2004). Although constructing mathematical models to explore the effects of such changes in behavior is helpful, empirical research in varied contexts is urgently needed to identify the variables that determine patterns of interaction among risky and preventive behaviors. Two such variables may be individual autonomy and awareness of the epidemiological context.

Societal Determinants of STIs. Sexual networks and patterns of sexual partnership formation and dissolution constitute a major mechanism through which the political economy and the sociolegal system influence the rate of spread of STIs in a population. Sexual networks that are highly critical to the rate of spread of STIs include those involving sex work; exchange of sex for drugs, gifts, or material needs; and anonymous sex. The frequency of sex in exchange for money or other goods appears to be highly sensitive to changes in the political economy and the sociolegal system. Internal conflicts, war, economic crises, and social collapse are accompanied by the establishment of major sex markets or the expansion of existing ones. For example, following the collapse of the former Soviet Union, the number and size of commercial sex and sex-drug networks expanded significantly (Aral and St. Lawrence 2002; Aral and others 2005). The availability and use of condoms also influence the rate of spread of STIs.

Many developing countries continuously face political conflict, war, economic deterioration, mass migration, and increasing inequality plus the effect of globalization. In addition, in most developing societies, gender power relationships are marked by great inequality. Those contextual factors lead to sexual networks and sexual mixing patterns that are highly conducive to the spread of STIs. Sexual partnerships are often not stable, and in the long-term absence of a spouse, both men and women (but especially men) have other partners.

In addition, as economic needs rise, the number of women who exchange sex for material needs increases. Wilson and others (1989) estimate that approximately 10 percent of the female population in Bulawayo, Zimbabwe, had engaged in full- or part-time sex work at some time in their lives, whereas Aral and St. Lawrence's (2002) estimates for Saratov, Russian Federation, are closer to 25 percent. As the supply of sex workers increases, the demand for their services often increases in parallel. Economic need also affects sexual mixing patterns. In most developing countries, young girls commonly have "sugar daddies"—that is, older, often married men who provide them with material goods in return for sex while also exposing them to chronic STIs typical of relatively older cohorts (Gregson and others 2002).

Gender inequalities put women in a highly vulnerable position in many ways. For example, Decosas and Padian (2002) find that, among women attending family-planning and primary health care clinics in Zimbabwe, 17 percent had at some time received a gift in exchange for sex, 22 percent had been forced to have sex with a steady partner, 5 percent had been forced to have sex with a nonsteady partner, 35 percent were certain their steady partner had other partners, 27 percent said their partners had STI symptoms, 24 percent said their partner was intoxicated during sexual intercourse more than half the time, and only 10 percent had used a condom in the previous three months.

Income and Inequality. A cross-country database (George Schmid, personal communication, September 15, 2004) enables us to analyze the association between national STI prevalence rates and two important economic variables: gross national income per capita and the degree of income inequality as measured by the Gini coefficient.¹ As table 17.1 shows, these two variables explain 45 percent of the variation in STI prevalence in low-risk groups and 16 percent of STI prevalence in high-risk groups. Figure 17.1 illustrates the relationship between each of these two economic variables and STI prevalence.

Poor countries' higher prevalence rates of STIs are unsurprising and could be explained by the fact that people in richer countries are likely to seek and find care for STIs more quickly. More notable is that income inequality is such a strong predictor of STI prevalence even after controlling for gross national income per capita. Furthermore, income inequality is a strong predictor of STI prevalence among high-risk groups, where income per capita performs less well. A possible explanation for this finding is that greater inequality creates more active markets for commercial and casual sex as higher-income men negotiate for the sexual services of lower-income sex workers (Aral 2002b; Over 1998).

Table 17.1 Cross-Country Regressions of Average STI Prevalence on Per Capita Income and the Gini Coefficient of Inequality for Low- and High-Risk Groups, Selected Countries

Category	Average prevalence of STIs in low-risk groups	Average prevalence of STIs in high-risk groups
Gross national income purchasing power parity per capita, log, 19–2001	−0.862**	−0.194+
Gini index, 1990s	7.731**	2.73*
Dummy for syphilis	0.093	−0.051
Dummy for chlamydia	1.992**	0.308
Dummy for herpes	3.611**	1.507**
Constant	−0.515	−1.751
R ²	0.45	0.16
Number of countries	204	147

Source: Authors' calculations from Schmid and others 2004.

Note: * = probability of less than 0.05 percent; ** = probability of less than 0.01 percent. Positive numbers indicate a probability of 0.1 to 0.2 percent. Both regressions pool data across these STIs: syphilis, chlamydia, and herpes. The coefficients of the dummies show that the estimated prevalence rates are significantly higher for herpes than for the other diseases. Among low-risk groups, the prevalence of chlamydia is higher than that of syphilis. Standard errors (not shown) are estimated using the White correction for heteroskedasticity under the assumption that the observations for a single country are comparable to a cluster of data. Other explanatory variables that were unsuccessful in explaining a significant proportion of the variance included percentage of the population foreign born, percentage of the population that is Muslim, male-to-female literacy gap, urban male-to-female population ratio, and military personnel per 1,000 urban population.

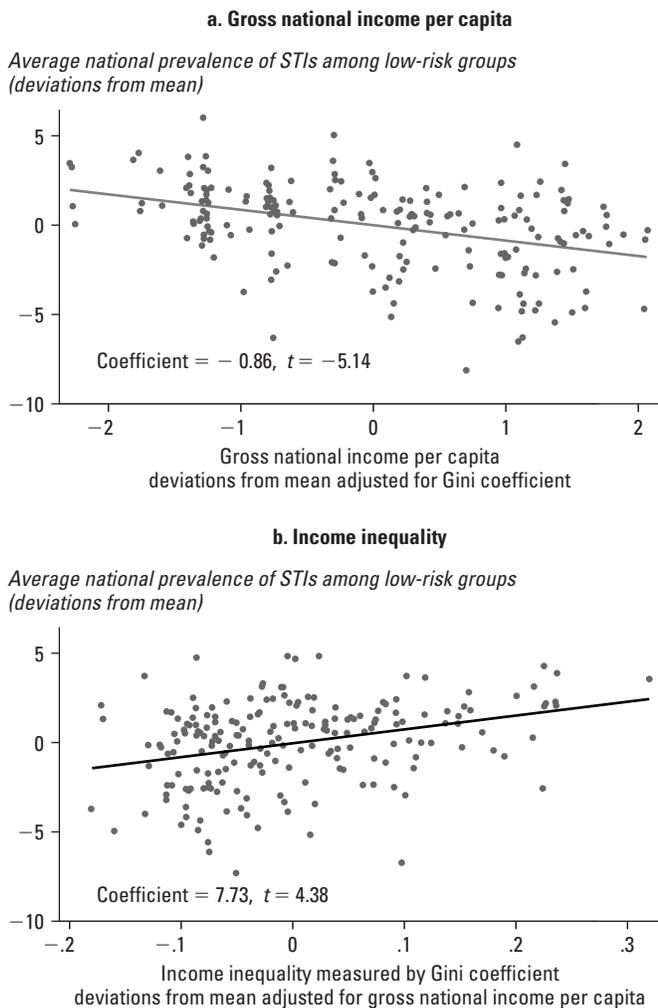

BURDEN OF STIs AND BENEFITS OF CONTROL

On the basis of an independent analysis of cross-country data on STI prevalence, we believe that WHO may have underestimated the burden of STIs relative to that of HIV and other diseases (www.fic.nih.gov/dcpp/gbd.html). Adjusting the WHO estimates on the basis of our calculations increases the estimate of years of life lost burden by about 18.1 percent and the overall estimate of disability-adjusted life years (DALYs) lost by about 8.2 percent.

DALYs Gained from Effectively Preventing or Treating STIs

In the first edition of this volume, chapter 20 presented estimates of the so-called static and dynamic burdens of preventing or curing a single case of an STI and of HIV (Over and Piot 1993). We reproduce those estimates in table 17.2 for four of the STIs.² The static benefit column estimates the average number of DALYs saved for a single person by curing or preventing his or her own case of each disease. These estimates are based on specific assumptions regarding the distribution of incidence, case-fatality rates, and severity across age ranges. Although updating these estimates to 2004 and varying them by region would ideally be possible, we have not found any more recent data. If the person who is cured of an STI ceases to be sexually active, the static benefit would be the only benefit of curing or preventing his or her case; however, most individuals who have contracted an STI remain sexually active and are therefore likely to communicate that STI to others. An STI prevented or cured in a sexually active person will prevent additional cases in that person's sex partners, in the sex partners' partners, and so on. Thus, the dynamic benefit columns indicate the magnitude of those additional benefits.

The key finding is that preventing or curing a case of any of the STIs in a core group member generates approximately

10 times the dynamic benefits of the same intervention in a person in a noncore group. This result is driven by the assumption that a member of a noncore group has a new sexual contact every 50 days, or about seven new contacts per year, whereas a member of a core group has 10 times as many contacts. Within this model, the results are proportional to the frequency of partner change, so that the dynamic benefits of curing or preventing a case in a sex worker who has two partners a day would be approximately 10 times as great as for a member of the core group in table 17.2. The implication is that preventing or curing a case of syphilis in a sex worker can result in up to 1,600 DALYs of benefit, a health effect that is likely to be competitive with any discussed in the other chapters in this volume.

Impact of STIs on HIV

The preceding discussion does not address the possibility that STI infections increase HIV transmission. On this point the evidence is mixed, with a study in Mwanza, Tanzania (Grosskurth and others 1995), demonstrating a statistically significant 40 percent reduction in HIV incidence attributable to an STI intervention, while two studies (Kamali and others 2003; Wawer and others 1999) in Uganda failed to show any such effect. Recent reanalyses (Orroth 2003) of the data from these studies suggest that the effect of an STI intervention on an HIV epidemic will vary depending on the sexual activity and resulting prevalence of STIs among those being treated.

None of the randomized controlled trials of the effect of STI treatment on HIV prevention exclusively targeted the most sexually active people in the community. In Mwanza, Tanzania, and Masaka, Uganda, treatment was provided to those who sought it at health care clinics. In Rakai, Uganda, treatment was given to all adults in all households, regardless of whether the individual complained of STI symptoms. Data on the prevalence of HIV infection in the three communities suggest that the HIV and STI epidemics were both at an earlier stage in Mwanza and were therefore more concentrated among those more sexually active. Thus, the people who became symptomatic and sought treatment were among the most sexually active people in Mwanza, and treating them would therefore have had a greater effect on HIV incidence than would treating an average person in the two Ugandan sites. Conversely, in the more generalized epidemics in Uganda, a larger proportion of new infections occurred within stable HIV-1 serodiscordant couples.

An alternative, less rigorous way to test for the effect of STI prevalence on HIV infection is to study the cross-sectional correlation in ecological data. In a replication of an earlier study (Over 1998), we have attempted to explain urban HIV prevalence in a cross-country sample by the prevalence of syphilis and gonorrhea seven years earlier after controlling for six other potentially confounding variables. The results of these cross-

country regressions are presented in table 17.3.³ Columns (1) and (2) of table 17.3 present the results of regressions estimated on the subsets of countries for which data are available on all eight explanatory variables and on the dependent variable (2002 urban HIV prevalence). Their specifications differ only by the replacement of the prevalence of syphilis as an explanatory variable in column (1) with the prevalence of gonorrhea in column (2). Columns (3) and (4) repeat the same two regressions by replacing missing values of the two prevalence rates with estimates that are based on a regression of these rates on the other variables in the regression. This procedure expands the samples dramatically from 56 and 38 to 181 and 180, respectively.⁴

In interpreting these regressions, note first that all four specifications explain more than half of the variance in 2002 urban HIV prevalence, a remarkably good fit for cross-sectional regressions. In all these specifications, the lagged value of an STI prevalence is a statistically significant predictor of HIV prevalence approximately seven years later. The coefficient for gonorrhea is larger than the coefficient for syphilis and is more statistically significant in the augmented sample, though less so in the basic sample.

After the age of the epidemic is controlled for, several other variables contribute to explaining the variation in HIV prevalence. These variables include national income per capita (richer countries have lower infection rates), the percentage of the population that is Muslim (a higher percentage is associated with lower infection rates), and the ratio of males to females in the sexually active age range (higher ratios are associated with higher infection rates).

The major difference between the regressions using the augmented sample and those using the basic sample is in the statistical significance of the estimated coefficient of income inequality as measured by the Gini coefficient. When the sample is expanded to take advantage of the available data, the coefficient stabilizes at about 5.3 and is statistically significant at the 0.01 probability value, suggesting that an increased degree of income inequality is associated with increased HIV infection even after controlling for STI prevalence. This result lends support to the idea that income inequality is just as important as poverty in setting the stage for HIV transmission.

As with the results of any ecological or cross-sectional analysis, questions of attribution and interpretation arise. Is the statistically significant coefficient of syphilis or gonorrhea capturing a biological effect of an STI on increasing the transmission probability during sexual intercourse? Or is the coefficient instead simply reflecting the fact that greater sexual activity spreads all STIs, including gonorrhea, syphilis, and HIV? Is the coefficient of the percentage of the population that is Muslim capturing differential sexual activity or the prevalence of male circumcision, which is increasingly recognized as biologically protective? A biological interpretation of both the STI and the Muslim coefficients is suggested by the fact that the variable

Source: Authors' calculations. Syphilis and gonorrhea prevalence in 1995 (George Schmid, personal communication, April 5, 2004). HIV prevalence circa 2002 is from the urban low-risk tables in the U.S. Bureau of Census database on HIV prevalence. Other variables are from World Bank data.

* = significant at 10 percent; ** = significant at 5 percent; *** = significant at 1 percent.

Note: The figures in parentheses are robust *t*-statistics.

a. Age of epidemic is defined as the number of years since the first case of HIV/AIDS was reported.

b. The logarithm of the ratio of the prevalence to 1 minus the prevalence of the given STI for the low risk population in 1995.

urban male-to-female ratio is probably already capturing much of the variation in the most risky sexual behavior: the practice of prostitution.

Increasing the availability of treatment for STIs and for HIV infection reduces the prevalence of the former and increases the prevalence of the latter. Thus, this statistical relationship between STI prevalence and HIV prevalence, even if once valid, will no longer obtain. Under current conditions, estimating the effect of a change in the prevalence rate of an STI on the incidence rate of HIV would be more relevant.

If we assume that in 2002 the HIV epidemic was approaching equilibrium in many urban settings and that prior to anti-retroviral treatment the median duration of the illness was about 10 years, the prevalence of HIV infection is approximately equal to 10 times the incidence rate. Thus, a 10 percentage point increase in the prevalence of syphilis or gonorrhea is estimated to increase the incidence of HIV by 0.27 percentage points for syphilis and 0.57 for gonorrhea. For comparisons,

the Mwanza trial found that a reduction in the prevalence of male urethritis of 0.6 percent was associated with a decrease of 0.7 percent in the incidence of HIV (Grosskurth and others 1995). Thus, the present study suggests an effect about one-fourth as strong as that of the Mwanza study.

EFFECTIVENESS OF THE PRINCIPAL INTERVENTIONS

Unlike HIV interventions, STI interventions benefit from a large body of rigorous evaluations. STI interventions that have been rigorously evaluated for effectiveness can be organized by intervention level (that is, individual, group, or community); by the outcomes measured; and by the intervention modality used (for example, behavior change, vaccination, topical microbicide use, screening, or treatment). Prevention outcomes may measure the prevention of acquisition, of

transmission, and of complications of STIs (Manhart and Holmes 2005). This section reviews the interventions for which the strongest evidence exists.

Individual-Level Interventions

A large number of STI interventions that have been rigorously evaluated are individual-level interventions.

Preventing Acquisition. The following have been the main means of preventing STI acquisition:

- *Behavior change.* Counseling on risk reduction was the most frequently used behavior-change approach. Most studies showed a reduction in risk behaviors as a result of counseling, and some showed decreases in STI outcomes (Kamb and others 1998).
- *Antimicrobial prophylaxis.* Two studies (Harrison and others 1979; Kaul and others 2004) showed reductions in the incidence of gonococcal, chlamydial, or trichomonal infections following antimicrobial prophylaxis.
- *Vaccines and passive immunization.* A yeast-derived HPV type 16 vaccine was 100 percent efficacious in preventing persistent HPV-16 infection in young college women (Koutsky and others 2002), and a bivalent HPV type 16 and type 18 vaccine was also highly efficacious in preventing those infections. An HSV-2 glycoprotein D-adjuvant vaccine among those with no serological evidence of prior HSV-1 infection partially protected women, but not men, from experiencing genital herpes disease, with 73 percent efficacy for such women in one trial and 74 percent in another (Stanberry and others 2002).
- *Microbicides.* To date, studies have not identified any efficacious topical microbicides.
- *Male circumcision.* Even though cross-sectional evidence suggesting that male circumcision decreases the risk of acquiring chancroid and HIV is strong, outcome data are not yet available from ongoing randomized trials in Kenya, South Africa, and Uganda.

Preventing Transmission. All individual-level interventions aimed at preventing transmission have involved curative or suppressive therapy. Giving tinidazole to male partners of females treated for vaginal trichomoniasis infections significantly reduced recurrences in the females; administering valacyclovir to positive members of HSV-2 serodiscordant couples reduced the incidence of symptomatic genital herpes and HSV-2 seroconversion in the uninfected partners; patient-delivered therapy to partners of women with chlamydial infection demonstrated a nonsignificant trend toward reduced risk of reinfection with *C. trachomatis*; and expedited partner therapy (usually patient delivered) significantly reduced persistent

or recurrent gonococcal or chlamydial infection in the index patient (Golden and others 2005).

Preventing Complications. Risk-based screening for *C. trachomatis* infection resulted in a 56 percent reduction in the subsequent risk of incident pelvic inflammatory disease (Scholes and others 1996). Several trials have shown that antiviral suppression decreases clinical and virological recurrences of genital herpes (Corey and Handsfield 2000).

Group-Level Interventions

Studies of behavior-change methods in small-group settings to reduce the acquisition of STIs had mixed outcomes. Behavior-change approaches resulted in significant reduction in incident STIs; antimicrobial prophylaxis and provision of female condoms did not.

Community-Level Interventions

Four community-level randomized trials have sought to reduce the prevalence and transmission of STIs by shortening the duration of infectiousness within the general population (Manhart and Holmes 2005).

The “Mema Kwa Vigara” study in Mwanza, Tanzania, randomized 20 communities to intervention and control communities. The intervention consisted of school-based sexual and reproductive health education, enhanced reproductive health services for youths, condom distribution, and community activities. Knowledge and reported behaviors improved; however, no differences were apparent between the intervention and control communities in relation to HIV or HSV-2 seroincidence, incidence of other STIs, or pregnancy outcomes (Hayes and others 2003).

A second study in Mwanza, Tanzania, randomized communities to intervention and control conditions. The intervention consisted of syndromic treatment of STIs. The results showed a 40 percent reduction in HIV incidence and reductions in symptomatic urethritis in men and prevalence of syphilis seroreactivity; the prevalence of gonorrhea or chlamydial infection in prenatal women did not change (Grosskurth and others 1995; Mayaud and others 1997).

In a community randomized trial in Masaka, Uganda, one community received information, education, and communication; a second community received information, education, and communication plus syndromic management of STIs; and the control received community development assistance. The results showed no differences in HIV-1 incidence. The incidence of HSV-2 seroconversion declined in the community receiving information, education, and communication only; the incidence of syphilis and of gonorrhea decreased in the community receiving information, education, and communication plus

STI syndromic management; and condom use increased in all three communities (Kamali and others 2003).

In Rakai, Uganda, a community randomized trial evaluated the efficacy of repeated mass treatment of STIs. Relative to control communities, in intervention communities the prevalence of *T. vaginalis* in women was reduced significantly, but no significant reduction was apparent in prevalence of gonorrhea, chlamydial infection, new syphilis seroreactivity, and bacterial vaginosis; in HIV incidence; or in history of urethral or vaginal discharge or genital ulcer disease (Wawer and others 1999). A subanalysis of pregnant participants showed a reduction in the prevalence of several STIs in women tested near delivery and in potentially STI-related pregnancy, puerperal, and neonatal morbidity (Gray and others 2001).

Conclusions on Interventions

The review of STI intervention research suggests several, perhaps counterintuitive, insights:

- First, most evidence is on individual-level interventions aimed at reducing STI acquisition, even though individual-level interventions may be costly and difficult to sustain.
- Second, behavior change is the most commonly evaluated modality, followed by treatment.
- Third, theory-based behavioral interventions failed to show an effect as often as behavioral interventions not based on theory.
- Fourth, behavioral interventions delivered in small group settings were as effective as those delivered to individuals (Manhart and Holmes 2005).
- Fifth, the effect of a particular behavior change on STI risk depended on the type of STI; however, the number of partners may be more predictive of risk for highly infectious STIs than for HIV, and unprotected sex acts may be more predictive of risk for HIV than for highly infectious STIs (Semaan and others 2002). Thus, behavioral interventions may have different effects on STIs of differing infectiousness.
- Finally, the number of intervention trials that demonstrate declines in risk behaviors combined with either no effect on STIs or increases in STIs is increasing. This observation calls into question the use of behavioral outcome measures as indicators of biomedical outcomes (Aral and Peterman 2002).

INTERVENTION COSTS AND COST-EFFECTIVENESS

Widespread implementation of effective interventions depends on cost and cost-effectiveness considerations.

Organization of STI Control Activities in Poor Countries

In poor countries, patients can typically obtain treatment for an STI in a public sector health care facility. Many countries have publicly funded, stand-alone STI clinics, but the typical pattern is for health care personnel to provide care for STIs as part of their regular practice in general outpatient clinics. Despite the availability of such publicly funded care, or perhaps because of concerns about anonymity, many STI patients in poor countries avoid public facilities in favor of traditional healers and private pharmacies. A recent study of the cost-effectiveness of delivering STI treatment through trained pharmacists in Peruvian cities included reports of the popularity of self-treatment in Brazil, Cameroon, Ghana, Nepal, South Africa, Thailand, Vietnam, and Zambia (Adams and others 2003). After reviewing this literature, Adams and others selected the point estimate of 0.4 as their best guess for the proportion of STI patients seeking treatment from a pharmacy in Lima.

Determinants of the Costs of Interventions

We adopt a government perspective in analyzing the costs and cost-effectiveness of interventions. Thus, we define the costs of an activity as the total budgetary expenditure attributable to that activity—that is, the total budget for buildings, equipment, personnel, and supplies, with adjustments made when buildings are used for multiple purposes.

We define the unit costs of an activity as the total budgetary expenditure during a stated time period divided by the number of units of output during that same period. Because the same activity can have several outputs, this definition necessarily entails some ambiguity. For example, an intermediate output of the delivery of STI treatment services is the patient treated, whereas a more final output is the patient cured. An even more complete measure of output would include the secondary infections averted as a result of the cure.

One of the reasons that many economists prefer cost-benefit analysis to cost-effectiveness analysis is that the former attaches a dollar value to each of the outputs of an activity and then aggregates across the outputs to construct a summary measure of the total benefit of the activity. However, this simple result hides many arbitrary assumptions that are required to value the separate outputs. One of the most arbitrary of these assumptions is the assignment of a dollar value to a healthy life year. So instead we present costs and cost-effectiveness denominated in the outputs for which we have data. We then go as far as we can toward aggregation by adopting the conventions of the healthy life year and the disability-adjusted healthy life year.

Kumaranayake and others' (2004) background study for this chapter reviews the literature on the unit costs of STI treatment. They identify 35 studies on this topic that provide a total of 77 unit cost estimates. These are grouped in table 17.4 by the disease or syndrome being treated and by the output that was

Table 17.4 Average Estimated Costs per Unit of Output, by Disease or Syndrome and Type of Output (2001 US\$)

Disease or syndrome	Treatment	Cure	Average
Syphilis	36.04 (5.91)	n.a. n.a.	36.04 (5.91)
Urethral discharge	14.29 (20.68)	89.07 (0)	29.25 (37.94)
Genital ulcer	23.16 (21.73)	100.60 (83.74)	48.97 (59.56)
Venereal disease	25.47 (18.56)	82.65 (111.55)	31.83 (37.12)
Pelvic inflammatory disease	7.12 (3.09)	n.a. n.a.	7.12 (3.09)
Vaginal discharge	48.23 (0)	102.92 (89.63)	81.04 (70.10)
Total	24.05 (19.04)	96.10 (73.44)	39.49 (47.23)

n.a. = not applicable.

Note: The figures in parentheses are standard deviations. The 42 observations in the table are individual unit cost estimates distributed across separate studies.

costed. Of the 46 estimates of the unit cost of treatment, only 33 could be interpreted as, or converted to, 2001 U.S. dollars, and the same applied to 9 of the 10 estimates of the unit cost of a cure. Table 17.4 summarizes the results of these studies by the disease or syndrome that occasioned the treatment.

The most notable thing about the summary statistics is their variability: the cost per unit of output can vary by a factor of 100 or more. Even though the mean dollar cost per cure could plausibly be almost four times that of treatment alone, the standard errors are so large as to make the difference statistically insignificant.

The same point—that is, that unit costs vary enormously from one site to another—is made by the preliminary results of a study by Dandona and others (2005). The cost per case treated in the study varies by a factor of 10 across the 14 sites. Furthermore, the two sites that treat the fewest and the most cases per year also display the highest costs, a finding that suggests the existence of both economies and diseconomies of scale.

The variables that determine the costs—and therefore the cost-effectiveness—of STI treatment include the following:

- delivery by the public or private sector
- economies of scale
- economies of scope
- prevalence and incidence
- epidemic phase
- transmission efficiency
- health system characteristics

- population composition and concentration
- resource combinations and input prices
- incentives to providers for high quality and quantity of service delivery
- willingness to pay for treatment as a function of price, income, and distance
- stigmatization
- disutility of condom use.

SCALING UP CONTROL STRATEGIES

Throughout the history of STI control, tension has been apparent between those who support prioritizing resources for the small proportion of people with the most sexual contacts and those who advocate spreading prevention, screening, and treatment resources more thinly over the entire population. Opponents of prioritization argue that most of the people who practice the riskiest behavior are hard to find and that attempts to find them would expose those individuals to stigmatization and repressive measures.

A group of researchers at the University of North Carolina has developed and applied a novel approach to STI interventions that has demonstrated in several countries that finding the people who practice the riskiest sexual behavior without targeting them as individuals is possible (Weir and others 2003). As an example of this approach, consider its application to Madagascar, a country where risky sexual behavior had previously been thought to be too common to be identified or to be distinguished from less risky behavior.

In May 2003, the Malagasy Steering Committee, which consisted of representatives of the Ministry of Health, local government officials, and other knowledgeable experts, selected five towns judged to be at high risk for STIs for a pilot study. The Priorities for Local AIDS Control Effort (PLACE) method applied in these towns was, first, to interview adults at random on the streets of the city to find out where people go to meet and socialize and, second, to visit and collect data on these locations and the people who frequent them.

In each of the five cities, the informants tended to agree on the most frequented sites. They identified between 70 and 267 unique socialization sites of various types, ranging from bars and restaurants to beaches and brothels. Interviews with people frequenting the sites revealed them to be much more sexually active than the average Malagasy adult. According to the 1997 demographic and health survey, 13 percent of women outside the capital city, Antananarivo, had two or more sexual partners in the previous year. In contrast, the percentage of women at the socialization sites who had had more than two partners ranged from 46 to 68 percent. According to the demographic and health survey, only about 3 percent of women outside Antananarivo had four or more partners in the previous year, but the percentage of women at the study sites

having this many partners was 10 times larger. The men interviewed at these sites were even more sexually active than the women.

The pilot study also investigated whether information on or products for prevention of STIs, HIV, or both were available at the socialization sites. In the five towns, the proportion of sites where condoms were available on the day of the visit varied from 27 to 54 percent. These percentages are not negligible and are undoubtedly much higher than they were 10 years ago, and the availability of condoms at so many of these sites is a tribute to the success of the condom social-marketing campaign. However, the statistics also indicate substantial room for improvement, for example, by distributing condoms in 100 percent of identified socialization sites. The feasibility of such a program is enhanced by information from the PLACE study that more than 80 percent of the owners or managers of these sites expressed their willingness to host STI and HIV prevention programs, and more than half were willing to sell condoms.

Researchers have carried out similar PLACE studies in Burkina Faso, Ghana, South Africa, and elsewhere. Unfortunately, in none of these countries has this extensive risk mapping been followed by the implementation of prevention programs at all the identified locations. Until such programs are implemented and evaluated, no African country will be able to claim that it has scaled up the most effective type of STI prevention to population levels.

RESEARCH AND DEVELOPMENT AGENDA

Priorities for global STI research include the following:

- The development and evaluation of therapeutic (drug treatment or vaccines), behavioral, and structural interventions to prevent or reduce STIs and their sequelae. Given the spread of drug-resistant strains of gonorrhea and other STIs, new pharmaceutical products and new combination therapies are needed to prevent and treat STIs.
- The development and evaluation of mechanisms to accurately quantify the disease burden in order to prioritize activities.
- The development and evaluation of inexpensive and practical rapid diagnostic tests to permit early detection and treatment of STIs.
- The conducting of studies to evaluate effective prevention modalities for persons at highest risk for STIs.
- The undertaking of health services research to gain an understanding of practical and cost-effective STI prevention strategies or systems that ideally can be integrated into existing public health infrastructure. When an individual is treated for an STI, this treatment has both positive and neg-

ative spillover effects (externalities). The right combination of patient and provider incentives needs to be found that will maximize the beneficial spillovers while minimizing the harmful ones.

- The implementation of studies in support of global elimination programs.

Because of the clandestine nature of most sexual behavior, STIs are probably massively underreported, which in turn leads to an underestimation of their importance. New survey and measurement tools have been developed. They now need to be applied to populations in poor countries to improve these estimates.

In addition, randomized controlled trials need to be conducted in different settings to test the hypothesis that treating or preventing STIs in high-risk individuals has beneficial spillover effects by preventing infections among low-risk individuals. An improved understanding of the determinants of high-risk sexual behavior and the role that such behavior can sometimes play in helping women to escape from poverty and helping men to cope with it is also needed, as is a better understanding of the full range of benefits of effective STI interventions for high-risk individuals and their dependents.

As concerns disease modeling and surveillance, further improvements are needed in understanding the implications for interventions of different kinds of local, regional, and international sex networks.

Tools

Because of the difficulty of persuading patients to adhere to a course of medication for the prescribed period, single-dose therapy would be valuable. Rapid, point-of-care diagnostics are also a high priority, so that drugs can be targeted at pathogens more accurately. New approaches for treating chronic STIs should be incorporated into prevention strategies, and blister packs of antibiotics that can be sold over the counter for syndromic management of STIs should be available.

Vaccines would be particularly valuable, both for preventing and for potentially treating chronic viral STIs and chlamydial infection, which is often asymptomatic but is responsible for considerable morbidity.

Diagnostics tests that could be used at home or at social meeting spots may help people decide whether to engage in risky sex. Packages of diagnostic tests that change color when the contents expire would also be useful.

Intervention Methods

Syndromic management algorithms have now existed for more than a decade. However, treatment algorithms are sensitive to changes in the relative prices of pharmaceuticals and diagnostic

reagents, in the prevalence of the various STIs, in pathogens' resistance, and so on. Thus, every country needs some ability to respond to local changes by developing or modifying algorithms as needed.

As concerns intervention packaging, many policy makers continue to believe that the most sexually active people are hard to find. This belief hampers efforts to target these people with STI prevention programs. The PLACE methods developed at the University of North Carolina offer an opportunity to correct that impression and should be packaged with other urban public health functions. Packaging sex education into school curricula is a challenge in most of the world. As enrollment rates for poor children, especially girls, rise, the presence of a strong, culturally appropriate, sex education curriculum will lay the foundation for strong STI prevention and treatment campaigns.

As this chapter has argued, the determinants of the unit costs of STI treatment and prevention are largely unknown. We recommend health services and operations research to study the determinants of the unit costs of STI prevention and treatment services. The purpose of this research would be to learn not only how to deliver care in the most cost-effective ways, but also how to build systems that achieve that technological frontier in a high percentage of public and private facilities and pass those cost savings on to the government and to patients. Given the beneficial spillover effects from effective STI prevention and treatment among those who are most sexually active, research is needed to learn how the PLACE approach to targeting can be implemented most cost-effectively in different cultural contexts.

Finally, improved understanding of the best way to design an STI treatment system, including the rewards and penalties that best motivate providers (to be polite, discrete, prompt, efficient, and accurate in following best practice, evidence-based treatment protocols) and patients (to seek and then to adhere to treatment) is a priority. Improved data on the costs of each STI intervention at the pilot stage and after scaling up to the national level are also necessary.

CONCLUSIONS

Regarding the cost-effectiveness of STI control, the position this chapter takes is "it depends." The health benefit in terms of numbers of disability-adjusted, discounted, healthy life years saved by curing or preventing a case of syphilis varies from 3 years in a person who has ceased all sexual activity to as many as 161 years in a sex worker with two partners a day. The cost of treating that prostitute for syphilis varies from US\$5 to US\$100. Thus, the cost per DALY of syphilis treatment can range from 100/3 or US\$33 per DALY to 5/161 or less than US\$0.05 per DALY.

As we learn more about the complexities of delivering STI treatment services and take into account the diversity of risk behavior, the ease with which STI interventions can be ascribed a simple cost-effectiveness ratio has declined. If no easy way to summarize experience to date with a simple cost-effectiveness ratio is available, how should we analyze economic investments in STI treatment? We believe that the way forward is a better understanding of why STI treatment and other health services vary so much in terms of their efficiency and effectiveness from one setting to another. By studying the determinants of this variation, we should gain an improved understanding of the full costs of high-quality STI service delivery and its place in the health sector investment picture.

ACKNOWLEDGMENTS

The authors would like to acknowledge Becca Feldman, Patricia Jackson, Dilip Parajuli, and Melanie Ross for their outstanding support in the preparation of this chapter.

NOTES

1. The Gini coefficient is a measure of inequality that here we apply to income. If income is distributed equally in the population, the coefficient is equal to 0, and if a few individuals hold almost all the wealth, the coefficient is close to 1.

2. Given that WHO has expended enormous efforts to estimate discounted years of life lost, disability years lost, and DALYs lost as a result of STIs, the simplest and most direct approach for computing the DALY benefits of preventing or curing an STI in a single patient would be to use WHO's years of life lost, disability years lost, or DALY per case assumptions. Alternatively, one could simply divide WHO's aggregate values of these indicators by the incidence rate of each disease in each region to obtain the estimated burden per incident case. Unfortunately, neither the case-specific burden numbers nor the incidence rates that correspond to the DALY aggregates are available from WHO.

3. In contemporaneous data, STIs can either affect or be affected by HIV prevalence. To focus on the effects of an STI on HIV infection, we lag infection by an STI by seven years. Though partially correcting for simultaneity bias, this strategy does not allow us to identify whether lagged STI prevalence is directly affecting HIV infection or only serving as a proxy for the risky sexual behavior that drives both epidemics.

4. The samples include two measures of HIV prevalence (low- and high-risk groups) for some countries. These measures enable us to expand the sample used in the column (1) regression from 40 countries to 56 separate observations. Equations are estimated with Stata's cluster option to correct the standard errors of the coefficients for the correlation between the errors on separate observations from the same country. The variable urban high-risk dummy is used to shift the intercept coefficient for the high-risk sample in comparison with the low-risk one.

Chapter 18

HIV/AIDS Prevention and Treatment

Stefano Bertozzi, Nancy S. Padian, Jeny Wegbreit, Lisa M. DeMaria, Becca Feldman, Helene Gayle, Julian Gold, Robert Grant, and Michael T. Isbell

Although global commitment to control the HIV/AIDS pandemic has increased significantly in recent years, the virus continues to spread with alarming and increasing speed. By the end of 2005, an estimated 40 million people worldwide were living with HIV infection or disease, a notable rise from the 35 million infected with HIV in 2001 (UNAIDS 2005). In 2005, close to 5 million new HIV infections and 3 million AIDS deaths occurred, more of both than in any previous year. Sub-Saharan Africa remains the region most affected by HIV/AIDS; however, the virus is now spreading rapidly in Asia and parts of Eastern Europe.

Despite the rapid spread of HIV, several countries have achieved important success in curbing its transmission. The extraordinary potential of HIV prevention is exemplified by such diverse efforts as Thailand's 100 percent condom program, Uganda's remarkable decrease in HIV prevalence, and the community-based syndromic management of sexually transmitted infections (STIs) in Mwanza, Tanzania. Box 18.1 describes characteristics common to these programs.

Successes also include the development and effective use of highly sensitive and specific HIV screening tests, which have virtually eliminated infection from the blood supply in the developed world and in most parts of the developing world (WHO 2002a). In addition, the administration of a short course of nevirapine to mothers during labor and to newborns postpartum reduces the risk of mother-to-child transmission (MTCT) by as much as 47 percent (Guay and others 1999). However, recent data suggest that such short-term successes may be at the expense of resistance and viral failure once treatment is introduced after delivery (Eshleman and others 2001).

Enormous advances in HIV/AIDS treatment regimens have fundamentally altered the natural history of the disease and sharply reduced HIV-related morbidity and mortality in countries where such treatments are accessible. The advent of antiretroviral drugs in the late 1980s began a revolution in the management of HIV, which can be seen as analogous to the use of penicillin for treating bacterial infections in the 1940s. The most notable advance on the treatment front is the use of combination antiretroviral therapy, which is far more effective than monotherapy (zidovudine or AZT), the standard of care when the first edition of this volume was published. Recent declines in the price of combination antiretroviral therapy in developing countries from US\$15,000 per year to less than US\$150 in some countries have prompted numerous developing countries to introduce antiretroviral therapy through the public sector. These declines also pose difficult questions regarding the optimal allocation of limited resources for HIV/AIDS, as well as the potential impact on already strained health care infrastructures.

OBSTACLES TO HIV CONTROL

Obstacles to effective HIV control include lack of prevention and care coverage and lack of rigorous evaluations. Both are discussed below.

Lack of Coverage and Access to Prevention Services

Notwithstanding these treatment strides, global efforts have not proved sufficient to control the spread of the pandemic or to extend the lives of the majority of those infected. The desired level of success has not yet been achieved for several reasons.

Box 18.1

Successful HIV Prevention Strategies

The HIV prevention success stories highlighted in this chapter stem in part from each country's unique cultural, historical, and infrastructural elements. Nevertheless, these successes share several common features, thereby offering potential guidance for the development and implementation of prevention strategies in other settings. These features include:

- high-level political leadership
- active engagement of civil society and religious leaders in a multisectoral approach

Source: Authors.

- population-based programs designed to change social norms
- increased open communication about sexual activities and HIV/AIDS
- programs to combat stigma and discrimination
- condom promotion
- STI surveillance and control
- interventions targeting key “bridge” populations—populations that transmit the virus from high-risk to low-risk groups.

Most people who could benefit from available control strategies, including treatment, do not have access to them. Modelers commissioned by the World Health Organization (WHO) and the Joint United Nations Programme on HIV/AIDS (UNAIDS) determined that existing interventions could prevent 63 percent of all infections projected to occur between 2002 and 2010 (Stover and others 2002). Nonetheless, a 2003 survey of coverage revealed that fewer than one in five people at high risk of infection had access to the most basic prevention services, including condoms, AIDS education, MTCT prevention, voluntary counseling and testing (VCT), and harm reduction programs (Global HIV Prevention Working Group 2003). WHO and UNAIDS estimate that only about 7 percent of the nearly 6 million people in need of treatment receive it and that the number of people who require antiretroviral therapy increases by 8,000 each day (UNAIDS 2004).

Current coverage shortfalls, combined with the relentless expansion of the epidemic, underscore the acute need for rapid scale-up of prevention and treatment interventions—an imperative that the international community has acknowledged but that remains to be realized after more than 15 years. However, the activities of the Global Fund to Fight AIDS, Tuberculosis, and Malaria and the U.S. President's Emergency Plan for AIDS Relief (a five-year, US\$15 billion initiative) suggest a growing commitment to tackle these issues. The latter aims to provide antiretroviral drugs for 2 million HIV-infected people, to prevent 7 million new infections, to provide care for 10 million individuals, and to develop health system capacity in Vietnam and in Africa and the Caribbean. Even though 15 countries are currently slated to receive support from the President's Emergency Plan, many of the countries most affected by HIV/AIDS—including Lesotho, Malawi, Swaziland, and Zimbabwe—are not included in the list of beneficiary countries.

Because antiretroviral therapy has historically been unavailable in most developing countries, national programs have lacked the means to undertake a comprehensive approach to HIV/AIDS (notable exceptions are Argentina, Brazil, and Mexico, which provide universal coverage for antiretroviral therapy). As discussed in chapter 8, control of the pandemic demands a two-front battle that emphasizes both prevention and care. Even though the prospect of greater access to treatment increases the feasibility of integrating prevention and care in resource-limited settings, it also raises new questions regarding the selection of optimal prevention programs to pair with treatment programs.

Lack of Rigorous Evaluations

In addition to poor coverage of key interventions, perhaps the greatest challenge to effective global control is the lack of reliable evidence to guide the selection of interventions for specific areas or populations. In the same way that global policy makers are increasingly recognizing the need for rigorous evaluation of development programs to ensure their success and eliminate waste, the need for reliable scientific evaluations of AIDS control programs is equally paramount for the same reasons. There are simply not enough resources to do everything everywhere; choices must be made and priorities set. In the HIV/AIDS field, this information deficit is especially pronounced with respect to HIV prevention in general and prevention implemented on a population level in particular. Currently, the allocation of resources for HIV/AIDS prevention is seldom evidence based, primarily because of a lack of data on both the effectiveness and the cost of interventions (Feachem 2004).

Few evaluations have collected data specifically on HIV infection as an outcome (Fleming and DeMets 1996). In the

case of care and treatment, success and failure are more readily and rapidly apparent, leading to a substantial degree of auto-correction of ineffective policies. In contrast, with respect to HIV prevention, it is unlikely that those infections that might have occurred in the absence of a prevention program would be monitored, thus reducing the meaningfulness of the auto-feedback cycle for prevention. This underscores the importance of proactive, rigorous evaluation to differentiate success from failure in a timely manner. Sound evidence on the effectiveness of HIV prevention measures is especially important in light of the tendency of many governments and international aid agencies to avoid programs that address sexual behaviors, drug use, and highly stigmatized and vulnerable populations.

In addition, prevention studies have rarely incorporated the well-defined control or comparison groups necessary to identify contextual factors that are essential for appropriately tailoring interventions to the diverse regional settings and the myriad of microenvironments in which HIV transmission occurs (Grassy and others 2001). Contextual data are similarly critical for developing strategies to combat HIV/AIDS-related stigma and restrictive social and gender norms, which often frustrate attempts to address sexual and addictive behaviors associated with HIV transmission. Even where national efforts have succeeded in curbing the spread of the epidemic, as in Senegal and Uganda, evidence often does not clearly indicate the specific, well-defined, contextual features that account for success.

The lack of both contextual data and sound evidence regarding the effectiveness of HIV interventions hinders policy makers' ability to tailor HIV interventions to the nature and stage of national epidemics, something that the authors argue is necessary to address HIV/AIDS effectively. In the absence of such data, HIV/AIDS expenditures undoubtedly incorporate an unacceptable degree of waste, people are unnecessarily becoming infected with HIV, and HIV-infected individuals are dying prematurely.

Why has this type of research not been more forthcoming? In part it is because, by definition, such research is less innovative scientifically and also typically less experimental than research to develop new interventions. It is handicapped both in competing for traditional research funding and in receiving academic recognition. The only way to redress the imbalance is through specific earmarking of significant research funds.

ACTION UNDER UNCERTAINTY

Even though the current deficit in evaluation research is glaring, the magnitude and seriousness of the global pandemic means that action is nevertheless required. Moreover, despite such gaps in knowledge, we can still improve control strategies by tailoring interventions to the nature and scope of the epidemic. Summarized below is what is known with regard to the

burden of disease, the determinants of transmission, and the effectiveness and cost-effectiveness of existing prevention interventions.

Burden of Disease

As a result of large-scale implementation of data collection methods for surveillance worldwide and enhanced methods for validating and interpreting HIV-related data, the HIV/AIDS epidemic is probably one of the best documented epidemics in history. An increasing number of data sources contribute to reasonably accurate estimates and a more nuanced understanding of the epidemic's trends. Unfortunately, this relatively accurate picture of where the epidemic is and has been is not matched by similarly convincing maps of the factors that explain its spread.

Although no single country has been spared the virus, the epidemic has affected certain regions of the world disproportionately, and Sub-Saharan Africa remains by far the hardest hit region (table 18.1). With only 10 percent of the world's population, it accounts for more than 75 percent of all HIV infections worldwide and more than 75 percent of AIDS-related deaths estimated for 2003. Asia and the Pacific, with several large and populous countries, account for 7.4 million infections, or 19.5 percent of the current burden of disease. Prevention and treatment efforts in Sub-Saharan Africa and Asia—regions that together represent 85 percent of all current infections—have dictated, and will continue to dictate, global trends in the burden of HIV- and AIDS-related mortality.

Between 1997 and 2001, the percentage of women living with HIV/AIDS increased from 41 to 50 percent. This trend is most apparent in Sub-Saharan Africa, where women represent 57 percent of adults living with HIV and 75 percent of HIV-infected young people. Even though women account for a smaller share of infections in Asia (28 percent), the disease burden among women and girls is likely to rise as the epidemic becomes generalized. More detailed information about the global burden of HIV/AIDS, regional differences, and trends over time is available in the UNAIDS (2005) report on the global AIDS epidemic.

Determinants of Infection

HIV transmission predominantly occurs through three mechanisms: sexual transmission, exposure to infected blood or blood products, or perinatal transmission (including breastfeeding). The likelihood of transmission is heavily affected by social, cultural, and environmental factors that often differ markedly between and within regions and countries. There is also some indication that molecular, viral, immunological, or other host factors might influence the likelihood of HIV transmission. For a more detailed discussion of sexual behaviors and the contextual determinants of infection, see chapter 17.

Table 18.1 Deaths and Disability-Adjusted Life Years Attributed to AIDS by Region, Age, and Gender, 2001

Region	Number (thousands)			Percentage female
	Total	Both sexes, age 0–14	Both sexes, age 15+

Table 18.2 Estimated HIV Transmission Risk per Exposure

Type of exposure	Estimated risk HIV transmission per exposure
Receptive anal intercourse	≤ 3.0 percent (1/125 to 1/31) (DeGruttola and others 1989)
Receptive vaginal intercourse	≤ 0.1 percent (1/2,000 to 1/667) (Mastro and others 1994; Wiley, Herschkorn, and Padian 1989)
Insertive vaginal or anal intercourse	≤ 0.1 percent (1/3,333 to 1/1,111) (Nagachinta and others 1997; Peterman and others 1988)
Needlestick injury	= 0.3 percent (1/313) (Henderson and others 1990)
Use of contaminated injecting drug equipment	= 0.6 percent (1/149) (Kaplan and Heimer 1992)
Mucous membrane	= 0.1 percent (1/1,111) (Ippolito, Puro, and De Carli 1993)

Source: Authors.

Sexual Transmission. Worldwide, sexual intercourse is the predominant mode of transmission, accounting for approximately 80 percent of infections (Askew and Berer 2003). Sexual intercourse accounts for more than 90 percent of infections in Sub-Saharan Africa. Although many people who know they are infected reduce their risk behaviors, studies in developed countries suggest that a substantial percentage nevertheless continue to engage in unprotected sex (Marks, Burris, and Peterman 1999). The risk of sexual transmission is determined by behaviors that influence the likelihood of exposure to an

infected individual and by infectivity in the event of exposure. This also includes factors related to the infectiousness of the infected partner and the susceptibility of the uninfected partner.

Infectivity The per contact infectivity of HIV from sexual transmission varies depending on sexual activity (Royce and others 1997). Anal intercourse carries a higher transmission probability than penile-vaginal intercourse, and male-to-female transmission is more likely than female-to-male transmission. Data on infectivity by transmission mode are shown in table 18.2.

Biological Mediators of Infectivity Untreated STIs increase the risk of sexual HIV transmission several-fold (Institute of Medicine 1997). Numerous epidemiological studies have supported the association of genital ulcers in general and of genital herpes (herpes simplex virus 2, or HSV-2) in particular with HIV infection (Hook and others 1992). Not only does the biological interaction between HSV-2 and HIV enhance the transmission and acquisition of HIV, but HIV infection is also associated with more frequent reactivation of HSV-2. The presence of herpetic ulcers and lesions allows an entry point for HIV in the uninfected individual, and the presence of high copy numbers of HIV ribonucleic acid (RNA) in HSV-2 lesions in HIV-infected individuals underscores the importance for HIV prevention of controlling HSV-2 infections (Mbopi Keou and others 1999).

Vaginal infections are also emerging as important risk factors for HIV. For example, infection with trichomonas increases the risk for HIV seroconversion (Buve 2002). In addition, higher trichomonas rates have been detected in regions of Sub-Saharan Africa that have higher HIV rates, and investigators working throughout Sub-Saharan Africa report similar results, with odds ratios from 1.5 to 56.8 (Gregson and others 2001). In addition, studies have shown an increased risk of HIV acquisition in patients who have bacterial vaginosis (Martin and others 1999).

Circumcision also affects HIV transmission. In a meta-analysis of 27 studies (Weiss, Quigley, and Hayes 2000), uncircumcised men were almost twice as likely to be infected with HIV as those who were circumcised. Studies that controlled adequately for other risks and studies that separately assessed risk in high-risk populations, such as STI clinic attendees or truck drivers, found an even stronger protective effect of circumcision. Similarly, an ecological study comparing two high-prevalence Sub-Saharan African cities with two low-prevalence cities found that circumcised individuals were substantially less likely to be infected with HIV (Avert and others 2001). Two recent studies conducted in Kenya and India (Donnelly 2004; Reynolds and others 2004) found that uncircumcised men had an HIV rate 7 to 11 times greater than circumcised men. More recently, results from a randomized controlled trial conducted in South Africa indicated that the risk of HIV acquisition was reduced by more than 60 percent of men randomized for circumcision (controlling for sexual behavior, including condom use and health seeking behavior) in a community where more than 30 percent of the women were infected (Avert and others 2005).

Before circumcision among adult males becomes a widespread policy recommendation, results are still pending in two similar trials. Obviously one issue is the acceptability of such a procedure as well as the fact that some increase in high risk sexual activity was noted among the men who were circumcised, although this did not offset the results of the intervention.

The risk of sexual transmission is also strongly correlated with the plasma level of virus in the infected individual (Quinn and others 2000); thus, infectivity varies over the natural progression of the disease. Individuals are most infectious subsequent to infection and again during the late stage of the disease. Antiretroviral therapy significantly reduces the level of virus, often to the point that standard tests cannot detect HIV in the patient's blood (Palella and others 1998). Available data suggest that viral load reductions induced by antiretroviral therapy will lower infectiousness. Studies have shown a close relationship between the amount of viral suppression and the risk of vertical transmission (Garcia and others 1999). Quinn and others (2002) show that the risk of sexual transmission between couples in Africa was strongly related to the level of viral load in the infected partner.

Exposure to Infected Blood or Blood Products. Injection drug use and blood transfusion are two mechanisms of HIV exposure to infected blood. Determinants of each are discussed below.

Injection Because of the efficiency of HIV transmission through needle sharing, the introduction of HIV into an urban network of injecting drugs users can quickly lead to extraordinarily high HIV prevalence in this population. Sharing of injection equipment and frequency of injection are both important correlates of HIV infection (Chaisson and others 1989). Attendance at shooting galleries, where sharing with anonymous injecting partners is likely to occur, is also an independent risk factor across many studies (Vlahov and others 1990). Injecting cocaine (associated with “booting” or “kicking,” where blood is drawn into the syringe and then injected) and having a number of needle-sharing partners are also associated with HIV infection (Anthony and others 1991).

Blood Transfusion The probability of becoming infected through an HIV-contaminated transfusion is estimated at more than 90 percent (UNAIDS 1997), and the amount of HIV in a single contaminated blood transfusion is so large that individuals infected in this manner may rapidly develop AIDS. Currently, between 5 and 10 percent of HIV infections worldwide are transmitted through the transfusion of contaminated blood products (WHO 2002a). Setting up and maintaining a safe blood supply will virtually eliminate HIV transmission through transfusions.

Perinatal Transmission. Perinatal HIV transmission includes both vertical transmission and transmission during breastfeeding. Determinants of each are discussed below.

Vertical Transmission Perhaps the most compelling evidence of the significance of viral load and transmission risk has been

documented with respect to MTCT. Maternal viral load, as quantified by RNA polymerase chain reaction, is associated with increased risk in each mode of vertical transmission. A recent randomized clinical trial in Kenya found that maternal plasma HIV RNA levels higher than 43,000 copies per milliliter were associated with a fourfold increase in vertical transmission (John and others 2001).

Independent of HIV RNA levels in maternal plasma, additional risk factors include cervical HIV deoxyribonucleic acid (DNA), vaginal HIV DNA, and cervical or vaginal ulcers. Chorioamnionitis has also been documented as a risk factor for MTCT among African mothers (Ladner and others 1998), as has exposure to maternal blood during labor and delivery. Newell (2003) estimates that for every hour an infant is exposed to ruptured membranes, the risk of transmission increases by 2 percent.

Breastfeeding Transmission through breastfeeding is likely associated with an elevated viral load in the breast milk, which in turn is associated with maternal plasma viral load and CD4 T cell levels. Mastitis has also been associated with increased risk of vertical transmission. Meta-analyses suggest that the cumulative probability of HIV infection increases from 0.6 percent at age 6 months to 9.2 percent at age 3 (Read 2003). A study in Malawi, however, indicates that most transmission occurs in the early breastfeeding months, with an incidence per month of 0.7 percent at age 1 to 5 months, 0.6 percent at age 6 to 11 months, and 0.3 percent at age 12 to 17 months (Miotti and others 1999). In one study, infants who were breastfed in combination with receiving other supplementary foods were twice as likely to be infected at age 6 months than infants fed exclusively on breast milk or on formula (Coutsoudis and others 2001). The hypothesis is that antigens and bacterial contaminants present in supplemental fluids and foods consumed by infants who are not exclusively breastfed may cause inflammation and microtrauma to the infant's intestinal gut, thereby facilitating viral transmission. Another hypothesis is that mixed feeding increases the risk of subclinical or clinical mastitis in the mother, which could increase milk viral load (Semba and others 1999).

Decisions about breastfeeding are further complicated by recent data indicating possible increased mortality among breastfeeding mothers (Nduati and others 2001) and by the stigma associated with not breastfeeding in countries where abstaining from breastfeeding is tantamount to disclosing a woman's HIV status.

Effectiveness and Cost-Effectiveness of Prevention Interventions

Below we discuss the need for ongoing surveillance and contextual data to determine the effectiveness of HIV interventions

and how best to implement those interventions. We then discuss the existing effectiveness and cost-effectiveness data.

Essential Background Data for Any Intervention. Because the prioritization of prevention strategies for any epidemic requires accurately identifying the epidemiological profile (discussed below), maintaining a sound and reliable public health surveillance system is a prerequisite for an effective prevention response. An understanding of HIV and STI prevalence and trends, as well as the prevalence and distribution of behaviors that contribute to the epidemic's spread, should be supplemented by national monitoring systems that track sources and uses of funding to promote greater accountability. In addition, data are needed to identify and characterize key contextual issues that affect the selection of interventions.

Although surveillance is essential for an optimally strategic public health response, its utility depends on the degree to which the information it yields is effectively deployed. As noted below, countries with concentrated epidemics should prioritize interventions that are targeted to the populations at highest risk. In Latin America, however, where information on national AIDS funding is strongest, the proportion of limited prevention resources that is not targeted to the populations at highest risk of infection varies from less than 5 percent to more than 50 percent (Saavedra 2000). This range strongly suggests that resource allocation is frequently not based on available epidemiological and effectiveness data.

Table 18.3 summarizes information about the effectiveness of the interventions discussed below.

Cost-Effectiveness Estimates for Prevention Interventions. How countries spend funds and which interventions they prioritize should be guided by estimates of the relative cost-effectiveness of such interventions. Unfortunately, reliable estimates of cost-effectiveness are largely lacking, for a number of reasons. The main reason is that HIV prevention interventions are difficult to force into a typology that clearly distinguishes one intervention from another. For example, the counseling component of VCT has a strong information-sharing element that overlaps with (a) information, education, and communication (IEC) through the media; (b) peer interventions; and (c) the counseling component of STI treatment. Similarly, the psychological support offered through counseling is comparable to support provided through support groups or to interventions designed to increase social support. Such overlap and duplication among components of different interventions complicate efforts to estimate both the effectiveness and the cost-effectiveness of different interventions.

Several authors have recently reviewed estimates of cost-effectiveness for the prevention interventions described here (Creese and others 2002; Jha and others 2001; Marseille and others 2002; Walker 2003). These reviews address a number of

Table 18.3 Effectiveness of HIV Interventions

Intervention	Outcome	Effect	Citations
School-based education	Sexual debut	The number of students reporting early sexual debut was significantly lower in the intervention group in both studies.	Hayes and others 2003; Stanton and others 1998
	Multiple sex partners	The number of students reporting multiple sex partners was significantly lower in the intervention group in both studies.	Fawole and others 1999; Hayes and others 2003
	Condom use	Condom use was significantly higher in the intervention group in three of the four studies and nonsignificantly higher in one study.	Fawole and others 1999; Harvey, Stuart, and Swan 2000; Hayes and others 2003; Stanton and others 1998
	HIV incidence	The study found no significant differences in HIV incidence.	Hayes and others 2003
	STI prevalence and incidence	The study found no significant differences in STI prevalence and incidence.	Hayes and others 2003

— = not available.

CE = cost-effectiveness.

Note: The authors have categorized each of the studies. The first time each study is mentioned, it is identified by whether it was modeled (M) or empirical (E); whether it calculated primary HIV infections averted (S, for static) or if it also showed secondary infections averted (D, for dynamic); and where appropriate, we indicate if the study also looked at the impact on STIs. The cost-effectiveness of these interventions will differ depending on the population to which they are targeted, (that is, mass interventions versus targeted interventions). In addition, the cost-effectiveness of each intervention may vary greatly by study, because each cost-effectiveness study is not uniform. No cost-effectiveness studies of male condom promotion were found, because condom promotion, distribution, and IEC are generally part of a larger program with many components and studies did not distinguish between the costs of individual components of such programs.

Box 18.2

Comprehensive Sex Education Versus Abstinence-Only Education

The available data on sex education suggest the following:

- Sex education, including condom promotion, does not encourage or increase sexual activity (Kirby 2001).
- Sex education reduces risk and positively affects sexual behaviors. In general, sex education programs increase knowledge about AIDS and related issues, increase intention to use condoms, and increase condom use among sexually active youths (Kim and others 1997).
- Abstinence-only education is not effective in promoting healthy sexual behaviors. Programs that promote both postponement of intercourse and contraceptive use were more effective in changing behaviors than those that stressed abstinence alone. None of the abstinence-only programs that have been evaluated demonstrated an overall positive effect on sexual behavior, nor did they affect contraceptive use among sexually active participants (Kirby 1997).

Source: Authors.

methodological issues that will not be repeated here. The reviews agree that the availability of cost and cost-effectiveness analyses for HIV/AIDS prevention strategies is limited and that the need for such knowledge for planning and decision-making purposes is urgent.

Table 18.4 summarizes available cost-effectiveness estimates for the four UNAIDS epidemic profiles that are described later in table 18.5. The estimates of cost per disability-adjusted life year (DALY) saved assume a uniform 20 DALYs lost per infected adult (Murray and Lopez 1996) and 25 DALYs lost per infected child (Marseille and others 1999) and do not account for the increasing proportion of people living with HIV/AIDS in developing countries who will have access to antiretroviral therapy over the coming years.

General Interventions Relevant for All Modes of Transmission

The following are general interventions not specifically targeting the mode of transmission:

- *Information, education, and communication.* This intervention includes education on HIV/AIDS and condom use through pamphlets, brochures, and other promotional materials in classroom or clinic settings or through the radio, television, or press. In general, discerning the effectiveness of IEC alone is difficult, because IEC is often included in condom promotion and distribution interventions. Here we consider the effectiveness of IEC in concert with condom promotion and distribution. Of all available prevention interventions, providing information and education about HIV/AIDS is perhaps the most difficult to assess for cost-effectiveness. Numerous studies have shown that information alone is typically insufficient to change risk behavior. Accurate information, however, is indisputably the basis for informed policy discourse—a vital ingredient in the fight against fear-based stigma and discrimination. In
- the absence of studies to guide the level of investment in IEC, the only reasonable alternative seems to be to implement IEC on the basis of data derived from relative levels of knowledge and understanding in the population. For example, if only 25 percent of the sexually active population were able to describe how HIV is transmitted and prevented, clearly more IEC would be needed, but if 75 percent of the population understood the basic facts about HIV/AIDS, the need for additional funding would be diminished.
- *School-based sex education.* School-based sex education programs, an aspect of IEC, provide information to young people and reinforce healthy norms in a school setting (Peersman and Levy 1998). Limited data have shown differences in students who have been exposed to school-based sex education (summarized in table 18.3). Box 18.2 reviews the effectiveness of abstinence-only education and comprehensive sex education, subsets of school-based sex education. In light of more recent controlled studies that have not shown an effect on condom use, STIs, or HIV infection, any cost-effectiveness estimate is extremely speculative.
- *Voluntary counseling and testing.* This intervention enables people to know their HIV status and provides counseling support to help them cope with the outcome. Knowledge of serostatus may lead individuals to avoid engaging in risky behaviors (Sweat and others 2000). Cost-effectiveness estimates of VCT vary widely, and as with many other prevention interventions, these estimates are extremely sensitive to the prevalence of HIV in the population that is seeking testing.
- *Peer-based programs.* Peer interventions use influential members of a targeted community to disseminate information or teach specific skills. Such interventions have generally been found to be effective in reducing unsafe behaviors. Work on the cost-effectiveness of peer-based interventions in developing countries has been minimal. In Chad, Hutton, Wyss, and N'Diekhon (2003) reviewed data on 12 prevention

interventions and integrated them into a comparative analysis. Their findings suggest that peer education for sex workers is likely to be highly cost-effective and to entail one-fifth the cost of the next most favorable intervention, blood safety. However, the estimated cost-effectiveness for the same intervention directed toward young people and high-risk men is 33- to 36-fold lower.

Interventions to Prevent Sexual Transmission Below we discuss the effectiveness and cost-effectiveness of interventions that target sexual transmission of HIV:

- *Condom promotion, distribution, and social marketing.* Condom promotion, distribution, and social marketing vary by epidemic profile. The evidence on condom promotion and distribution programs indicates that such programs result in significantly higher condom use and significantly lower STI incidence (see table 18.3). Given the central role that condom promotion, distribution, and social marketing has played in HIV prevention programs, the lack of data on the relative cost-effectiveness of such programs 20 years into their implementation is striking. It is beyond dispute that the use of a condom by sexual partners who are HIV-discordant is extraordinarily cost-effective, given the low cost and high effectiveness of the condom in preventing HIV transmission. Information on the relative costs and effectiveness of different approaches to increasing condom use by serodiscordant sexual partners is not available, with the shortage of information being far more acute for effectiveness than for costs. In the absence of empirical evidence, decision makers are reduced to formulating policy on the basis of theory and common sense. Even inefficient use of condoms by seroconcordant couples is likely to be highly cost-effective because of the reduction in other STIs, cervical cancer, and unwanted pregnancies. However, more reliable information on

strategies to optimize the effectiveness and cost-effectiveness of condom programs is urgently needed.

- *STI screening and treatment.* The latest analyses suggest that STI control may be most effective as an HIV prevention strategy when initiated earlier in the course of national epidemics and when sexual risk behaviors are high (Orroth and others 2003). In most developing countries, the greatest benefits from treating STIs almost certainly accrue from averting the morbidity and mortality caused directly by STIs rather than indirectly because of reduced HIV transmission. Estimates of the cost-effectiveness of STI treatment purely as a way to reduce HIV transmission vary widely.

Prevention of Mother-to-Child Transmission The existing data on the effectiveness and cost-effectiveness of HIV interventions target MTCT in order of decreasing cost-effectiveness as follows:

- *Avoidance of unwanted pregnancies among infected mothers.* One of the most effective strategies to reduce HIV among infants is to provide better contraception services. See box 18.3 for details.
- *Use of antiretroviral therapy.* Evidence indicates that the provision of antiretroviral drugs to infected mothers significantly reduces vertical transmission (see table 18.4). The provision of antiretroviral therapy to prevent MTCT is highly cost-effective, to the point of being cost-saving for women who already know that they are infected. When screening of women is involved, cost-effectiveness declines as HIV prevalence falls, because of the larger number of women who must be screened to identify an HIV-positive woman (Rely and others 2003).
- *Feeding substitution.* Whereas in high-income countries the health community recommends complete avoidance of breastfeeding for HIV-infected mothers to prevent postnatal

Box 18.3

Preventing Mother-to-Child Transmission: Antiretroviral Therapy or Contraception?

The differential effect of contraceptive delivery versus antiretroviral therapy in preventing HIV can be shown by comparing the provision of effective contraception and of nevirapine to a population of 1,000 HIV-infected women. In the absence of an intervention, approximately 150 infants would be infected with HIV during delivery (Cates 2004). If nevirapine were available, the number of infected infants would be reduced to 82 (the expected 47 percent decline). If effective contraceptive services were

available, this number would be reduced to 49. If both strategies were adopted, the number of infected infants would be further reduced to 25.

The greatest difference between providing antiretroviral therapy and providing contraception is the number of infants orphaned in the future because their mothers die of HIV infection. Three models all come to this conclusion (Reynolds and others 2004; Stover and others forthcoming; Sweat and others 2004).

Source: Authors.

HIV transmission, in developing countries the feasibility of this approach is often limited by such factors as cost, sustainability, lack of safe water, health, and child spacing and by sociocultural factors (Coutsoudis 2002). Prolonged breastfeeding more than doubles the likelihood of MTCT (Nduati and others 2000). Because evidence indicates that mixed feeding (breast milk and formula or other substance) has a higher risk of transmission than exclusive breastfeeding (Coutsoudis and others 1999), mothers should be counseled on the superiority of early weaning over mixed feeding. Even fewer data are available on the cost-effectiveness of feeding substitution.

Prevention of Bloodborne Transmission Below we discuss the effectiveness and cost-effectiveness of harm reduction for injecting drug users, implementation of blood safety practices, and provision of sterile injections:

- *Harm reduction for injecting drug users.* Harm reduction involves a combination of health promotion strategies for users, including needle and syringe exchange programs, ready access to effective drug treatment and substitution, and provision of counseling and condoms. Brazil, which has reduced the incidence of HIV and kept HIV prevalence from reaching projected levels, has relied on strong official support for harm reduction as a cornerstone of its national prevention program (Mesquita and others 2003). A limited number of studies have shown significant reductions in HIV incidence among those exposed to needle exchange programs, and several studies have shown significant reductions in needle sharing (see table 18.3). Methadone maintenance is both safe and effective as a treatment for drug addiction (National Consensus Development Panel on Effective Medical Treatment of Opiate Addiction 1998) and may help reduce the risk of HIV transmission by enabling individuals to avoid the drug-using behaviors that can lead to HIV infection (Metzger, Navaline, and Woody 1998; Needle and others 1998). However, the effect of drug treatment modalities on the rate of HIV transmission is currently limited by laws in many countries that prohibit or restrict the use of methadone maintenance or other drug substitution strategies. The evidence supporting the cost-effectiveness of needle exchange programs in high-income countries is strong. However, little has been published in relation to developing countries, partly because these programs have not been as widely implemented as hoped. Given the low cost of syringes, the extremely high efficiency of HIV transmission by this route, and the demonstrated effectiveness of harm reduction programs in changing syringe-sharing behavior, needle exchange programs should be one of the most cost-effective interventions.
- *Implementation of blood safety practices.* Transmission of HIV can be virtually eliminated in health care settings

through a blood safety program that ensures (a) a national blood transfusion service; (b) the recruitment of voluntary, low-risk donors; (c) the screening of all donated blood for HIV; and (d) the reduction of unnecessary and inappropriate transfusions (UNAIDS 1997). Available evidence indicates that HIV screening is effective in reducing HIV infections (see table 18.4). Blood screening for HIV is costly but has been shown to be cost-effective in numerous studies in developing countries (see table 18.3) (Foster and Buve 1995; Hutton, Wyss, and N'Diekhhor 2003; Watts, Goodman, and Kumaranayake 2000). The evidence appears to support the WHO and UNAIDS recommendations that all countries, regardless of the nature of the epidemic in the country, should implement a comprehensive blood safety program.

- *Universal precautions.* A critical component of standard infection control in health care settings is a prohibition on reusing needles and syringes. A controversy has recently arisen among researchers who contend that HIV infections have been significantly misclassified because of the undercounting of cases that result from unsafe injection practices by misattributing such cases to heterosexual transmission (Gisselquist and others 2003). However, after much investigation, WHO and the U.S. Department of Health and Human Services concluded that even though transmission caused by unsafe injections may have been underreported, it nevertheless does not account for an appreciable amount of HIV transmission (WHO and UNAIDS 2003). Cost-effectiveness analyses indicate that a combined policy strategy of single-use syringes and interventions to minimize injection use could reduce injection-related infections by as much as 96.5 percent, or 8.86 million DALYs between 2000 and 2030, at an average cost of US\$102 per DALY. Additional cost-effectiveness studies are needed to guide decisions regarding the optimal choice of technology in this area.

To prevent bloodborne transmission of HIV and other diseases, health care workers, emergency personnel, and others who might experience occupational exposure to blood or body fluids are advised to take universal precautions. This approach, which treats all bodily fluids as potentially infectious, includes the use of gloves, gowns, and goggles; the proper disposal of waste; and the use of sterile injection and other infection control practices (CDC 1989). Studies have demonstrated that the use of protective gear, such as gloves, reduces the likelihood of blood exposure in health care settings.

Although the cost-effectiveness of implementing universal precautions increases as HIV prevalence increases, universal precautions are unlikely to be cost-effective in resource-limited settings especially where HIV prevalence is low. Postexposure prophylaxis with antiretroviral agents is considered the standard of care after occupational needle-stick exposure to blood from an HIV-infected person.

Cost-effectiveness analyses of postexposure prophylaxis have been conducted only in high-income countries and have concluded that this intervention is not cost-effective (Low-Beer and others 2000; Pinkerton, Holtgrave, and Bloom 1998).

PREVENTION IN THEORY AND PRACTICE: USING EPIDEMIC PROFILES AND CONTEXTUAL FACTORS TO INFORM PREVENTION GUIDELINES

Prevention studies and national experiences over the past 20 years strongly suggest that prevention strategies are likely to be most effective when they are carefully tailored to the nature and stage of the epidemic in a specific country or community. UNAIDS has developed epidemiological categories for characterizing individual epidemics on the basis of prevalence of infection in particular subpopulations and in the general population (table 18.5).

As a complement to the guidance provided by the epidemic profile, Grassly and others (2001) recommend assessing the prevalence of other STIs; estimating the extent of mixing between high- and low-risk groups (for example, men who have sex with men who have sexual contact with female partners); and estimating the prevalence of high-risk sexual behaviors in the population (such as lack of condom use with casual partners). They also cite two other critical contextual factors: the capacity of the health service and the social, economic, and legislative context, including social norms and attitudes about sexual and drug use behaviors and the acceptance of breastfeeding. Contextual factors that may play a role in the success of interventions include the status of women, the stigmatization of high-risk groups, and the presence of armed conflict and social upheaval. Together, the epidemic profile and the context in which the epidemic occurs suggest various prevention strategies.

General Prevention Guidelines by Type of Epidemic

Generally, it is more important to change the behavior of people who have high levels of risk behavior than it is to change that of

people with lower levels of risk behavior. However, the difference in the effectiveness between the two falls as epidemics become more generalized, and as the average and maximum size of the connected components (number of people linked to each other directly or through others by their sexual or injecting risk behavior). Thus, in heavily affected countries, or those where the virus has the potential to spread rapidly, prevention interventions are likely to become extremely cost-effective even when targeted at individuals with relatively low levels of risk behavior. Consequently, countries with low-level and concentrated epidemics should emphasize interventions that target individuals at especially high risk of becoming infected or of transmitting the virus, whereas countries with generalized epidemics should also invest heavily in interventions that target entire populations or population subgroups. Thus, any determination of the likely effectiveness and cost-effectiveness of specific interventions in particular circumstances requires an accurate understanding of the stage and nature of the national epidemic.

The countrywide successes discussed in boxes 18.4 and 18.5 highlight population-level interventions that modify social norms as well as highlighting legislative and economic factors. Other examples include instituting government regulation of brothels and interventions to change social norms among sex workers in Thailand, implementing national sex education and blood safety programs in Senegal in concert with creating a national registry of sex workers, and mandating involvement by women in politics in Uganda.

Low-Level Epidemic. Providing widespread VCT, screening for STIs, universal precautions, and postexposure prophylaxis may not be cost-effective in a low-level epidemic. In this setting, such as in the Middle East and North Africa, HIV/AIDS control strategies should emphasize the following:

- surveillance and individual-level interventions that target key populations
- IEC, including limited education through the mass media and sex education in schools

Table 18.5 Epidemic Profiles

Extent of HIV infection	Highest prevalence in a key population ^a (percent)	Prevalence in the general population (percent)	WHO region
Low level	< 5	< 1	Middle East and North Africa
Concentrated ^b	> 5	< 1	East Asia and the Pacific, Europe and Central Asia, Latin America and the Caribbean, South Asia
Generalized low level	≥ 5	1–10	Sub-Saharan Africa
Generalized high level	≥ 5	≥ 10	Sub-Saharan Africa

Source: Adapted from UNAIDS 2004.

a. Key populations include sex workers, men who have sex with men, and drug injecting users.

b. We consider three types of concentrated epidemics depending on the key population most affected: sex workers, men who have sex with men, or drug injecting users.

Box 18.4

Thailand's 100 Percent Condom Program

Thailand's HIV prevalence, fueled primarily by high rates of commercial sex work and low levels of condom use, began to rise rapidly in the late 1980s. Beginning in 1989, the Thai government initiated a nationwide condom distribution and education campaign focusing on commercial sex workers and their clients to ensure 100 percent condom use in all commercial sex encounters. Elements thought to contribute to the program's success include

- government-mandated 100 percent condom use in commercial sex establishments
- mass condom promotion advertising campaign
- education in commercial sex workplaces

Source: Authors.

- government-distributed condoms
- STI testing and treatment
- surveillance and tracking of infections to points of origin
- strong political and financial commitment
- active involvement of provincial and local governments.

Despite this unprecedented success, evidence indicates that enforcement of the 100 Percent Condom Program is not as strong today as when it was initially implemented. A recent study in Bangkok found that 89 percent of sex workers used condoms, a decline from 96 percent in 2000 (UNDP 2004).

Box 18.5

Uganda HIV/AIDS Prevention Program

Like many countries in Sub-Saharan Africa, Uganda experienced a rapid increase in HIV incidence and a generalization of the epidemic in the late 1980s and early 1990s. By 1991, overall HIV prevalence was 21 percent (Low-Beer and Stoneburner 2003); however, the trajectory of Uganda's epidemic has differed markedly from that of its neighbors. By 2001, overall HIV prevalence had fallen to 5 percent, with dramatic decreases in incidence among key populations, such as soldiers, pregnant women, and young women (USAID 2002). Critical components of Uganda's HIV prevention program include

- having strong political support, especially from President Yoweri Museveni

Source: Authors.

- implementing interventions to empower women and girls
- having a strong focus on youths
- engaging in active efforts to fight stigma and discrimination
- emphasizing open communication about HIV/AIDS
- engaging the religious leadership and faith-based organizations
- creating Africa's first confidential VCT interventions
- emphasizing STI control and prevention.

- prevention programs for people living with HIV/AIDS and harm reduction for injecting drug users
- VCT that is available to key populations with the highest levels of risk behavior and infection rates
- MTCT prevention to mothers known to be infected with HIV
- screening all blood for transfusions and providing sterile injections
- addressing market inefficiencies in condom procurement and distribution—including strategies such as bulk purchases and incentives

- responding to community attitudes toward sexual activity, as they may dictate people's response to sex education materials.

Concentrated Epidemic. In a concentrated epidemic, as in countries in East Asia and the Pacific, Europe and Central Asia, Latin America and the Caribbean, and South Asia, prevention priorities should include the following:

- ongoing surveillance
- subsidized VCT and promotion of VCT among key populations

- HIV screening of pregnant women, guided by individuals' risk profiles
- peer-based programs for key populations to educate individuals at risk, promote safer behaviors, and distribute condoms
- harm reduction for injecting drug users, including needle exchange and drug substitution programs
- STI screening and treatment for key risk groups
- targeted distribution and promotion of condoms to key populations with condom distribution linked to VCT and STI care.

In addition, contextual factors, such as government acceptance of needle exchange programs, incarceration of drug users, and harassment of sex workers, will likely have a major impact on the effectiveness of prevention efforts. Because HIV/AIDS is typically concentrated in socially or economically marginalized populations in countries with concentrated epidemics, attention to socioeconomic factors and to the stigmatization of key populations will also be vital to an effective response.

Generalized Low-Level Epidemic. In a generalized low-level epidemic, such as in some countries in Sub-Saharan Africa (for example, Tanzania), the emphasis on targeted interventions must be maintained or even strengthened. Interventions for broader populations must also be aggressively implemented. These prevention priorities should include the following:

- maintaining surveillance of STIs, risk behaviors, and HIV infections in the entire population, with a particular focus on young people
- extending mass media IEC beyond basic education
- providing routine voluntary and confidential HIV testing and STI screening and promoting treatment beyond key populations
- providing subsidized and social marketing of condoms and strengthened distribution to ensure universal access
- offering HIV screening to all pregnant women
- broadening peer approaches and targeted IEC to include all populations with higher rates of STIs and risk behavior.

Contextual factors remain critical to the success of prevention efforts in generalized low-level epidemics, but population-level factors now have greater priority. The most important is likely to be the status of women, especially with regard to their ability to control their sexual interactions, to negotiate VCT, to be protected from abuse, and to have property rights following the death of a spouse.

Generalized High-Level Epidemic. In a generalized high-level epidemic, such as in some countries in Sub-Saharan Africa (for instance, Botswana and Zimbabwe), an attack on all fronts is required. Prevention efforts should focus on broadly based,

population-level interventions that can mobilize an entire society so as to address prevention and care at all levels. Prevention should include the following:

- mapping and maintaining surveillance of risk behaviors, STIs, and HIV infection
- offering routine, universal HIV testing and STI screening and universal promotion of treatment
- promoting condom use and distributing condoms free in all possible venues
- providing VCT for couples seeking to have children
- counseling pregnant women and new mothers to make informed and appropriate choices for breastfeeding.
- implementing individual-level approaches to innovative mass strategies with accompanying evaluations of effectiveness
- using the mass media as a tool for mobilizing society and changing social norms
- using other venues to reach large numbers of people efficiently for a range of interventions—workplaces, transit venues, political rallies, schools and universities, and military camps
- establishing official institutional policies to provide for harm reduction among injecting drug users.

In a generalized high-level epidemic, contextual factors—such as poverty and the fragility of the health care infrastructure—will dramatically affect service provision at every level. The status of women, an important factor in all epidemics, becomes an overriding concern in this setting, requiring priority action to radically alter gender norms and reduce the economic, social, legal, and physical vulnerability of girls and women.

PREVENTION-CARE SYNERGY

In addition to the benefits antiretroviral therapy has for the individual being treated (Komanduri and others 1998; Ledergerber and others 2001), it almost certainly has other effects on populations where therapy is widely available. Effective antiretroviral therapy appears to decrease the infectiousness of treated individuals. Chemoprophylaxis in exposed, uninfected people may reduce transmission. In addition, availability of treatment may destigmatize the disease and make prevention programs more effective (Castro and Farmer 2005).

However, these benefits in relation to reduced transmission may be offset by a “disinhibition” of risk behavior that is associated with greater availability of antiretroviral therapy, by the spread of drug-resistant HIV, or by increases in the incidence of exposure to partners with HIV infection because of increased survival. These sometimes opposing effects of offering therapy may differ to such a degree that the net effects of widespread therapy on transmission rates may vary among risk groups and across geographic regions.

Table 18.6 Effect of Antiretroviral Therapy on Transmission Dynamics

Area or behavior affected	Treatment effects expected to decrease transmission	Treatment effects expected to increase transmission
Viral load	Decreased infectiousness of the treated partner is substantial even with monotherapy (Musicco and others 1994). Transmission after exposure to individuals with a viral load of less than 1,500 copies per milliliter is extremely rare (Quinn and others 2000). No cases of sexual transmission from a partner with undetectable viremia have been reported.	As survival increases, the incidence of exposure to partners with HIV infection may increase (Hammer and others 1997).
Prophylaxis	Decreased susceptibility may occur during postexposure prophylaxis (Cardo and others 1997).	None.
Drug resistance	Impaired fitness and decreased viral load during drug-resistant viremia (Deeks and others 2000) appear to allow persistent decreases in infectiousness even after drug resistance has occurred (Leigh Brown and others 2003).	Impaired virological responses to therapy in the person who is infected by a resistant virus may partially offset the beneficial effect on infectiousness (Little and others 2002; Grant, Kahn, and others 2002). However, primary infection with a resistant virus may also be associated with slower progression of the disease (Grant, Hecht, and others 2002).
Risk behavior	Treatment may provide incentives for HIV testing and counseling, which has been associated with decreased risk behavior and HIV incidence. The availability of treatment may reduce stigma directly, and also indirectly by increasing the visibility of people living with HIV/AIDS. Risk reduction counseling during treatment programs may reduce risk behavior.	Decreased fear of HIV and disinhibition of risk behavior are possibilities (Katz and others 2002). Risk behavior by people who are sick and who recover their health status may increase (Stolte and others 2001).
Sexual networks	Decreased fear of HIV may foster more informed risk behavior, including increased use of testing and more thoughtful partner selection, including serosorting and sorting by risk level (McConnell and Grant 2003).	Decreased fear of HIV may disinhibit risk behavior, reduce serosorting, and increase mixing between higher- and lower-risk groups in the population.
Epidemiological	The effective prevalence of infectious people will decrease because of treatment effects on infectiousness or increased serosorting.	Treatment-induced reduction in mortality may increase the prevalence of infection, although many being treated will be less infectious or better informed regarding risk reduction strategies. A rebound of viral load with treatment failure may mean that treatment postpones transmission rather than reducing it.

Source: Authors.

Table 18.6 reviews the information available on the population effects of antiretroviral therapy and makes suppositions about potential effects for those areas for which data and research are lacking. The information in the table suggests that widespread therapy using currently available combination regimens will provide a net benefit in relation to the transmission of HIV. However, because confidence in this prediction is not high, the population consequences of therapy programs must be evaluated and monitored with active surveillance of prescribing patterns, sexual risk behavior, STI prevalence, HIV incidence and prevalence, and prevalence of primary drug resistance and sexual networks of risk behavior.

CARE AND TREATMENT

This section reviews evidence of the cost-effectiveness of HIV/AIDS care and treatment interventions in resource-limited settings. Until relatively recently, the majority of HIV

clinical care in resource-limited countries was confined to managing the terminal stage of infection, including extremely late diagnosis of opportunistic infections and cancers, use of basic palliative symptom management, and short-term hospitalization just before death. Few people were aware of their HIV status until the onset of severe HIV-associated illness, and most did not seek help from the health care system until they were already terminally ill.

The advent of primary prophylaxis and treatment for opportunistic infections, including tuberculosis, prolonged survival to a limited extent but did nothing to restore immune function. Such restoration was not possible until the advent of antiretroviral therapy. Because clinical intervention in HIV is so recent in resource-limited settings, few cost-effectiveness studies are available. Those that are available on the treatment of and prophylaxis for opportunistic infections were largely conducted before the availability of antiretroviral therapy and therefore need to be reestimated to be relevant for decision

making today. Fortunately, because the determinants of biological responses are better conserved across countries and cultural settings than the determinants of behavior, effectiveness data from high-income countries can help inform decisions about treatment in resource-limited settings.

Unlike drugs for many other high-burden health conditions in developing countries, antiretroviral therapy for HIV and drugs for some of its associated opportunistic infections depend on medications that are still under patent protection. Nevertheless, generic drug makers in India and Thailand have produced a range of effective antiretroviral therapies that combine multiple drugs into single tablets and reduce the pill burden to one tablet twice daily. These companies have made it possible for prices to drop dramatically for some antiretroviral therapy combinations—to less than US\$250 per year, compared with more than US\$4,000 for the same combinations (from the original manufacturers) in high-income countries. In response to this threat, some multinational pharmaceutical companies have introduced a system of price differentiation among countries depending on their per capita income and HIV/AIDS burden.

In addition, the World Trade Organization's Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) includes a provision that permits compulsory licensing of pharmaceutical products in cases of national emergency and other circumstances of extreme emergency, which is clearly the case for HIV/AIDS in much of the developing world. A 2003 World Trade Organization decision also made it easier for low- and middle-income countries (LMICs) to import cheaper generics made under compulsory licensing if the countries are unable to manufacture the medicines themselves (WTO 2003). As a result, some countries, including Brazil, India, and Thailand, have begun to produce generic versions of antiretroviral drugs to be sold at greatly reduced prices. The TRIPS provision has also improved developing countries' bargaining power with large pharmaceutical companies, to the point that some countries have been able to secure drugs from the original manufacturers at substantially reduced prices. As a result, the relative cost-effectiveness of different drug combinations has been in rapid flux, increasing the importance of updating recommendations frequently.

Diagnostic HIV Testing

A positive HIV test can be confirmed within one month of infection. Infection is diagnosed in two ways: by a biological test that detects the presence of HIV antibodies or by diagnosis of an opportunistic infection that is a clear sign of HIV disease. The most widely used biological test in high-income countries, conducted in a laboratory on a blood sample, is called an ELISA (enzyme-linked immunosorbent assay). Obtaining a result may take several days. Rapid tests that can provide results in 20 minutes are being used more widely as their costs fall. When the prior probability of infection is low and resources are

abundant, following up an initially positive ELISA with a second ELISA—and even a Western blot test if the second ELISA is positive—may be appropriate (this is typically done in high-income countries).

However, in a high-prevalence environment where the prior probability is high and resources are scarce, such an approach is almost certainly not cost-effective. Each additional confirmatory test decreases the number of false positive results, thereby averting the costs associated with such a result. The costs of averting a false positive result range from US\$425 with a single confirmatory rapid test or ELISA to more than US\$500,000 for a confirmatory Western blot test following two positive ELISAs as the prevalence of HIV in patients who are clinically suspected of being infected is varied from 5 to 50 percent (these calculations are based on assumptions in John Snow, Inc. 2003 and WHO 2004). These results suggest that LMICs should not use a second confirmatory test unless the prevalence among patients is extremely low.

Palliative Care

Palliative care has traditionally focused on patients in the terminal stages of disease. More recent definitions of palliative care, including WHO's definition, have been broadened to encompass quality-of-life issues of patients and their families throughout the course of a life-threatening illness (WHO 2002b). The control of pain and other symptoms is the crux of any palliative care model, but the WHO model also addresses patients' and their families' psychological, social, and spiritual problems. Under this definition, in many developing countries, most people living with HIV/AIDS are not receiving the minimum standard of palliative care. Of the 5 million people living with HIV/AIDS in South Africa, one of the wealthiest countries in Sub-Saharan Africa, Carlisle (2003) estimates that only 250,000 have access to palliative care services. In the face of a growing epidemic of historic dimensions, the provision of comprehensive palliative care represents a critical, but neglected, global priority.

Health care professionals have promoted community home-based care as an affordable way to expand the coverage of palliative care (Hansen and others 1998), but the great heterogeneity among home-based care programs complicates comparisons. Most programs for which data are available are community-based outreach programs administered by local clinics or hospitals. These programs can consist of simple home visits to provide basic care for AIDS patients or may be comprehensive schemes that provide care, palliative medications, meals, psychosocial support and counseling, and links to primary and secondary health care.

Studies indicate that home-based care has considerable potential to deal cost-effectively with the palliative care needs of HIV/AIDS patients (Ramsay 2003; UNAIDS 2001; Uys and Hensher 2002; Wenk, Bertolino, and Pussetto 2000). Although

a Zimbabwe study found that home visits were associated with extensive travel time and costs (Hansen and others 1998), little research has examined the extent to which home-based care can be used to substitute for hospitalization, nor is evidence available to determine the most cost-effective combination of palliative care strategies. Most people living with HIV/AIDS do incur some end-of-life costs in the formal health care sector. In one South African study, primary care clinic and hospital costs accounted for 39 and 18 percent, respectively, of the costs of care in the last year of life, whereas community home-based care accounted for 42 percent (Uys and Hensher 2002).

Higginson and others' (2003) meta-analysis concludes that overall evidence demonstrates a positive effect of home-based palliative care, especially its effect on pain management and symptom control. Available data do not permit estimating a cost per DALY of community-based palliative care programs, but a review of available studies suggests that palliative care provided by health professionals in the home is unlikely to be cost-effective in low-income countries. However, low-cost, community-based models have been developed that require minimal external resources and function almost like care cooperatives among affected households. These models are likely to be highly cost-effective.

Symptom-Based Care. Pain management is extremely important in HIV and is addressed in chapter 52. Diarrhea, nausea, vomiting, and skin problems are all symptoms that are targeted for treatment in palliative care. Oral rehydration for diarrheal treatment costs pennies per episode. Nausea and vomiting are prevalent in people with AIDS and can lead to anorexia and weight loss (UNAIDS 2000). Treating nausea costs an estimated US\$1.75 per episode (Willbond and others 2001), and continuous treatment of nausea and vomiting in end-stage patients costs about US\$2 per day (World Bank 1997).

Approximately 90 percent of people with HIV suffer from some form of skin condition. These conditions include infections, drug reactions, scabies, pressure sores, and cancers. Skin often becomes dry in the middle and late stages of AIDS because of dehydration caused by persistent diarrhea, vomiting, and malabsorption. The cost of treating an episode of skin rash is estimated to be US\$2 (UNAIDS 2000). No estimates are available on the benefits of providing such care in terms of DALYs, especially to terminally ill patients.

Psychosocial Support. Psychosocial support is an integral component of the multidisciplinary management strategies that care providers regard as essential for people with HIV (Murphy and others 2004). Support for patients and families can have a positive effect on adherence to therapies and can contribute to the critical aim of integrating prevention with treatment and care.

Psychosocial support and counseling has a positive effect on the quality of life of people living with HIV/AIDS. Cook's

(2004) study of U.S. women demonstrated that the use of mental health services was associated with reduced mortality and that AIDS-related deaths were more likely among women who had symptoms of chronic depression. While results have not been replicated in resource-constrained countries, an assessment of clinic-based psychosocial support and counseling services in northern Thailand showed that 50% of PLWHA became more positive about their lives and 40% stated that they learned how to live with the disease (Tsunekawa and others 2004). Although few data are available on the costs of various strategies, interventions for psychosocial support appear to be cost-effective—especially where innovative solutions, such as group counseling sessions, are implemented. Although studies indicate an improved quality of life for these patients, little information is available on the cost of the interventions. Additional evaluation research is needed to guide decisions about how much to invest in psychosocial support.

Nutrition Programs and Food Security. Strong evidence indicates that malnutrition and AIDS work in tandem at both the individual and the societal levels. Infection with HIV increases the risk of malnutrition in the individual, while malnutrition worsens the impact of HIV and AIDS. Similarly, HIV/AIDS can both cause and be worsened by food insecurity. This reciprocity must be considered when planning specific program responses.

Protein deficiency is a well-known cause of cell-mediated immunodeficiency (Vanek 1953). HIV-infected individuals need to consume more energy than uninfected individuals: as much as 10 percent greater consumption for asymptomatic individuals and 20 to 30 percent more for symptomatic individuals. Malnutrition alters the susceptibility of individuals to HIV infection and their vulnerability to its various sequelae, increases the risk of HIV transmission from mothers to babies, and accelerates the progression of HIV infection (Gillespie, Haddad, and Jackson 2001).

Small studies of adults with AIDS, including those on antiretroviral therapy, have shown that daily micronutrient supplementation increases bodyweight, reduces HIV RNA levels, improves CD4 counts, and reduces the incidence of opportunistic infections. Fawzi and others' (2004) large trial among pregnant women infected with HIV in Tanzania demonstrates that multivitamin supplements (a) decrease the risk of progression to WHO stage 4 (progression from HIV to AIDS, the most advanced level of HIV infection) or death from AIDS-related causes and (b) reduce many HIV-related symptoms. The multivitamins used in the trial cost US\$15 per person per year (Fawzi and others 2004).

The World Food Program guidelines prioritize three nutrition interventions for people living with HIV/AIDS: counseling on specific behaviors, prescribed or targeted nutrition supplements, and links with food-based interventions and

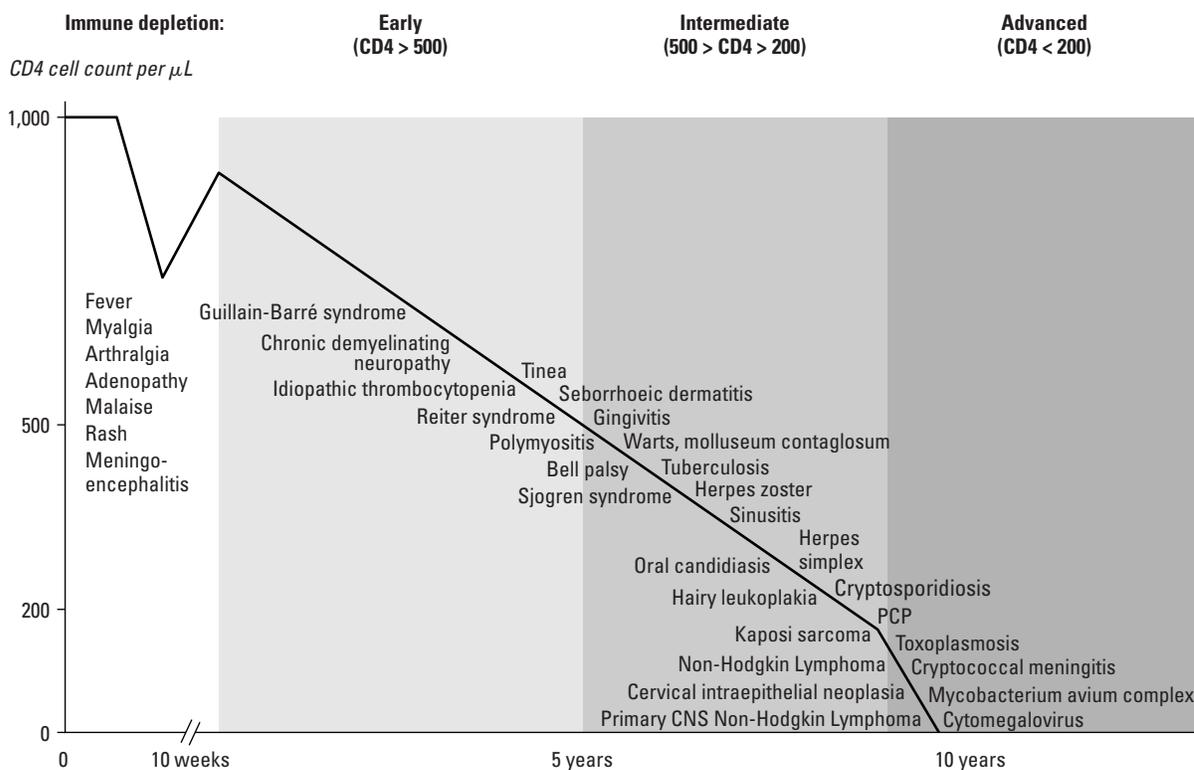

programs. The guidelines cite three types of nutrition supplements: food rations to manage mild weight loss and nutrition-related side effects of antiretroviral therapy and to address nutritional needs in food-secure areas; micronutrient supplements for specific HIV-positive risk groups; and therapeutic foods for addressing moderate and severe malnutrition in HIV-positive adults and children. Cost-effectiveness data in support of these recommendations are not available, but the low costs of supplementation, coupled with the likely benefits to other malnourished household members, suggest that such interventions will be highly cost-effective.

Infection with HIV/AIDS can severely undermine an individual's food security, affecting the availability, stability, access to, and use of essential foods. The epidemic is stunting progress in rural development and causing significant increases in rural poverty and destitution in the countries most affected by the epidemic (Bonnard 2002). Thus, interventions must consider the epidemic's impact on the broader community and not solely on people living with the disease. Care-related household and community-level interventions include school feeding with special take-home rations for families caring for orphans, food for training programs that promote income-generating activities, and food for work to support homestead production

activities (Van Liere 2002). Chapter 56 estimates that sustained community nutrition programs would *save* US\$200 to US\$250 per DALY. Such programs targeted at communities at especially high risk are likely to be even more cost-effective (World Food Programme 2001).

Treatment of Opportunistic Infections and Secondary Prophylaxis

Even as the availability of antiretroviral therapy increases in many developing countries, appropriate diagnosis and management of life-threatening opportunistic infections, including HIV-associated cancers, remain the most important aspects of the care of patients with HIV disease. Opportunistic infections usually begin five to seven years after infection (Munoz, Sabin, and Phillips 1997) and occur progressively as uncontrolled HIV replication destroys the immune system (Colebunders and Latif 1991). Figure 18.1 describes the cascade of infections that occur as the immune system is depleted. Opportunistic infections are typically caused by organisms that exist in the environment of the body (on the skin, in the lungs and gastrointestinal system) and remain latent until HIV has impaired the immune system.

Source: Authors.

Figure 18.1 Cascade of Infections and Cancers That Develop as Immune Function Is Depleted

The epidemiology of opportunistic infections is complex; it is related to the severity of individual immune depletion and shows considerable intercountry variation. Each infection has its unique clinical expression, requiring specific diagnostic techniques and treatment. Many opportunistic infections can be prevented by judicious use of chemoprophylaxis, ranging from the low-cost (cotrimoxazole to prevent *Pneumocystis jiroveci* pneumonia [PCP] at less than US\$20 per year) to the extremely expensive (ganciclovir to prevent cytomegalovirus at more than US\$10,000 per year) (Schneider and others 1995; Spector and others 1996). In high-income countries, antiretroviral therapy has so effectively controlled viral replication that the process of HIV-related immune destruction has been slowed or halted, leading to marked declines in the incidence of opportunistic infections and a dramatic reduction in their resultant high death toll (McNaghten and others 1999). Unfortunately, the emerging problem of poor adherence to drug regimes is now making HIV resistance to antiretroviral therapy more prevalent in high-income countries, triggering a resurgence of opportunistic infections.

More than 20 infections and cancers have been associated with severe immune depletion. The most common pathogens and cancers include bacteria such as *Mycobacteria tuberculosis* and *avium*; protozoa such as *Cryptosporidium*, *Strongyloides*, and *Toxoplasma*; fungi such as *Candida*, PCP, *Cryptococcus*, *Aspergillus*, and *Penicillium* (the latter largely restricted to South and Southeast Asia); viruses such as cytomegalovirus, herpes simplex, and herpes zoster; and cancers such as Kaposi sarcoma and non-Hodgkin lymphoma.

The range of complications arising from continued HIV infection varies from country to country, reflecting the differences in infectious agents that populations have encountered earlier in life or are exposed to when immunosuppressed. In high-income countries, the most common opportunistic infections are PCP, esophageal candidiasis, cytomegalovirus retinitis, cryptococcal meningitis, toxoplasma encephalopathy, cryptosporidium diarrhea, and human herpes virus-8 and Kaposi sarcoma (Bacellar and others 1994; Hoover and others 1993; Lanjewar and others 1996; Selik, Starcher, and Curran 1987). In resource-limited countries, because of the higher background prevalence of infectious agents, it is more common to encounter tuberculosis, cryptococcal meningitis, toxoplasma encephalopathy, infectious diarrhea, and nonspecific wasting (slim disease) (Hira and others 1998; Hira, Dore, and Sirisanthana 1998a; Sengupta, Lal, and Srinivas 1994).

The time from HIV infection to manifestation of the first AIDS-defining illness varies within populations. In high-income countries, reports on the natural history of untreated HIV infection suggest that AIDS occurs between 7 and 10 years after infection (Alcabes and others 1993; Lui and others 1988). The time can be as short as 24 months (Anzala and others

1995) in some individuals, whereas some long-term survivors remain disease free for longer than 15 years (Easterbrook 1994). In developing countries, disease progression, though not as well studied, appears to be more rapid (Morgan and others 1997). Once an AIDS-defining illness occurs, the average time to death seems to be similar across countries, reported at approximately 12 to 18 months in Uganda and the United States (Carre and others 1994).

The time from presentation with an AIDS-defining opportunistic infection to death depends on the type of infection, the availability of care, and the patient's adherence to prescribed prophylaxis and treatment. Even as access to antiretroviral therapy increases, prophylaxis for opportunistic infections remains one of the most important ongoing and successful care strategies for patients with advanced HIV disease. In high-income countries, the widespread use of such simple interventions as cotrimoxazole for PCP prophylaxis has had a significant effect in delaying the onset of PCP, the most common initial AIDS-defining event, thus positively influencing survival (Hoover and others 1993). However, prophylaxis for opportunistic infections appears to be underused in LMICs.

Prevention of PCP or any other opportunistic infection does not halt the relentless erosion of the immune system and provides only a short-term prolongation of life (Morgan and others 1997). The only way to halt or delay the progression of HIV disease is to interrupt viral replication.

Role of Antiretroviral Therapy in Relation to Opportunistic Infections. Antiretroviral therapy is effective in reducing viral load and partially enabling immune restoration, thereby preventing the onset and recurrence of opportunistic infections. If taken strictly according to directions, antiretroviral therapy can induce a sustained recovery of CD4 cell reactivity against opportunistic pathogens in severely immunosuppressed patients (Li and others 1998). The effectiveness of antiretroviral therapy is determined by its ability to rapidly reduce viral load and to sustain low levels of viral activity. This viral activity is what has an independent effect on increasing or decreasing susceptibility to opportunistic infections (Kaplan and others 2001).

Initiating antiretroviral therapy can also have detrimental effects by causing complications from latent or undiagnosed opportunistic infections, especially in resource-poor settings. One of the challenges in initiating antiretroviral therapy in resource-limited settings is that patients tend to present late in their illness, usually when they have an opportunistic infection that prompts them to seek medical care, or in the case of countries with lax pharmaceutical policy, when they buy antiretroviral therapy from a private pharmacy. It is well documented that initiating antiretroviral therapy in severely immunosuppressed patients can result in illnesses associated with reconstitution of the immune system (Shelburne and

others 2005). These illnesses can occur with all presenting opportunistic infections and may be more serious than the infection itself. The major problem with care of patients in this situation is that they may believe the illness is a side effect of their antiretroviral therapy and refrain from medicating. Training clinicians to recognize and treat immune reconstitution disease is therefore essential.

Management of Opportunistic Infections. The three components of effective management of opportunistic infections are diagnosis, treatment, and secondary prophylaxis. As immune function continues to deteriorate, secondary prophylaxis is required to prevent recurrence of the treated infection. Some of the most common infections, such as PCP, can be diagnosed with a reasonable degree of confidence by clinical history and treated empirically (Kaplan, Masur, and Holmes 2002). Less frequently occurring infections often require sophisticated diagnostic equipment and skilled clinicians to confirm a diagnosis from a wide range of pathogenic possibilities before starting complex and expensive treatment. For example, toxoplasmosis can be accurately diagnosed only by a lumbar puncture and CT brain scan (and in some cases an MRI), and cryptosporidium diagnosis requires specialized laboratory techniques.

The full spectrum of options for treating opportunistic infections in developing countries has not been systematically evaluated for cost-effectiveness. Because of the effect of antiretroviral therapy on both the efficacy of treatment of individual infections and on life expectancy (and therefore on potential DALYs gained from treating a life-threatening infection), the limited economic evaluations conducted are already out of date. In particular, chronic infections such as *Mycobacterium avium* complex and cytomegalovirus may be more effectively treated over the medium term by reversing immunosuppression with antiretroviral therapy than by directly treating the infectious agent. Other treatment regimens for opportunistic infections that were marginally cost-effective before antiretroviral therapy may now become substantially more cost-effective if the patient can begin the therapy following treatment of the infection, thereby extending life expectancy. Table 18.7 shows the cost-effectiveness of care and treatment options for opportunistic infections and antiretroviral therapy.

In most resource-limited settings, few specialized diagnostic facilities are available for opportunistic infections. Clinicians have little training in the diagnosis and management of complex opportunistic infections, and laboratory backup is either nonexistent or so expensive that end users cannot afford it. The spectrum of opportunistic infections in LMICs is such that most require highly technical facilities for confirmation of diagnosis. Consider *M. tuberculosis*, the most prevalent such infection in Thailand. The rate of latent tuberculosis becoming clinically active in the presence of HIV increases from a lifetime

risk of 10 percent in the general population to an annual risk of 10 percent for those coinfecting with HIV (Pape and others 1993). Hence, after five years, about 40 percent of HIV-infected people with latent tuberculosis will have developed active disease.

Primary Prophylaxis for Opportunistic Infections

Before the advent of antiretroviral therapy, the use of prophylaxis to decrease the risk of acquiring opportunistic infections was the only intervention available to delay the onset of life-threatening infections (Kitahata and others 1996). With the development of antiretroviral therapy in the 1990s, the prevalence of many opportunistic infections has been greatly reduced, and the use of prophylaxis has decreased correspondingly (Palella and others 2003). Nevertheless, prophylaxis for opportunistic infections remains necessary in patients who lack access to antiretroviral therapy, in extremely immunosuppressed patients until the therapy takes effect, in patients who do not wish to or who cannot take antiretroviral therapy, in patients for whom such therapy fails, and in the small group of patients who are unable to recover sufficient CD4 cells despite good inhibition of viral replication (Berenguer and others 2004). Note that extensive clinical research is still being carried out in relation to the withdrawal of secondary prophylaxis following immune restoration with antiretroviral therapy.

Treatment of HIV Infection with Antiretroviral Therapy

Combination therapy with multiple antiretroviral drugs is associated with prolonged survival. Whereas monotherapies are associated with one year or less of additional survival, the survival benefit conferred by combination therapy appears to be sustainable for extended periods (Palella and others 2003). Long-term toxicities related to treatment may include atherosclerosis, lipodystrophy, hepatic failure, and cardiac failure. Researchers are still evaluating the effects of these toxicities on HIV/AIDS mortality.

Cost-Effectiveness Considerations in the Choice and Initiation of Antiretroviral Therapy.

WHO has issued global guidelines for scaling up antiretroviral therapy access; the guidelines promote a combination of stavudine, lamivudine, and nevirapine (as a fixed-dose formulation) as initial therapy. A number of clinical trials have produced results outlining differential efficacy for a number of antiretroviral therapy combinations, which provide guidance in the selection of appropriate drugs for treating HIV (Yeni and others 2004). The preferred first-line medications in developing countries are dictated by these considerations, in addition to pricing and patent concerns.

Table 18.7 Cost-Effectiveness of Care and Treatment for HIV/AIDS

Intervention	Source	Cost-effectiveness (2001 US\$/DALY)		
		Before or when initiating antiretroviral therapy	Failed or no antiretroviral therapy

a. Antiretroviral therapy for the poorest HIV positive adults. The estimates include the cost of drugs, clinic visits, and laboratory tests for physician monitoring of treatment and assumes 50 percent condom use in the general population.

Box 18.6

Antiretroviral Drugs

Current antiretroviral drugs can be divided into three classes:

- *Nucleoside analogue reverse transcriptase inhibitors* (NRTIs) were the first type of drug available to treat HIV infection in 1987. When HIV infects a cell, it copies its own genetic code into the cell's DNA, and the cell is then programmed to create new copies of HIV. To reproduce, HIV must first convert its RNA into DNA using the enzyme reverse transcriptase. Nucleoside analogue reverse transcriptase inhibitors act like false building blocks and compete with the cell's nucleosides, thereby preventing DNA synthesis. This inhibits reverse transcriptase, which prevents HIV from infecting cells and duplicating itself.
- *Nonnucleoside reverse transcriptase inhibitors* (NNRTIs) started to be approved in 1997. Like nucleoside analogue reverse transcriptase inhibitors, nonnucleosides also interfere with HIV's ability to infect cells by targeting reverse transcriptase. In contrast to nucleoside analogue reverse transcriptase inhibitors, nonnucleosides bind directly to the enzyme. This blocks the binding site of the reverse transcriptase and inhibits the binding of nucleotides.
- *Protease inhibitors* (PIs) were first approved in 1995. PIs interfere with viral replication by binding to the viral protease enzyme and preventing it from processing viral proteins into their functional forms and thereby rendering the resulting viral particles non-infectious (Peiperl, Coffey, and Volberding 2005).

Source: Authors.

In recent years, the most volatile parameter in cost-effectiveness analyses for HIV/AIDS has been the prices of antiretroviral drugs, which have dropped by about two orders of magnitude for some LMICs. Price reductions have not been consistent across countries, nor have they necessarily been larger for the poorest countries. This variability in pricing greatly complicates the establishment of national guidelines regarding which regimens to prescribe under which circumstances, because the ranking of regimens varies among and within countries as relative prices change. Box 18.6 discusses the three classes of drugs used in antiretroviral therapy.

Because of their higher manufacturing costs and their more recent introduction into the market, protease inhibitors are more expensive than either nucleoside reverse transcriptase inhibitors or nonnucleoside reverse transcriptase inhibitors. They are also more difficult to manufacture, making them less attractive to generic manufacturers. Although the difference is less marked, nucleoside reverse transcriptase inhibitors tend to cost less than nonnucleoside reverse transcriptase inhibitors.

Ranking different antiretroviral therapy regimens by their cost-effectiveness is more complex than doing so for most therapeutic situations, because a high proportion of patients will develop resistance to or intolerance of initial therapy and will need to stop their initial regimen and then initiate a second (and perhaps a subsequent) regimen, if available. One U.S. cohort study suggests that for 50 percent of patients the

prescribed protease inhibitor–based regimen fails within a year (Deeks and others 1999). As a result, the cost-effectiveness of a regimen is a function not only of its effectiveness in isolation, but also of its impact on the effectiveness of future regimens. Thus, the comparative cost-effectiveness of different sequences of regimens needs to be considered.

The effectiveness of antiretrovirals depends on not only the benefits conferred but also the associated side effects, the toxicity level of the drugs, and patients' adherence to the drug regimen. The ability of care providers to detect incipient toxicity at an early stage also influences the magnitude of side effects and toxicities. In low-income settings with limited laboratory capacity, a greater proportion of side effects will not be detected until they become severe. As a result, the relative cost-effectiveness profiles will change depending on the availability of toxicity monitoring.

Initiating antiretroviral therapy has a proven benefit for patients with a CD4 count of fewer than 350 cells per cubic millimeter (Palella and others 2003). In patients with a higher CD4 count, the benefits of antiretroviral therapy are believed to be outweighed by the toxicities that may accrue from continued drug exposure (Mallal and others 2000). Concerted research efforts are needed to gauge both the average costs of care and the survival benefits of identifying patients and initiating antiretroviral therapy while their immune function is still competent, compared with the costs and survival benefits associated with starting care late, on

presentation of an opportunistic infection—as is currently the norm in LMICs.

Drug Resistance. Drug resistance occurs as the virus evolves to escape the inhibitory effects of antiretroviral drugs. The capacity of HIV to mutate is extraordinary, as the wide diversity of HIV variants that occurs worldwide demonstrates. Viral diversification is driven by low-fidelity enzymes (which have a high rate of mutation) that carry out replication of the viral genome.

Drug resistance resulting from being infected by a drug-resistant HIV strain is known as primary drug resistance. Secondary drug resistance develops as a consequence of treatment. Primary HIV drug resistance to nucleoside reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors, and protease inhibitors has been reported (Salomon and others 2000; Wegner and others 2000). The first reports of transmission of drug resistance have typically occurred within a few years of a drug's introduction into clinical practice. The proportion of newly infected people who acquire drug-resistant HIV has implications for the choice of first-line regimen. Primary resistance in recently infected individuals in high-income countries is stable or has been in decline since 2000, following a rise between 1996 and 1999. Almost nothing is known regarding primary drug resistance among those recently infected in low-income countries, although this question will become more important with the increased availability of antiretroviral therapy in resource-limited settings.

Drug resistance is associated with increases in plasma viral RNA levels and attenuation of the responses of CD4 counts to therapy. Nonetheless, clinical and epidemiological observations suggest that drug resistance does not completely offset the benefits of therapy (Deeks and others 1999; Ledergerber and others 1999). Individuals with drug-resistant HIV typically have plasma viral RNA levels that remain 3- to 10-fold lower than pretreatment levels. Furthermore, patients with drug resistance experience more rapid immunological decline and disease progression if they discontinue their drugs (Nijhuis, Deeks, and Boucher 2001).

Importance of Adherence to Prescribed Therapy. With certain drugs, resistance can develop in as little as two weeks if therapy is suboptimal (which can be less than 90 percent adherence). Conversely, patients who adhere to therapy can obtain continued viral suppression for many years without the need for second- or third-line options. Research has shown that drug adherence is one of the most important predictors of continued treatment response (Mannheimer and others 2002). Patients in resource-limited countries are likely to be subjected to a number of influences that challenge their

ability to adhere to the prescribed therapy, including limited education and the consequent poorer understanding of their disease state, unstable housing and financial circumstances, a limited number of treatment options, and clinicians with limited antiretroviral therapy treatment experience (Kitahata and others 1996). Those factors, in addition to the toxicity of the therapy, influence adherence and future disease progression rates (Duran and others 2001) and lead to an increase in drug resistance. Thus, poorly coordinated scale-up of antiretroviral therapy in some developing countries has the potential to jeopardize both the duration of clinical benefit for the first wave of patients who receive substandard care and future response rates as the prevalence of drug resistance increases (Harries and others 2001).

Studies in India, Mexico, Senegal, and Uganda point to poor adherence (which for some classes of drugs can be adherence of less than 95 percent), inadequate doses and regimens, and poor monitoring as factors that contribute to more rapid development of antiretroviral therapy resistance (Oyugi and Bangsberg 2004, Laniece and others 2004, Bautista and others 2003, Liechty and Bangsberg 2003). By contrast, experiences in Haiti and Uganda suggest that it is possible to achieve adherence rates in developing countries equal to or better than those observed in high-income countries (Farmer and others 2001; Mitty and others 2002).

Second-Line and Subsequent Therapies. Studies from high-income countries have unequivocally demonstrated that the probability that an antiretroviral therapy regimen will achieve viral suppression diminishes with each subsequent regimen (Deeks and others 1999). Similarly, the mean duration of viral suppression for those who achieve suppression is also lower for subsequent regimens (Deeks and others 1999). This finding is entirely expected because failing a previous regimen is associated with lower adherence, higher toxicity, or side effects and increased resistance, all of which increase the probability of similar problems occurring with subsequent regimens. Thus, the expected survival benefit per month of antiretroviral therapy declines with each change of regimen. In contrast, the monthly cost of therapy rises as a patient moves from first-line to more expensive protease inhibitor-based second-line and subsequent therapies. Given this steadily declining cost-effectiveness, wealthier countries are likely to offer a greater number of regimen changes than poorer countries.

Laboratory Monitoring of Immune Function to Guide Therapy

Laboratory monitoring determines when antiretroviral therapy should be initiated and when it should be changed because of toxicity, lack of efficacy, or resistance. The optimal frequency

and precision of monitoring depends on numerous factors, principally the following:

- the expected rate of change of variables of interest
- the expected frequency of events, such as development of resistance, adherence failure, and side effects
- the relative cost of monitoring versus the cost of providing ineffective treatment
- the magnitude of the secondary effects of monitoring (motivating prevention, motivating adherence).

WHO has suggested a pragmatic approach to monitoring, with inexpensive, easy-to-measure parameters (bodyweight or body mass index, body temperature, hemoglobin, liver enzymes, and clinical symptoms) for monitoring in low-income countries. More specialized markers—namely, CD4 count, viral load, and resistance genotyping—would be restricted to sentinel sites and tertiary care services (Gutierrez and others 2004), at least initially.

The large price reductions for antiretroviral drugs are only now starting to be mirrored in the costs of monitoring tests as new technologies are introduced, collective bargaining is undertaken, and international pressure mounts on diagnostic manufacturers to provide more favorable pricing for LMICs. Commercial cytometric CD4 measurements are now available to some developing countries at less than US\$5 per test (R. Göhde, personal communication, 2004). Viral load testing is still significantly more expensive, but even those prices have dropped to US\$20 following negotiations on behalf of low-income countries by the William Jefferson Clinton Foundation. Even when the potential savings become an operational reality in developing countries, the costs of laboratory monitoring will still represent an important proportion of the costs of providing antiretroviral therapy.

Monitoring to Guide Initiation of Antiretroviral Therapy. If laboratory monitoring is performed, its optimal frequency must be determined. The closer patients get to an antiretroviral therapy threshold, the more often they must be tested to detect a CD4 decline that falls within a specific CD4 range. As use of antiretroviral therapy expands in LMICs and as the costs of drugs fall relative to the costs of laboratory monitoring, collecting empirical data and constructing models to compare different monitoring strategies is becoming increasingly urgent.

In the absence of capacity to perform CD4 counts, several studies suggest that total lymphocyte count can be used as a proxy because of the correlation between the two counts (Badri and Wood 2003). Research has also shown that falling body mass index is highly predictive of disease progression (Pistone and others 2002). In light of those findings, the cost-effectiveness of CD4 monitoring in developing countries must be considered in terms of its incremental improvement over total lymphocyte

monitoring or body mass index monitoring rather than being compared with no monitoring at all.

Testing for Primary Resistance. Testing for resistance in individual patients is still costly, because of both the cost of the diagnostic kit and the sophisticated laboratory capacity required to perform the tests. Because primary resistance is far less prevalent in LMICs than in high-income countries, no serious consideration is being given at this time to initiating individual resistance testing in the developing world. However, the choice of optimal first-line and subsequent treatment strategies should be guided by information about the prevalence of primary resistance to different antiretroviral drugs in a particular country, which indicates that population-level monitoring of the prevalence of resistance among antiretroviral-naïve people living with HIV/AIDS is important.

Monitoring Response to Therapy. Ideally, therapeutic failure should be detected as soon as possible to permit the implementation of clinical strategies to address toxicity, drug resistance, or poor adherence. Therapeutic failure leads to rising viral load and falling immune competence and to the subsequent development of opportunistic infections. Unfortunately, earlier detection comes at a price: testing for increases in viral load, which can be detected soonest, is more expensive than CD4 testing, which in turn is more expensive than the less sensitive monitoring of total lymphocyte count, which is more expensive than monitoring body mass index or waiting until clinical signs of failure appear. Where facilities for detecting early failure are absent, first-line therapy should be replaced by a completely new combination at failure, usually a protease inhibitor-based combination.

Monitoring Toxicity. Available antiretroviral drugs have significant toxicity. Such toxicity is often insidious, progressing unnoticed until the patient's health has been seriously impaired. Examples include zidovudine-associated anemia, nevirapine-associated impaired liver function, and didanosine-associated pancreatitis. Fortunately, the most commonly encountered serious toxicities can be detected either on clinical examination or with inexpensive laboratory tests. Data on the relative cost-effectiveness of different toxicity monitoring regimens are unavailable. Current guidelines identify what monitoring should be conducted in conjunction with specific antiretroviral drugs, depending on whether laboratory capacity is available (WHO 2004).

Unfortunately, in the absence of a quantitative analysis of the costs of monitoring and the benefits associated with early detection of toxicity, it is difficult to provide guidance on the minimum laboratory capacity that should accompany the delivery of specific treatment combinations. Clearly, extremely low-cost monitoring tests are warranted for toxicities that

occur frequently. The preeminent example is anemia monitoring for patients receiving zidovudine. Hemoglobin levels can be monitored for less than US\$0.02 per test, which is almost certainly cost-effective given that the incidence of anemia with zidovudine therapy is approximately 10 percent in advanced-stage patients and that anemia frequently progresses to life-threatening levels if not detected.

RESEARCH AGENDA

As in many other areas of public health in developing countries, a profound tension exists between (a) the need for research to discover new technologies and interventions for both prevention and care and (b) the need for research to learn how to effectively apply the technologies that are currently available. The most important barrier to control is lack of

Box 18.7

Interventions in the Pipeline or in Trial

The following interventions are currently being developed or evaluated:

- *Microbicides*. Most microbicide products are currently in preclinical development; however, 18 products are being evaluated in clinical research studies, most in small phase 1 safety and acceptability trials. Three phase 3 effectiveness trials are currently under way.
- *Diaphragms*. The safety and effectiveness of the diaphragm and Replens gel in preventing HIV and STIs among women are being tested in an ongoing phase 3 randomized controlled trial in South Africa and Zimbabwe. Two trials, in the Dominican Republic and Madagascar, are planned to test the diaphragm's effectiveness against bacterial STIs. Several other trials in Sub-Saharan Africa are planned to test the acceptability and safety of the diaphragms plus microbicides.
- *Circumcision*. Two randomized controlled trials are under way in Kenya and Uganda to examine whether circumcision confers protection among adult men.
- *Community-based VCT*. Project Accept is a community-based VCT trial in 32 communities in South Africa, Tanzania, and Zimbabwe and 14 communities in Thailand. Communities are randomized to receive either a community-based VCT intervention or a standard clinic-based VCT. The community-based VCT intervention has three major strategies: to make VCT more available in community settings, to engage the community through outreach, and to provide posttest support.
- *HSV-2 treatment*. One study in six countries will determine the efficacy of twice-daily acyclovir in reducing susceptibility to HIV infection among high-risk, HIV-negative, HSV-2 seropositive women and men who have sex with men. A companion study will also be

conducted to assess whether acyclovir reduces HIV infectiousness in individuals infected with both HSV-2 and HIV.

- *Tenofovir for preexposure use*. Studies are now enrolling participants at three West African sites and will soon begin in Botswana, Malawi, Thailand, and the United States.
- *Antiretroviral therapy to prevent sexual transmission*. A phase 3, randomized, controlled, multisite trial to assess whether antiretroviral therapy can prevent sexual transmission of HIV in serodiscordant couples will begin in Brazil, India, Malawi, Thailand, and Zimbabwe.
- *Vaccines*. Although preliminary results from a phase 3 clinical trial in Thailand found that AIDSVAX failed to protect against infection, several other vaccines are being developed. Merck and GlaxoSmithKline have unveiled sizable vaccine programs and moved products into human testing. An International AIDS Vaccine Initiative U.K.-Kenya team is in the midst of intermediate human trials of DNA/MVA (modified vaccinia virus Ankara), and Aventis Pasteur is taking ALVAC-AIDSVAX into the final phase of trials. The South African AIDS Vaccine Initiative is preparing for the country's first trials, India's prime minister has pledged national resources for vaccines, and the European Union is broadening its vaccine research for HIV.
- *Behavior change programs for people with HIV*. In recent years, a growing number of public health experts have proposed implementing prevention interventions that target people with HIV (De Cock, Marum, and Mbori-Ngacha 2003; Janssen and others 2001), although evidence on the most effective strategies to encourage safer behavior among people with HIV is lacking.

Source: Authors.

knowledge about how best to implement packages of existing interventions at the appropriate scale to maximize the effect of prevention and care interventions and to protect the human rights of those affected by the epidemic. Accurate surveillance data are needed on risk behaviors, and effectiveness research is needed to discern what interventions work where and how they do so. Unfortunately, few rigorous evaluations of new or existing interventions have been conducted using large prospective cohorts, with the result that, for many interventions, convincing data on effectiveness are not available. Finally, research on policy or structural interventions, which by definition must be conducted on a population level, is also insufficient. These interventions include the development and testing of such policy tools as changing the tax structure, regulating the sex industry, and guaranteeing property rights and access to credit for women.

Box 18.7 lists new prevention interventions in the pipeline. Although numerous promising interventions are listed, results for most of these strategies are at best years away. Centuries hence, when future generations study the history of our time and the epidemic that killed 50 million or perhaps many more, the most difficult question to answer may well be “why did they invest so little for so long in developing a vaccine?” Creating such knowledge is about as close as one can get to a pure international public good, and the lack of global cooperation in adequately funding such research is an indictment of global commitment to multilateral cooperation. However, given both the uncertainty about whether developing an effective vaccine is possible and the long delay until a new vaccine can be widely applied, vaccine development efforts must be accompanied by the development of other new biomedical and behavioral prevention technologies.

In contrast, research on care and treatment has been far more successful than research on prevention, and innovation in new therapies continues apace. The ability of HIV to rapidly evolve resistance to antiretroviral drugs, combined with the existence of an important market in high- and middle-income countries, appears to ensure continued investment in new drug development. In addition, because treatment generally has important commercial returns, HIV therapies, unlike behavioral interventions, have benefited the most from private sector investment. The paradox is that research on the behavioral aspects of adherence to drug regimens would improve the effectiveness of antiretroviral therapy, and thereby benefit both commercial and public interests.

The greatest research challenges in relation to care and treatment in developing countries do not revolve around new drug development. They revolve around how to adapt care and treatment strategies to low-income, low-technology, low-human resource capacity settings in ways that maximize adherence; minimize toxicity, monitoring, and costs; and maximize

the prolongation of high-quality life from antiretroviral therapy—all without damaging existing and often fragile health care infrastructure that must also address other health concerns. Although simplified regimens, such as delivering multiple drugs in a single tablet and fewer doses per day, are desirable everywhere, they are especially important in low-resource settings. Similarly, low-technology, low-cost monitoring tests for antiretroviral therapy toxicity and for immunological and virological responses to treatment are especially needed in low-income countries, which otherwise must centralize testing—an especially difficult prospect when transport and communications systems are poorly developed.

CONCLUSION

Despite the glaring deficits in AIDS research, the magnitude and seriousness of the global pandemic calls for action in the absence of definitive data. The appropriate mix and distribution of prevention and treatment interventions depends on the stage of the epidemic in a given country and the context in which it occurs. In the absence of firm data to guide program objectives, national strategies may not accurately reflect the priorities dictated by the particular epidemic profile, resulting in highly inefficient investments in HIV/AIDS prevention and care. This waste undoubtedly exacerbates funding shortfalls and results in unnecessary HIV infections and premature deaths. The lack of good data—and thus the ability to tailor responses to epidemics—may be somewhat understandable when the burden of disease is minimal and the resources dedicated to it are similarly small. Neither is the case for HIV/AIDS.

ACKNOWLEDGMENTS

We are deeply indebted to Andrew Beggs, Susan Foster, James Kahn, Lilani Kumaranayake, Elliot Marseille, Fern Terris-Prestholt, Seema Vyas, and Charlotte Watts for their background papers that have informed this chapter. We also owe thanks to Sevgi Aral, Geoffrey Garnett, Robin Jackson, Marie Laga, Meg Newman, Mead Over, and David Vlahov for their work on several sections of this chapter. Finally, we would like to thank Martin Gross and Phillip Machingura for their invaluable contributions throughout this chapter.

Chapter 19

Diarrheal Diseases

Gerald T. Keusch, Olivier Fontaine, Alok Bhargava, Cynthia Bosch-Pinto, Zulfiqar A. Bhutta, Eduardo Gotuzzo, Juan Rivera, Jeffrey Chow, Sonbol A. Shahid-Salles, and Ramanan Laxminarayan

Diarrheal diseases remain a leading cause of preventable death, especially among children under five in developing countries. This chapter reviews and prioritizes a number of available interventions.

The normal intestinal tract regulates the absorption and secretion of electrolytes and water to meet the body's physiological needs. More than 98 percent of the 10 liters per day of fluid entering the adult intestines are reabsorbed (Keusch 2001). The remaining stool water, related primarily to the indigestible fiber content, determines the consistency of normal feces from dry, hard pellets to mushy, bulky stools, varying from person to person, day to day, and stool to stool. This variation complicates the definition of *diarrhea*, which by convention is present when three or more stools are passed in 24 hours that are sufficiently liquid to take the shape of the container in which they are placed. The frequent passage of formed stool is not diarrhea (Black and Lanata 2002). Although young nursing infants tend to have five or more motions per day, mothers know when the stooling pattern changes and their children have diarrhea (Ronsmans, Bennish, and Wierzba 1988). The interval between two episodes is also arbitrarily defined as at least 48 hours of normal stools. These definitions enable epidemiologists to count incidence, relapses, and new infections.

TRANSMISSION

Diarrhea is caused by infectious organisms, including viruses, bacteria, protozoa, and helminths, that are transmitted from the stool of one individual to the mouth of another, termed

fecal-oral transmission. Some are well known, others are recently discovered or emerging new agents, and presumably many remain to be identified. They differ in the route from the stool to the mouth and in the number of organisms needed to cause infection and illness. Among bacteria, the ability to survive stomach acid is an important determinant of the inoculum size required to cause illness. For example, *Shigella* bacteria are resistant to low pH, and a few thousand organisms suffice, which are readily transferred by direct person-to-person contact or through contamination of inanimate objects, such as a cup. In contrast, bacteria readily killed by acid, such as *Vibrio cholerae*, require millions of organisms to cause illness, and therefore must first multiply in food or water to an infectious dose. Some pathogens, such as rotavirus, display a sharp host species preference, and others have a broad host range. Among *Salmonella* bacteria, certain bio-serotypes are adapted to infect animals and pose no threat to humans, and others are adapted to humans and do not infect animals. The majority, however, are not adapted to a specific host and can infect either humans or domestic animals, thus facilitating transmission of these organisms to humans. Less than a dozen of the more than 2,500 individual *Salmonella* cause the majority of human infections, reflecting the requirement for genes that encode essential virulence factors.

The ability to identify virulence genes and their products has led to new molecular approaches to epidemiology and diagnosis, and undoubtedly will lead to new measures to prevent and treat diarrhea. Molecular methods also allow the separation of organisms that otherwise appear to be identical. Nonpathogenic *Escherichia coli* in normal stool cannot be

separated from diarrhea-causing *E. coli* by standard methods; however, identification of virulence genes or factors distinguishes five groups of *E. coli* that cause illnesses ranging from cholera-like watery diarrhea to neonatal diarrhea, persistent diarrhea, and bloody diarrhea (Nataro and Kaper 1998).

LABORATORY DIAGNOSIS

Etiologic diagnosis of diarrhea is valuable for public health interventions and case management. Microbiological culture and microscopy remain the standard, despite their limited sensitivity. Their effectiveness is further reduced by antibiotic use, and patients with severe illness are more likely both to be cultured and to have taken antibiotics. Even when cultures are positive, the delay in laboratory identification limits their cost-effectiveness for managing individual patients. The information is always epidemiologically and clinically important; however, during epidemics, culturing every patient is unnecessary when the causative organism is known. Antimicrobial resistance data are essential to guide initial antibiotic choices.

New rapid tests to detect inflammatory mediators or white or red blood cells in stool offer the promise of distinguishing between secretory and inflammatory disease and optimizing case management (Huicho and others 1996). High background levels, probably from frequent infections, limits the use of such tests in developing countries, where they would be most useful (Gill and others 2003).

Simple microscopy for protozoa or helminths can be quick and effective when the proper sample is obtained and a well-trained technician is available to examine a fresh specimen, but these prerequisites are often not available in developing countries. Newer immunological and nucleic acid-based tests to detect pathogen-specific factors hold great promise for all diarrhea agents, but they are too expensive or require specialized instrumentation and trained technicians. For the foreseeable future, then, syndromic diagnosis will be the norm.

SYNDROMIC DIAGNOSIS

Three major diarrhea syndromes exist. They are acute watery diarrhea, which results in varying degrees of dehydration; persistent diarrhea, which lasts 14 days or longer, manifested by malabsorption, nutrient losses, and wasting; and bloody diarrhea, which is a sign of the intestinal damage caused by inflammation. The three are physiologically different and require specific management. Syndromic diagnosis provides important clues to optimal management and is both programmatically and epidemiologically relevant.

Acute watery diarrhea can be rapidly dehydrating, with stool losses of 250 milliliters per kilogram per day or more, a

quantity that quickly exceeds total plasma and interstitial fluid volumes and is incompatible with life unless fluid therapy can keep up with losses. Such dramatic dehydration is usually due to rotavirus, enterotoxigenic *E. coli*, or *V. cholerae* (the cause of cholera), and it is most dangerous in the very young.

Persistent diarrhea is typically associated with malnutrition, either preceding or resulting from the illness itself (Ochoa, Salazar-Lindo, and Cleary 2004). Even though persistent diarrhea accounts for a small percentage of the total number of diarrhea episodes, it is associated with a disproportionately increased risk of death. In India, persistent diarrhea accounted for 5 percent of episodes but 14 percent of deaths, and a mortality rate three times higher than briefer episodes (Bhan and others 1989). In Pakistan, persistent diarrhea accounted for 8 to 18 percent of episodes but 54 percent of deaths (Khan and others 1993). In Bangladesh, persistent diarrhea associated with malnutrition was responsible for nearly half of diarrhea deaths, and the relative risk for death among infants with persistent diarrhea and severe malnutrition was 17 times greater than for those with mild malnutrition (Fauveau and others 1992). Persistent diarrhea occurs more often during an episode of bloody diarrhea than an episode of watery diarrhea, and the mortality rate when bloody diarrhea progresses to persistent diarrhea is 10 times greater than for bloody diarrhea without persistent diarrhea. HIV infection is another risk factor for persistent diarrhea in both adults and children (Keusch and others 1992). Management focuses on overcoming the nutritional alterations initiated by persistent diarrhea.

Bloody diarrhea, defined as diarrhea with visible or microscopic blood in the stool, is associated with intestinal damage and nutritional deterioration, often with secondary sepsis. Some dehydration—rarely severe—is common, as is fever. Clinicians often use the term *bloody diarrhea* interchangeably with dysentery; however, dysentery is a syndrome consisting of the frequent passage of characteristic, small-volume, bloody mucoid stools; abdominal cramps; and tenesmus, a severe pain that accompanies straining to pass stool. Those features show the severity of the inflammation. Agents that cause bloody diarrhea or dysentery can also provoke a form of diarrhea that clinically is not bloody diarrhea, although mucosal damage and inflammation are present, and fecal blood and white blood cells are usually detectable by microscopy. The release of host-derived cytokines causes fever, altering host metabolism and leading to the breakdown of body stores of protein, carbohydrate, and fat and the loss of nitrogen and other nutrients. Those losses must be replenished during convalescence, which takes much longer than the illness does to develop. For these reasons, bloody diarrhea calls for management strategies that are markedly different than those for watery or persistent diarrhea. New bouts of infection that occur before complete restoration of nutrient stores can initiate a downward spiral of nutritional status terminating in fatal protein-energy malnutrition (Keusch 2003).

DIARRHEA, ENVIRONMENT, AND POVERTY

Diarrheal disease affects rich and poor, old and young, and those in developed and developing countries alike, yet a strong relationship exists between poverty, an unhygienic environment, and the number and severity of diarrheal episodes—especially for children under five.

Poverty is associated with poor housing, crowding, dirt floors, lack of access to sufficient clean water or to sanitary disposal of fecal waste, cohabitation with domestic animals that may carry human pathogens, and a lack of refrigerated storage for food—all of which increase the frequency of diarrhea. Poverty also restricts the ability to provide age-appropriate, nutritionally balanced diets or to modify diets when diarrhea develops so as to mitigate and repair nutrient losses. The impact is exacerbated by the lack of adequate, available, and affordable medical care. Thus, the young suffer from an apparently never-ending sequence of infections, rarely receive appropriate preventive care, and too often encounter the health care system when they are already severely ill.

Although the presence of blood in the stool is a recognized danger signal, prompting more urgent care seeking, even these patients either are not treated early or receive poor medical care. Ironically, the poor spend considerable amounts on inappropriate care and useless drugs purchased from local shops and untrained practitioners. If antibiotics are properly prescribed, poverty often limits the purchase of a full course of treatment or leads to cessation of treatment as soon as symptoms improve, even though the infection has not been cured.

PUBLIC HEALTH SIGNIFICANCE OF DIARRHEAL ILLNESSES

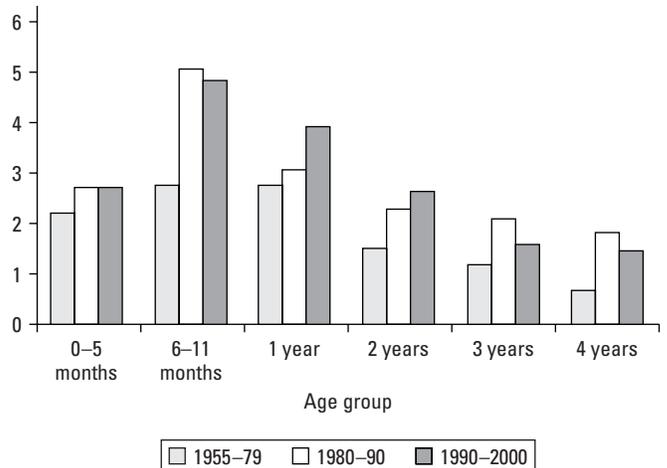

Continuing surveillance and longitudinal studies allow tracking of current levels and trends in diarrhea incidence and mortality and provide the basis for future projections and for evaluations of different control strategies.

Morbidity

Comparisons over time of the global burden of diarrheal diseases have revealed secular trends and demonstrated the impact of public health interventions (Bern and others 1992; Kosek, Bern, and Guerrant 2003; Snyder and Merson 1982). The long-term consequences of diarrhea are only now being systematically assessed and are not reflected in earlier studies.

Reviews in 1992 (Bern and others) and 2003 (Kosek, Bern, and Guerrant) are similar in many ways—for example, assessing morbidity at least twice weekly—but differ significantly in the use of different sources for data on children under five and in the inclusion of studies differing in design and data

Number of episodes per person per year

Figure 19.1 Median Age-Specific Incidences for Diarrheal Episodes per Child per Year from Three Reviews of Prospective Studies in Developing Areas, 1955–2000

collection protocols (and only the later study includes data from China). Remarkably, the estimated median incidence of diarrheal disease in children under five in developing countries has not changed much since the early 1990s (figure 19.1): 3.2 episodes per child per year in 2003 (Parashar and others 2003) compared with 3.5 episodes per child per year in 1993 (Jamison and others 1993). However, many fewer surveys were available for the most recent review (31 in 20 countries) compared with the 1993 consensus (276 in 60 countries), reflecting diminished support for the systematic collection of incidence data. Incidence rates in Sub-Saharan Africa and Latin America are clearly greater than in Asia or the Western Pacific, while subject to greater data limitations from individual countries. Incidence continues to show a peak in infants age 6 to 11 months, dropping steadily thereafter.

The seemingly lower estimates of diarrheal incidence before 1980 (Snyder and Merson 1982) are likely due to methodological differences. These estimates are not precise or directly comparable; the trends are most relevant. The persistently high rates of diarrhea throughout the 1990s despite intensive efforts at control, particularly among children age 6 to 24 months, is of particular concern. Early childhood diarrhea during periods of critical postnatal development may have long-term effects on linear growth and on physical and cognitive functions.

Data on the incidence of shigellosis, the principal cause of bloody diarrhea in developing countries, are even more limited. Kotloff and others' (1999) review of studies on *Shigella* infection estimates that more than 113 million episodes occur every year in children under five in developing countries, or 0.2 episodes of bloody diarrhea per year caused by *Shigella* species.

Figure 19.2 Estimates of Diarrhea Mortality, 1975–2000

Mortality

Bern and others (1992); Kosek, Bern, and Guerrant (2003); and Snyder and Merson (1982) also estimate diarrheal mortality using data from longitudinal studies with active surveillance in place (figure 19.2). The estimate before 1980 was 4.6 million deaths per year. This estimate dropped to 3.3 million per year between 1980 and 1990 and to 2.6 million per year between 1990 and 2000. Two other studies (Parashar and others 2003; Boschi-Pinto and Tomaskovic forthcoming) report even lower figures for 1990–2000: 2.1 million and 1.6 million deaths per year, respectively. Methodological variations (inclusion of studies with different designs and data collection methods and inclusion of data from China, different sources for estimating the number of children under five, and different strategies for calculating mortality for this age group) may account for some of the striking differences. However, the end of the 20th century witnessed significant reductions in diarrheal deaths in children under five.

This steady decline in diarrheal mortality, despite the lack of significant changes in incidence, is most likely due to modern case management (introduced since the 1980s) and to the improved nutrition of infants and children. Major recommendations include the following:

- counseling mothers to begin suitable home-prepared rehydration fluids immediately on the onset of diarrhea
- treating mild to moderate dehydration early with oral rehydration solution (ORS), reserving intravenous electrolytes for severe dehydration
- continuing breastfeeding and complementary foods during diarrhea and increasing intake afterward
- limiting antibiotic use to cases of bloody diarrhea or dysentery and avoiding anti-diarrheal and antimotility drugs

- advising mothers to increase fluids and continue feeding during future episodes.

Victora and others' (2000) review provides evidence that this strategy, and especially oral rehydration therapy (ORT), has influenced the outcome of dehydrating diarrhea. Data from 99 national surveys carried out in the mid 1990s and compiled by the United Nations Children's Fund (UNICEF) increasingly show that diarrhea patients are appropriately managed in most parts of the world, with overall use rates of ORS or recommended home fluids reaching 49 percent. Country case studies in Brazil, the Arab Republic of Egypt, Mexico, and the Philippines showed a dramatic reduction of diarrhea mortality as ORT use rates increased from close to zero in the early 1980s to 35 percent in Brazil, 50 percent in Egypt, 81 percent in Mexico, and 33 percent in the Philippines in the early 1990s. Hospital admissions for diarrhea also plummeted (Victora and others 2000). As mortality attributable to acute dehydration decreased, the proportionate mortality associated with persistent diarrhea increased. Data from Brazil and Egypt suggest that even relatively low ORT use rates can positively affect mortality, because ORT use tends to be much higher for severe illness (Victora and others 2000).

Worldwide mortality caused by *Shigella* infection is estimated to be 600,000 deaths per year among children under five, or a quarter to a third of all diarrhea-related mortality in this age group (Kotloff and others 1999). Because mortality caused by bloody diarrhea is not tracked separately, it is difficult to assess the impact of standard case management recommendations, and disease-specific trends cannot be tracked. In the past few years, however, data from the International Centre for Diarrheal Disease Research, in Bangladesh, have shown a marked decrease in the rate of hospitalization caused by *Shigella*, especially *S. dysenteriae* type 1, the most severe form of shigellosis. Some investigators have suggested that this decrease may be because *Shigella* infections are now in the low part of a 10-year cycle (Legros 2004). The observed change could also be explained by better case management with more efficacious antimicrobials. More comprehensive, syndrome-specific surveillance data will be required if rational control priorities are to be set, because the options for dehydrating and bloody diarrheal diseases differ substantially.

Despite national data that indicate a significant decline in mortality (Baltazar, Nadera, and Victora 2002; Miller and Hirschhorn 1995), diarrheal diseases remain among the five top preventable killers of children under five in developing countries and among the top two in many.

Long-Term Consequences

The long-term consequences of diarrheal diseases remain poorly studied, and analyses of global trends have not considered them. Niehaus and others (2002) recently evaluated the

long-term consequences of acute diarrheal disease on psychomotor and cognitive development in young children. Following a cohort of 47 children in a poor urban community in northeastern Brazil, they correlated the number of diarrheal episodes in the first two years of life with measures of cognitive function obtained four to seven years later. They found a significant inverse correlation (average decrease of 5.6 percent) between episodes of early diarrheal disease and overall intellectual capacity and concentration, even when controlling for maternal education or helminth infection, which are known to be independent predictors of malnutrition and cognitive defects. Test scores were also 25 to 65 percent lower in children with an earlier history of persistent diarrhea.

Recent evidence suggests that genetic factors may also be involved in the developmental response to repeated diarrhea (Oria and others 2005). Better and more sensitive assessment tools are needed to define the relationships between diarrheal diseases and developmental disorders and to calculate individual and societal costs and the cost-effectiveness of interventions. In addition, early childhood malnutrition resulting from any cause reduces physical fitness and work productivity in adults (Dobbing 1990).

PREVENTIVE STRATEGIES

Strategies for controlling diarrheal diseases have remained substantially unchanged since the 1993 edition of this volume (Martinez, Phillips, and Feachem 1993). The World Health Organization (WHO 2004) recently reevaluated these interventions to determine the extent to which they have been effectively implemented and their effect.

Promotion of Exclusive Breastfeeding

Exclusive breastfeeding means no other food or drink, not even water, is permitted, except for supplements of vitamins and minerals or necessary medicines. The optimal duration of exclusive breastfeeding is six months (WHO 2001). A meta-analysis of three observational studies in developing countries shows that breastfed children under age 6 months are 6.1 times less likely to die of diarrhea than infants who are not breastfed (WHO Collaborative Study Team 2000). Exclusive breastfeeding protects very young infants from diarrheal disease in two ways: first, breast milk contains both immune (specific) and nonimmune (nonspecific) antimicrobial factors; second, exclusive breastfeeding eliminates the intake of potentially contaminated food and water. Breast milk also provides all the nutrients most infants need up to age 6 months. When exclusive breastfeeding is continued during diarrhea, it also diminishes the adverse impact on nutritional status.

Those data underpin the global campaign to promote exclusive breastfeeding for the first six months of life by increasing both the initiation and the duration of exclusive breastfeeding. The strategies include the following:

- hospital policies and actions to encourage breastfeeding and discourage bottle feeding
- counseling and education provided by peers or health workers
- mass media and community education
- mothers' support groups.

Interventions focused on hospital practices apply where most women deliver in such facilities. Such interventions have shown up to a 43 percent increase in exclusive breastfeeding with good institutional policies and retraining of health staff (Westphal and others 1995). Interventions focused on education and counseling increase exclusive breastfeeding by 4 to 64 percent (Sikorski and others 2002). Peer-counseled women are less likely to stop exclusive breastfeeding than are those who receive either professional support or no support, and their infants are 1.9 to 2.9 times less likely to have diarrhea (Barros and others 1995; Haider and others 1996). No large-scale peer counseling programs exist; therefore, feasibility is unknown. Community-based mother's support groups are sustainable, but they have low coverage and are biased toward women who are already motivated to breastfeed (Bhandari and others 2003). Mass media can be effective where media coverage is high, where production skills are good, and where it addresses barriers to breastfeeding instead of just proclaiming its benefits. We found no studies that examined the relationship between breastfeeding promotion and diarrheal disease mortality; however, estimates suggest such promotion could decrease all-cause mortality in children under five by 13 percent (Jones and others 2003).

Maternal HIV infection has put a new wrinkle in the "breast is best" dogma because of the risk of transmission of infection to the infant (De Cock and others 2000). There is a trade-off, however, between the risk of mortality associated with replacement feeding and the risk of HIV infection, especially where safe replacement feeding is difficult. For women who are HIV-negative or whose status is unknown, WHO currently recommends exclusive breastfeeding for at least six months (WHO 2000). The best option for HIV-positive women is acceptable, affordable, sustainable, and safe replacement feeding. If this option is not possible, there are four alternatives: (a) heat-treated breast milk, (b) HIV-negative wet nurses, (c) uncontaminated donor milk, or (d) exclusive breastfeeding for six months and rapid discontinuation thereafter (WHO 2003).

A danger of promoting replacement feeding is that uninfected women or women with unknown HIV status will adopt the practice. Even in high-prevalence communities, the best

option for women with unknown status for the overall health of their children appears to be exclusive breastfeeding for six months. In Coutsoudis and others' (1999) cohort study in South Africa, the risk of mother-to-infant transmission of HIV after three months of exclusive breastfeeding was similar to that with no breastfeeding and significantly lower than that with mixed feeding. Providing antiretroviral therapy to the mother should significantly extend the period of safe breastfeeding for the initially HIV-negative infants of HIV-positive mothers.

Improved Complementary Feeding Practices

Ideally, complementary foods should be introduced at age 6 months, and breastfeeding should continue for up to two years or even longer to increase birth intervals (WHO 2003). There is a strong inverse association between appropriate, safe complementary feeding and mortality in children age 6 to 11 months. Malnutrition is an independent risk predictor for the frequency and severity of diarrheal illness. There is a vicious cycle in which sequential diarrheal disease leads to increasing nutritional deterioration, impaired immune function, and greater susceptibility to infection. The cycle may be broken by interventions to decrease infection incidence to reduce malnutrition (Keusch and Scrimshaw 1986) or improving nutritional status to reduce the burden of infection (Victora and others 1999).

Improved feeding practices to prevent or treat malnutrition could save as many as 800,000 lives per year (Jones and others 2003). Pediatricians have long been aware of an increase in diarrhea incidence during weaning from exclusive breast milk feeding. Microbial contamination of complementary foods (Mondal and others 1996) and nutritionally inadequate diets during and after diarrhea episodes (Badruddin and others 1991) increase the risk. Contamination of complementary foods can potentially be reduced by educating caregivers on hygienic practices (Guptill and others 1993), improving home food storage (English and others 1997), fermenting foods to reduce pathogen multiplication (Kimmons and others 1999), or ingesting nonpathogenic probiotic microorganisms that colonize the gut and help resist pathogens (Allen and others 2004). These interventions have not been evaluated at scale in communities, and effectiveness trials are lacking.

We could not find any reports on the effects of complementary feeding interventions on mortality. Five efficacy trials to improve the intake of complementary foods noted a net increase in energy intake of between 65 and 300 kilocalories a day and improvements of 0.25 to 0.46 standard deviations in weight-for-age and 0.04 to 0.35 standard deviations in height-for-age (Caulfield, Huffman, and Piwoz 1999). By extrapolation, this increment in growth should translate into a 2 to 13 percent reduction in deaths associated with malnutrition (Black and others 1995).

Brown, Dewey, and Allen (1998) reviewed experiences with large-scale complementary feeding interventions in 14 countries. They demonstrate that it is possible to provide nutritionally improved complementary foods in diverse cultural settings and that poor mothers are willing to prepare new foods their children will eat. However, caregivers face considerable time and resource constraints in providing such foods, especially during episodes of illness. A pilot study in Brazil that implemented nutritional counseling through the Integrated Management of Childhood Illness Program reported significant weight gain in children age one year or more, but not in younger children (Santos and others 2001).

Unfortified complementary foods do not meet all essential micronutrient requirements. Although improvements in vitamin A status do not significantly reduce the incidence of diarrhea and other common childhood illnesses, vitamin A supplementation can reduce the frequency of severe diarrhea (Barreto and others 1994) and mortality (Ross and others 1995). Chapter 28 describes interventions to promote vitamin A intake. Zinc supplementation also reduces the incidence of diarrhea.

Rotavirus Immunization

Almost all infants acquire rotavirus diarrhea early in life, and rotavirus accounts for at least one-third of severe and potentially fatal watery diarrhea episodes—primarily in developing countries, where an estimated 440,000 vaccine-preventable rotavirus deaths per year occur (Parashar and others 2003), compared with about a dozen in a developed country such as France (Fourquet and others 2003). An effective rotavirus vaccine would have a major effect on diarrhea mortality in developing countries.

In 1998, a quadrivalent Rhesus rotavirus–derived vaccine that reduced the frequency of severely dehydrating rotavirus—but not the overall incidence of rotavirus infections—was licensed in the United States (Glass and others 1999). It was cost-effective, even at US\$100 for a full course of immunization, when direct economic losses resulting from health care expenses and indirect costs of lost productivity and wages for the caretakers were considered (Tucker and others 1998). The strategy was clear: use the high-priced vaccine routinely in industrial countries to subsidize its use in developing countries. However, postmarketing surveillance detected an apparent increase in a relatively rare event, intussusception, a condition in which the intestine telescopes on itself, causing a potentially serious obstruction (CDC 1999a). The relationship was strongest with the first dose of vaccine given with the first or second dose of diphtheria-pertussis-tetanus vaccine (Peter and others 2002), although this was counterbalanced by a decrease in the incidence of intussusception in older children (Murphy and others 2003).

The overall reduced incidence in immunized infants compared with nonimmunized infants in these studies suggested that the vaccine may actually protect against later adverse events. Nonetheless, the ensuing controversy led to a reversal of the recommendation for universal immunization in the United States and withdrawal of the vaccine from the market, precluding the possibility of its deployment in developing countries (CDC 1999b). Because very young infants are less prone to develop intussusception, initial immunization at birth might have been entirely safe.

Despite this setback, efforts to produce an effective and safe rotavirus vaccine continue. The Rhesus vaccine has been relicensed to another manufacturer, and new vaccines derived from human or bovine rotavirus are undergoing field trials in developing countries (Dennehy 2005). A monovalent human rotavirus vaccine was introduced in Mexico in 2005. The entry of both China and India into rotavirus vaccine development and their potential for manufacturing quality vaccines at low cost will make it easier to deploy an effective vaccine where it is really needed.

Cholera Immunization

Endemic cholera is primarily a pediatric disease, although adult morbidity and mortality are significant, especially during epidemics. The lethality of cholera is due to the physiological consequences of rapid and profound dehydration. Oral rehydration therapy has dramatically improved survival and reduced the cost of treatment. Wherever parenteral and oral rehydration is readily available, even in epidemic situations, a cholera mortality rate above 1 percent indicates failure of the public health system to provide appropriate case management.

A vaccine would further reduce the morbidity and mortality associated with cholera in endemic areas; however, developing an effective, safe vaccine has proven difficult. The most immunogenic and protective vaccines tested thus far are administered orally. Two such vaccines have been licensed: an attenuated live vaccine and a heat-killed vaccine combined with recombinant cholera toxin B subunit, which functions as an immunoadjuvant (Graves and others 2000; Ryan and Calderwood 2000). Many developing countries can produce the killed vaccine, especially without cholera toxin B. Current oral cholera vaccines appear to be safe and offer reasonable protection for a limited period; however, the main users have been individual travelers from industrial countries who may be exposed to the risk of cholera while traveling in endemic areas.

The use of oral cholera vaccine in mass vaccination campaigns as an adjunct to good case management, disposal of fecal waste, and access to safe water during humanitarian disasters has recently been reviewed (WHO 1999). Analysis of an

outbreak in Micronesia suggested that a single dose was useful in limiting the spread of cholera (Calain and others 2004). But because ORT is so inexpensive and useful in preventing death, immunization is not a high priority. Only Vietnam routinely deploys cholera vaccine.

Operational information on the costs, logistics, and availability of vaccines for use by global programs and on the vulnerable populations in high-risk settings who would benefit from cholera vaccine remains limited. Although scientific interest in a cholera vaccine remains high, its public health priority is less than that of a vaccine for rotavirus or *Shigella*.

Measles Immunization

Measles is known to predispose to diarrheal disease secondary to measles-induced immunodeficiency. Feachem and Koblinsky (1983) estimate that measles vaccine given to 45 to 90 percent of infants would prevent 44 to 64 percent of measles cases, 0.6 to 3.8 percent of diarrheal episodes, and 6 to 26 percent of diarrheal deaths among children under five. Global measles immunization coverage is now approaching 80 percent, and the disease has been eliminated from the Americas, raising hopes for global elimination in the near future (GAVI 2005), with a predictable reduction in diarrhea as well.

Improved Water and Sanitary Facilities and Promotion of Personal and Domestic Hygiene

Human feces are the primary source of diarrheal pathogens. Poor sanitation, lack of access to clean water, and inadequate personal hygiene are responsible for an estimated 90 percent of childhood diarrhea (WHO 1997). Promotion of hand washing reduces diarrhea incidence by an average of 33 percent (Huttly, Morris, and Pisani 1997); it works best when it is part of a package of behavior change interventions. Effects on mortality have not been demonstrated. However, the required behavior change is complex, and significant resources are needed. Antiseptic soaps are more costly than plain hand soap and confer little advantage. Washing hands after defecating or handling children's feces and before handling food is recommended, but it entails an average of 32 hand washes a day and consumes 20 liters of water (Graef, Elder, and Booth 1993). If soap is too costly, ash or mud can be used, but access to water remains essential (Esrey 1996).

Six rigorous observational studies demonstrated a median reduction of 55 percent in all-cause child mortality associated with improved access to sanitation facilities (Esrey, Feachem, and Hughes 1985). The greatest effect of improving sanitation systems will be in areas of high population density and wherever the entire community, rather than single households, adopts the intervention. Current technology can be costly and difficult to maintain, and in some settings it is simply not feasible.

CASE MANAGEMENT

Two recent advances in managing diarrheal disease—(a) newly formulated ORS containing lower concentrations of glucose and salts and (b) zinc supplementation—used in combination with promotion of exclusive breastfeeding, general nutritional support, and selective and appropriate use of antibiotics, can further reduce the number of diarrheal deaths among children. Families and communities are key to achieving case management goals by making these recommendations routine practice in homes and health facilities.

New Oral Rehydration Solutions

For more than 25 years, UNICEF and WHO have recommended a single formulation of glucose-based ORS considered optimal for cholera, irrespective of cause or age group affected. This formulation has proven effective and without significant adverse effects (Ruxin 1994), but because watery stools persist and duration of diarrhea is not reduced, mothers' and health workers' acceptance of current ORSs has been suboptimal.

During the past 20 years, efforts to improve ORS to treat dehydration from all types of diarrhea and reduce stool output or duration have continued—for example, by reducing the sodium content in line with sodium losses for noncholera diarrhea. Compared with standard ORS, lower sodium and glucose ORS reduces stool output, vomiting, and the need for intravenous fluids (Hanh, Kim, and Garner 2001). If household use increases, new ORS can reduce childhood deaths from noncholera diarrhea (Duggan and others 2004), and it appears to be as effective as standard ORS for children or adults with cholera. A WHO expert group now recommends that ORS containing 75 milliequivalents of sodium and 75 millimoles of glucose per liter (total osmolarity, 245 milliosmoles per liter) be used everywhere (WHO and UNICEF 2004).

Zinc Supplementation

A review of all relevant clinical trials indicates that zinc supplements given during an episode of acute diarrhea reduce both duration and severity and could prevent 300,000 deaths in children each year (Black 2003). WHO and UNICEF now recommend that all children with acute diarrhea be given zinc in some form for 10 to 14 days during and after diarrhea (10 milligrams per day for infants younger than 6 months and 20 milligrams per day for those older than 6 months) (WHO and UNICEF 2004).

Pilot studies in Brazil, Egypt, Ethiopia, India, Mali, Pakistan, and the Philippines that include zinc routinely in the management of acute diarrhea not only show an improvement over ORS alone but also suggest two important new effects: (a) use rates of ORS increase, and (b) use rates of antidiarrheals and

antimicrobials decrease significantly (Baqui and others 2004). Large community-based studies are being implemented to corroborate these potentially important findings.

Management of Bloody Diarrhea

The primary treatment for shigellosis, the most common and severe cause of bloody diarrhea, is antimicrobials. The choice of effective, safe, and inexpensive oral drugs for use in developing countries has, however, become problematic because of the increasing prevalence of antimicrobial drug resistance (Salam 1998). Tetracycline, ampicillin, and the fixed-ratio combination of trimethoprim and sulfamethoxazole, once used as first-line treatment, are no longer reliably effective. When epidemic dysentery caused by multidrug-resistant *S. dysenteriae* type 1 appeared in Africa and Asia in the 1980s and 1990s, nalidixic acid was pressed into use (Salam and Bennish 1988). Nalidixic acid is a drug used primarily for urinary tract infections, but it is also effective against *Shigella*. Clinical responses were initially excellent, but with continued use, resistance to nalidixic acid has been increasing in many parts of the world (Dutta and others 2003).

A number of other drugs have been tested and shown effective, including ceftriaxone, azithromycin, pivmecillinam, and some new generation 5-fluoroquinolones, such as ciprofloxacin (Salam 1998). Because of its effectiveness, safety, ease of administration by the oral route, short course, and low cost (US\$0.10 for a three-day course for a 15-kilogram child), ciprofloxacin is the current drug of choice for shigellosis (Zimbasa Dysentery Study Group 2002). However, ciprofloxacin-resistant strains are already appearing (Pazhani and others 2004), and it is only a matter of time before resistance becomes widespread, especially if the drug is readily available and indiscriminately used. Because of these concerns, development of a vaccine for *Shigella* is critical. The Diseases of the Most Impoverished initiative, supported by the Bill & Melinda Gates Foundation (Nossal 2003), which promotes vaccine development for *Shigella*, cholera, and typhoid, is a significant advance since the previous edition of this volume.

COST-EFFECTIVENESS OF INTERVENTIONS

Cost-effectiveness ratios of diarrheal disease interventions were calculated by World Bank region in terms of disability-adjusted life years (DALYs) averted for a model population of 1 million, following the standardized guidelines of the Disease Control Priorities Project for economic analyses (see chapter 15). Europe and Central Asia were excluded because data were lacking owing to the low prevalence of disease. Input variables included (a) region-specific diarrhea morbidity rates adapted from Kosek, Bern, and Guerrant (2003); (b) region-specific

underlying mortality rates and age structures provided by the Disease Control Priorities Project; (c) median intervention effectiveness rates (that is, percentage of diarrheal morbidity reduction and percentage of diarrheal mortality reduction); and (d) median per capita intervention costs gathered from the literature and from personal communications (table 19.1).

Because approximately 90 percent of all cases in the developing world occur in children under five, the analysis focused on this age group alone. Uniform intervention effectiveness rates were assumed for all regions because region-specific information was not available. Regional variations in cost-effectiveness were due to regional variations in the prevalence of diarrheal disease, in the diarrhea-attributable morbidity and mortality, and in the intervention cost, where region-specific information was available.

Disability-adjusted life years are averted through the avoidance of cotemporaneous disability and mortality attributable to diarrhea. We did not consider long-term developmental and cognitive effects of childhood diarrhea or the external benefits of interventions unrelated to diarrhea (for instance, benefits of measles immunization unrelated to diarrhea or other health benefits of improved public water and sanitation). Therefore, our estimates err on the conservative side.

We explored two general categories of interventions: early interventions that take place within the first year of life—breastfeeding promotion and immunizations for rotavirus (with the prototype Rhesus reassortant tetravalent vaccine), cholera (with live oral vaccine), and measles—and other interventions that treat an entire cohort of children under five simultaneously (improved water and sanitation). For early interventions, cost-effectiveness ratios were calculated by considering the cost of treating all newborns in a single year and the benefits (DALYs averted) from those treatments that occur over the first five years of life. These benefits include avoided mortality that allows individuals to live to the expected life expectancy for the region. Other interventions included ORT and improved water and sanitation infrastructure. Because a single year of these interventions yields only cotemporaneous benefits—because effectively treated individuals do not necessarily live to life expectancy given that they are likely to be reinfected the next year—we calculated cost-effectiveness of a five-year intervention. Analysis of a five-year intervention enabled us to consider the case in which an entire cohort of children age zero to four avoids early childhood diarrheal mortality because of the intervention and receives the benefit of living to life expectancy.

Disability and deaths averted for those benefiting from improved water and sanitation were calculated from only the fraction of the model populations currently without access. For each region, the proportion of rural and urban children age zero to four currently without access to improved water and sanitation was calculated using region-specific information from *World Bank Development Indicators* (World Bank 2002)

for 2000. Infrastructure improvements for rural and urban populations were considered separately because of differences in infrastructure type and cost, although the same effectiveness rates were used for both.

The per child treatment costs and effectiveness rates used are presented in table 19.1. Cost per treatment of ORT varied widely depending on the type and method of ORT implemented. Oral rehydration therapy can be as inexpensive as US\$0.02 per child treated—the cost of a home remedy with sugar and salt. However, treatment can become substantially more expensive if commercially manufactured ORS is used or if there are substantial personnel or infrastructure costs (Martinez, Phillips, and Feachem 1993). Finally, our analysis considered only long-run marginal costs (which vary with the number of individuals treated) and did not include fixed costs of initiating a program where none currently exists.

Figure 19.3 shows the cost-effectiveness of all interventions over the first five years of life. Two interventions administered during the first year of life—breastfeeding promotion (US\$930 per DALY) and measles immunization (US\$981 per DALY)—were the most cost-effective. ORT (US\$1,062 per DALY) and water and sanitation in rural areas (US\$1,974 per DALY) were the next most cost-effective, but only if they were implemented continuously for five years, thereby allowing an entire cohort of effectively treated children age zero to four to survive past the age at which they are most at risk for diarrheal infection, disability, and mortality. Rotavirus immunization (US\$2,478 per DALY), cholera immunization (US\$2,945 per DALY), and water and sanitation in urban areas (US\$6,396 per DALY) were the least cost-effective.

Among the early interventions, breastfeeding promotion was less effective than other interventions but also less expensive than rotavirus and measles vaccination (table 19.1). Cholera vaccination was less expensive than breastfeeding promotion, but it was also many times less effective because of the significantly higher prevalence of diarrhea that is not related to cholera—making cholera vaccination the least cost-effective of the early interventions considered. Oral rehydration therapy and water and sanitation interventions were more effective than breastfeeding and vaccination interventions in reducing morbidity and mortality caused by diarrhea, but they were also more expensive. However, our analysis for water and sanitation did not consider the benefits of this intervention other than those related to health, and the high cost-effectiveness ratio is more a limitation of our methodology than of the intervention itself.

The high cost-effectiveness ratio for ORT is attributable to the high variation in reported treatment costs, which may inflate the median cost used in this analysis (table 19.2). Given the range of reported treatment costs (table 19.1), the cost-effectiveness ratio of ORT could be as low as US\$4 per DALY or as high as US\$2,124 per DALY in low- and middle-income countries. High variation in reported treatment costs results in

Table 19.1 Cost and Effectiveness Values Used to Calculate Cost-Effectiveness Ratios for Select Interventions for Diarrhea for Children under Age Five

Model regions	Sources	Source regions or countries	Median cost/child (2001 US\$)	Cost/child range (2001 US\$)	Median diarrhea morbidity reduction (percent)	Morbidity reduction range (percent)	Median diarrhea mortality reduction (percent)	Mortality reduction range (percent)

high variation in cost-effectiveness for the other regions as well. There remains little doubt, however, about the effect of widespread use of ORT on diarrhea morbidity and mortality and about the associated direct and indirect cost savings for treatment and hospitalization.

RESEARCH AGENDA

Good evidence now supports the view that promoting ORT in conjunction with other key interventions, preventive as well as curative, has had a large role in the marked reduction in deaths of children caused by diarrhea (Victora and others 2000).

Preventive strategies—such as breastfeeding, improving complementary feeding and using micronutrient supplementation or fortification, and increasing coverage with the full set of Expanded Programme on Immunization vaccines (especially measles vaccine)—are all useful and effective (GAVI 2005). Failure to separately track the full impact of bloody diarrhea—especially *Shigella* infection—on morbidity and mortality or to effectively implement good clinical management (including guidelines for and control over the use of antibiotics) has contributed to the continuing burden of bloody diarrhea and dysentery worldwide and the alarming increase in antibiotic resistance. The challenges for the next decade will be to increase or ensure universal appropriate implementation of these interventions in developing countries and to avoid a situation in which they compete for funding and staff time. Delivery of good-quality services is essential, and much remains to be learned through research before this requirement can be met.

Other interventions, such as vaccines against rotavirus, *Shigella*, or cholera, are either not yet available or not ready for universal administration. Progress toward the development of these vaccines, with the highest priority for the first two, is encouraging, but further investments in research and development will be required before large-scale implementation of these interventions can be considered. The cost of these vaccines will remain a major constraint for poor people, who cannot pay for the costs of development and ensure reasonable profits for industry. However, increased public investment in

fundamental and applied research, vaccine purchase schemes, and development of low-cost, high-quality manufacturing capacity in developing countries may change the prevailing dynamics. By creating public-private partnerships for vaccine development, organized as targeted product development programs, the public sector, private foundations, and industry are taking steps toward these goals.

Because of the fecal-oral transmission of enteric pathogens, improving the supply of safe water and the ability to safely dispose of fecal waste are the best ways to reduce the burden of morbidity and mortality. However, major investments and critical improvements in water and sanitary waste disposal on the necessary scale are unlikely to occur in the next decade or two. Local low-tech solutions can be useful, and enhanced efforts to find ways to improve water cleanliness at the point of use and to build simple latrines that will be used consistently are needed (chapter 41). However, in the face of HIV and the attention being given to tuberculosis and malaria, coordinated efforts to build safe water and sanitation capacity at the local level, one village at a time, that are sufficient to significantly influence the burden of illness are unlikely—even though many more infants and children die each year of preventable and treatable diarrhea than of HIV/AIDS.

The cycle of research, followed by implementation, followed by research has enabled the development of improved tools to manage diarrheal diseases—tools that have the potential to further drive down diarrhea mortality. The challenge is to achieve high coverage and good practice with ORT and correct diarrhea case management, including antimicrobial and nutrition interventions. Interventions to integrate health care through programmatic initiatives such as the Integrated Management of Childhood Illness program, critically evaluated elsewhere in this book (chapter 63), could be essential to ensure this high coverage. Some concern remains that in low-resource settings such targeted vertical programs may be abandoned, to the detriment of the goals for disease burden reduction that they were established to achieve.

The challenge posed by the case management of bloody diarrhea is a different matter. Until a vaccine is available, the keystone for managing bloody diarrhea will continue to be the early use of effective antimicrobial agents. That is made difficult by increasing drug resistance, aided by the widespread indiscriminate and inappropriate use of antimicrobials, and the increasingly difficult task of finding a safe, inexpensive, and effective oral agent and then ensuring that the drug is given in a clinically optimal manner. From a technical perspective, the development of a vaccine against *Shigella* infections is still in its infancy and in need of greater investment. For both watery and bloody diarrhea, the challenge of developing drugs to normalize the pathophysiology caused by the infection remains a scientific challenge and a distant hope.

CONCLUSIONS

Existing interventions to prevent or treat diarrheal diseases have proven their efficacy in reducing mortality, but a major challenge for the next 10 years will be to scale up these interventions to achieve universal utilization coverage. The United Nations Millennium Development Goal to reduce the mortality rate among children under five by two-thirds by 2015 will be easier to attain if the scale-up goals are reached. New products and tools could significantly improve the efficacy of these interventions—for example, rapid specific diagnostics, new treatment strategies based on reversing the pathophysiology of the infection, simple and effective ways to produce clean water and control human waste, and vaccines to prevent illness. However, these products and tools will not become widely available in time to influence the achievement of the Millennium Development Goals. Continued investment in diarrheal disease research across the spectrum of basic, social and behavioral, and applied investigations is, therefore, essential, including expanded behavioral research to understand how parents assess risk and how actionable health messages can be presented in different cultures and settings.

Chapter 20

Vaccine-Preventable Diseases

Logan Brenzel, Lara J. Wolfson, Julia Fox-Rushby, Mark Miller, and Neal A. Halsey

Vaccination against childhood communicable diseases through the Expanded Program on Immunization (EPI) is one of the most cost-effective public health interventions available (UNICEF 2002; World Bank 1993). By reducing mortality and morbidity, vaccination can contribute substantially to achieving the Millennium Development Goal of reducing the mortality rate among children under five by two-thirds between 1990 and 2015. Accelerated research into the development of new vaccines has been made possible in part by innovative public-private partnerships, such as the Global Alliance for Vaccines and Immunization (GAVI). GAVI focuses on expanding access by immunization programs in developing countries to new and underused vaccines, such as those for hepatitis B and *Haemophilus influenzae* type B (Hib). These newer, more expensive vaccines are challenging previous notions of the cost-effectiveness of immunization. Analyses of their costs and cost-effectiveness are particularly important because of the need to determine the level of resources required in the future to improve immunization programs, to cover the costs of new vaccines, and to allocate scarce public and external resources available for immunization in the most optimal manner.

This chapter analyzes the costs and cost-effectiveness of scaling up the EPI and introducing selected new vaccines into the program. It also summarizes the epidemiology of diseases preventable through immunization and estimates the disease burden with and without immunization programs. In addition, the chapter discusses the organization, delivery, and financing of immunization programs and highlights future prospects and areas for further study.

Several areas overlap with other chapters. For example, the vaccines that prevent measles, tuberculosis, diphtheria,

pertussis, Hib, and *Neisseria meningitidis* prevent respiratory diseases. Some vaccines, such as those against measles and pertussis, prevent diseases that cause or contribute to malnutrition. Chapter 16 provides an in-depth review of tuberculosis and a discussion of the potential impact of bacillus Calmette-Guérin (BCG) vaccines. This chapter also does not discuss some new vaccines, including conjugate *Streptococcus pneumoniae*, influenza, typhoid fever, and rotavirus, because other chapters deal with those diseases and vaccines. Vaccines to prevent mumps and varicella that are routinely used in some developed countries are not included in most vaccination programs in developing countries. Other interventions that can reduce the burden of vaccine-preventable diseases and are not covered in this chapter include clean umbilical cord care to reduce the incidence of neonatal tetanus, vitamin A therapy to reduce the case-fatality rate (CFR) from measles, and intensive clinical care that can reduce the mortality associated with most of the vaccine-preventable diseases.

CAUSES AND EPIDEMIOLOGY OF DISEASES PREVENTED BY VACCINES USED IN NATIONAL IMMUNIZATION PROGRAMS

The epidemiology and burden of vaccine-preventable diseases vary by country and region partly because of differences in vaccine uptake. Numerous other factors that contribute to the disease burden include geography, seasonal patterns, crowding, nutritional status, travel to and from other countries, and possibly genetic differences in populations that affect disease severity. Table 20.1 summarizes the features of selected vaccines

Table 20.1 Selected Vaccine-Preventable Diseases and Vaccines

Category	Tuberculosis	Diphtheria	Tetanus	Pertussis	Polio	Measles ^a	Rubella	Hib	Hepatitis B	Yellow fever	Meningococcal disease	Japanese encephalitis
Causative agent	Mycobacterium tuberculosis	Toxin-producing bacterium (<i>Corynebacterium diphtheriae</i>)	Toxin-producing bacterium (<i>Clostridium tetani</i>)	Bacterium (<i>Bordetella pertussis</i>)	Virus (serotypes 1, 2, and 3)	Virus	Virus	Bacterium (<i>Haemophilus influenzae</i> type B)	Virus	Virus	<i>Neisseria meningitidis</i> groups A, B, C, Y, W135	Virus
Reservoir	Humans (some bovine)	Humans	Animal intestines; soil	Humans	Humans	Humans	Humans	Humans	Humans	Monkeys and humans	Humans	Birds and mammals
Spread	Airborne droplet nuclei from sputum-positive persons	Close respiratory or cutaneous contact	Spores enter the body through wounds or the umbilical cord stump	Close respiratory contact	Fecal-oral; close respiratory contact	Close respiratory contact and aerosolized droplets	Close respiratory contact and aerosolized droplets	Close respiratory contact	Blood, perinatal, household, occupational, or sexual transmission	Bites by infected mosquitoes	Close respiratory contact	Bites by infected mosquitoes
Transmission period	As long as sputum acid-fast bacilli are positive	Usually under two weeks; some chronic carriers	No person-to-person transmission	Usually under three weeks (starts before cough is apparent)	A few days before and after acute symptoms	Four days before rash until two days afterward	A few days before to one year of age in congenitally infected	Chronic carriage for months	Up to lifelong chronic carriage and transmission	Infected individuals can transmit the disease when bitten by a mosquito vector during the viremic phase (the first three or four days of illness)	Chronic carriage for months	Unknown, rare cases for several months
Subclinical infection	Common but not important in transmission	Common	No	Mild illness common; may not be diagnosed	More than 100 subclinical infections for each paralytic case	May occur in children under one, but relative importance is minimal	Common	Common	Common, especially in infants	Common	Common	Common
Duration of natural immunity	Not known; reactivation of old infection commonly causes disease	Lasting protective immunity not produced by infection; second attack possible	Lasting protective immunity not produced by infection; second attack possible	Incomplete and waning protection	Lifelong type-specific immunity	Lifelong	Lifelong	Uncertain; no protection against previously infected may develop some disease (epiglottitis)	If develops, lifelong	Lifelong	Uncertain; no protection against carriage	Lifelong

Risk factors for infection (for unvaccinated individuals)	High population densities in regions with historically poor control; low socioeconomic status; poor access to care; immunodeficiency; malnutrition; alcoholism; diabetes	Crowding; low socioeconomic status	Young age; crowding	Poor environmental hygiene and sanitation	Highly transmissible agent with nearly 100 percent infectivity except for isolated populations; crowding; low socioeconomic status	Highly transmissible; crowding; low socioeconomic status	Failure to breastfeed; crowding; low socioeconomic status; immune deficiency, including HIV	Carrier mother, sibling, or sex partner; multiple sex partners; intravenous drug use; unsafe injection practices	Young age; forest workers; rainy season (late rainy season, early dry season)	Crowding; respiratory viral infections, especially influenza	Young age; forest workers; season
Case-fatality rate ^b	See chapter 16	2 to 20 percent	Up to 10 percent in infants and children	2 to 10 percent	0.05 to 10.0 percent	Less than 0.1 percent	Meningitis, 5 to 90 percent; pneumonia 5 to 25 percent	Acute, more than 1 percent; chronic, 25 percent (delayed)	10 to 40 percent	Untreated 90 to 100 percent; treated 5 to 20 percent	5 to 30 percent
Vaccine (number of doses); route	BCG attenuated <i>Mycobacterium bovis</i> (1); intradermal	Diphtheria toxoid (three to five primary including booster doses in most countries); intramuscular	Killed whole-cell or acellular pertussis (three to five, including booster doses in most countries); intramuscular	Live (OPV) (three to four primary plus campaigns) ^c killed (IPV) (three to four)	Measles (two); subcutaneous	Rubella (one or two); subcutaneous	Capsular polysaccharide linked to protein Hib (three to five); intramuscular	Hepatitis B surface antigen (three to four); intramuscular	Yellow fever attenuated live virus (1 plus boosters); subcutaneous	Vaccines for A, C, Y, W135 only; unconjugated polysaccharides given subcutaneously or intramuscularly; one dose with repeat three to five years later for high-risk persons; conjugated: for C only or A, C, Y, + W135, one dose given intramuscularly	Live attenuated (two, China only); killed (two); booster commonly used but of uncertain value
Vaccine efficacy	0 to 80 percent for pulmonary tuberculosis; 75 to 86 percent for meningitis and military tuberculosis	More than 87 percent	70 to 90 percent	OPV: more than 95 percent in industrial countries; 72 to 98 percent in developing countries; lower protection against type 3 than 1 and 2; IPV: more than 95 percent	95 percent at 12 months of age; 85 percent at 9 months of age from one dose, more than 98 percent from two doses	95 percent (at 12 months and up)	More than 95 percent for invasive disease	75 to 95 percent; efficacy against chronic infection in infants born to carrier mothers; more than 95 percent for exposure at older ages	90 to 98 percent	Unconjugated polysaccharides: poor efficacy under two years of age; conjugated polysaccharides: approximately 95 percent and up serogroup specific	Live attenuated: 90 percent (after one dose at one year); 94 to 100 percent (after two doses one to two months apart); inactivated: 80 percent (declining to 55 percent after one year; no decrease in another study)

(Continues on the following page.)

Table 20.1 Continued

Category	Tuberculosis	Diphtheria	Tetanus	Pertussis	Poliomyelitis	Measles ^a	Rubella	Hib	Hepatitis B	Yellow fever	Meningococcal disease	Japanese encephalitis
Duration of immunity after primary series wanes with time	Unknown; some evidence that immunity wanes with time	Variable; probably around five years; longer in presence of natural boosting or booster doses	10 years or more	Unknown; wanes with time	Presumed lifelong for both OPV and IPV, but unknown	Lifelong in most; rare cases of waning immunity after one dose, not two	Lifelong in most; presumed rare cases of waning immunity after one dose, not two	Unknown, but lasts for at least three years beyond period of greatest exposure	More than 15 years; further follow-up is continuing	For at least 10 years and possibly for life	Unconjugated wanes rapidly for children under five, more than three to five years for older children; conjugated uncertain	Unknown, may be lifelong
Schedule	Given at or near birth in populations at high risk	Three-dose schedule recommended at 6, 10, and 14 weeks in developing countries for DTP vaccine; other schedules in common use; booster doses at 18 months and four to six years also suggested	Normally given as DTP vaccine to children; unimmunized pregnant women should be given two doses of tetanus toxoid or tetanus-reduced diphtheria toxoid, and a total of five doses is required to provide protection through all childbearing years	Usually given in childhood as combination vaccine (DTP)	OPV: four doses (birth, 6, 10, and 14 weeks) in polio-endemic countries; birth dose may be omitted elsewhere with fourth dose given later; supplemental doses (up to 10) given in national campaigns for eradication; IPV: three to four doses: 2, 4, 6 to 18 months, and four to six years	First dose at 9 or 12 to 15 months; a second opportunity to receive a dose of measles vaccine (either through routine [18 months or four to six years] or supplemental immunization activities) should be provided for all children	First dose at 12 to 15 months; when given, a second dose with measles vaccine	Three or four doses; usually given during the same visit as for DTP	Several schedules: at birth, 6, and 14 weeks; with first three doses of DTP; birth dose needed if mother is a carrier and recommended if perinatal transmission of hepatitis B is frequent; four doses total can be given although only three are required	One dose at 9 to 12 months with measles in countries where yellow fever poses a risk	Unconjugated: one dose at two years or older and killed: days 0, 7, and 30 followed by booster two years later and then every three years	Live: one year and two years; one dose at two years or older and killed: days 0, 7, and 30 followed by booster two years later and then every three years

Status as of the end of 2001	158 countries using BCG; 85 percent coverage	All countries; 78 percent coverage	Childhood: all countries; 78 percent coverage	All countries; 78 percent coverage	All countries; 79 percent routine, plus supplemental coverage	Routine first dose all countries, 77 percent coverage; second opportunity, 164 out of 192 countries	110 countries in 2003	89 countries; global coverage less than 18 percent	147 countries; global coverage 42 percent	29 of 43 countries at risk using vaccine; 30 percent coverage in target population	European countries, Canada (and United States in 2005)	Southeast Asia
Comments	Reasons for varying efficacy are multifactorial, including differences in vaccines	Recent trends to lower antibody levels in adults without booster doses because of waning immunity and less natural boosting	Five doses in adults provide protection for more than 20 years	Variability in whole cell vaccines; acellular vaccines used in some developed countries	Primary series gives incomplete protection in developing countries	Lower efficacy when maternal antibody present	Lower efficacy when maternal antibody present	None	Efficacy lower if injected into fat	None	None	None

Sources: WHO 2002, 2004.

DTP = diphtheria-tetanus-pertussis; IPV = inactivated polio vaccine; OPV = oral polio vaccine.

a. Measles vaccine is given as measles, measles-rubella, or measles-mumps-rubella vaccine. The latter two vaccines are routinely used in industrial countries and are increasingly being adopted in other countries. The World Health Organization recommends that the combination measles-rubella or measles-mumps-rubella vaccines be introduced only after careful evaluation of public health priorities within each country and following the establishment of an adequate program for measles control as demonstrated by high coverage rates as part of a well-functioning childhood immunization program.

b. Note that variations in case-fatality rates are related to access to care, type of care administered, setting, age at onset of disease, and other factors. The ranges presented in this table reflect both uncertainty as to actual case-fatality rates and the variability of populations.

c. As of 2003, an injected IPV is given alone or in combination with OPV in 31 countries. IPV is currently not recommended for routine use in developing countries because of its relatively high cost and uncertain efficacy when given at 6, 10, and 14 weeks. The usual recommended IPV schedule is 2, 4, and 6 to 18 months. Routine use of OPV is expected to cease following polio eradication. Stockpiles of monovalent OPV for each of the three virus types are under development to protect against vaccine-associated paralytic poliomyelitis and outbreaks of circulating vaccine-derived polioviruses.

in use in childhood immunization programs throughout the world.

Burden of Vaccine-Preventable Diseases

A number of vaccine-preventable diseases are not reportable events in many countries. The estimates of the burden of disease by the World Health Organization (WHO) are based on a combination of often incomplete vital registration data, mortality survey data, and mathematical models using numerous assumptions. Most models of vaccine-preventable diseases are derived from the susceptible fraction of the population (calculated from natural immunity from presumed historical infections in regions without previous vaccination and historical immunization coverage rates), infectivity rates of disease, sequelae of diseases, and estimates of local CFRs. The degree of accuracy of these models is only as good as the data supporting the assumptions. The disease burden is most appropriately represented by a range of values reflecting uncertainty. In this chapter, we estimate the burden of disease as the number of deaths and DALYs per World Bank region in 2001. The following description draws in part on discussion of methods for burden of disease calculations reflected in the Global Immunization and Vision Strategy of WHO and the United Nations Children's Fund (UNICEF) (Wolfson and Lydon 2005).

Diphtheria

Diphtheria is caused by a toxin-producing strain of the bacterium *Corynebacterium diphtheriae*, which is transmitted by means of respiratory droplets. The 2001 WHO estimates of diphtheria mortality are extrapolations from reported deaths in countries with full or partial vital registration systems.

Before the widespread use of immunization, more than 5 percent of people living in temperate climates suffered from clinical diphtheria at some point during their lifetimes (Griffith 1979). Rates exceeding 100 cases per 100,000 population were seen in Europe during World War II (Galazka, Robertson, and Oblapenko 1995). The CFRs from respiratory tract diphtheria have been 2 to 20 percent, with an average of 10 percent for patients receiving good medical care (Feigin, Stechenberg, and Hertel 2004). To estimate diphtheria deaths in the absence of vaccination and to project future deaths with and without vaccination, we assumed an average incidence rate of 15 per 100,000 and CFRs of 2.5 percent in developed countries, 5.0 percent in Europe and Central Asia, and 10.0 percent elsewhere (Birmingham and Stein 2003; Galazka and Robertson forthcoming).

Tetanus

Clostridium tetani is maintained in nature and is found in all countries. Spores remain viable for many years in soil and dust,

especially in areas contaminated by animal feces (Cherry and Harrison 2004). The organism is usually transmitted through burns, cuts, and other penetrating injuries. Neonatal tetanus is the most common presentation in developing countries. The portal of entry is usually the umbilical stump but has been associated with circumcision and other surgical procedures (Birmingham and others 2004; Stanfield and Galazka 1984). Children born to women who do not have protective levels of tetanus antibody are susceptible to neonatal tetanus.

The estimated burden of neonatal tetanus assumes that in areas with low rates of skilled delivery, all births not protected by the immunization of pregnant women are subject to a preimmunization era neonatal tetanus mortality rate expressed as deaths per 1,000 live births (Birmingham and others 2004; Griffiths and others 2004). In other areas, we assume that births not protected through immunization or skilled delivery are subject to an incidence and CFR equal to 25 percent of the preimmunization era neonatal tetanus mortality rate.¹

CFRs are directly associated with the quality of medical care available. With the availability of secondary and tertiary care, CFRs have declined to 25 percent or less (Cherry and Harrison 2004; Wassilak and others 2004). The CFRs used to derive cases from estimated deaths range from 40 percent in developed countries to 80 percent in the poorest developing countries. We estimate the tetanus burden other than for neonates by applying an estimated age distribution of total tetanus to the estimated neonatal tetanus deaths (Galazka and others forthcoming) and region-specific CFRs, which indicate a range of from 27 percent among children age one to four in developed countries to 65 percent among those age 80 or older in developing countries.

Pertussis

Bordetella pertussis is transmitted through respiratory excretions and occurs throughout the world. Most pertussis in developing countries occurs in school-age children. In developed countries, mild or asymptomatic infections in adults are believed to be common sources of transmission to very young infants (Edwards and Decker 2004). Clinical manifestations include an initial 7 to 10 days of rhinorrhea progressing to a cough that becomes paroxysmal or spasmodic, usually associated with profuse rhinorrhea (Cherry and Heininger 2004). Clinical pneumonia is seen in approximately 10 percent of infants.

Our estimates for the burden of pertussis followed the model described in Crowcroft and others (2003). We estimated that the proportion of susceptible children becoming infected in countries with vaccination coverage of less than 70 percent over the previous five years was 30 percent by age 1, 80 percent by age 5, and 100 percent by age 15. For countries with coverage of more than 70 percent in the past five years, we assumed

that 10 percent of susceptible children were infected by age 1, 60 percent by age 5, and 100 percent by age 15. A vaccine efficacy of 80 percent was assumed for preventing infection and 95 percent for preventing deaths. The CFR was 0.20 percent in infants, 0.04 percent in children age one to four, and 0 percent in those older than five in low-mortality countries; and 3.7 percent among infants, 1 percent among children age one to four, and 0 percent in those older than five in high-mortality countries.

Poliomyelitis

Before the availability of polio vaccines, as many as 90 percent of children in the developing world were infected with all three types of the polio virus in the first two or three years of life (Sutter and Kew 2004). In developed countries, transmission occurred primarily in school-age children and more than 90 percent of infections were asymptomatic; 4 to 8 percent of children had nonspecific febrile illness and less than 1 percent developed acute flaccid paralysis (Sutter and Kew 2004).

Children with residual paralysis require rehabilitation. Surgical intervention is necessary if contractures develop because of the lack of rehabilitative services following the acute illness. These children are at increased risk of premature death because of late onset postpolio muscle atrophy (postpolio syndrome), which occurs 20 to 40 or more years after acute illness.

Disease burden estimates are based on actual active surveillance. The estimated 1,000 deaths a year caused by polio reflect past infections and current deaths. Following Robertson (1993), we obtained the number of cases and deaths in the absence of immunization by applying an incidence rate of 1 per 1,000 population under age five and CFRs of from 2.5 percent in developed countries to 10.0 percent in Sub-Saharan Africa. To determine current cases, we applied an estimate of notification efficiency to reported cases.

Measles

Measles is an acute respiratory viral infection. Children born to immune mothers are protected against clinical measles from passively acquired maternal antibodies until they are five to nine months of age. More than 90 percent of infections are associated with clinical disease (Krugman 1963). Complications include pneumonia, diarrhea, encephalitis, and blindness, especially in children with vitamin A deficiency. In recent years, CFRs have been estimated at 3 percent in many developing countries, but historically they have been as high as 30 percent in some community-based studies (Aaby 1988; Aaby and Clements 1989; Moss, Clements, and Halsey 2003; Perry and Halsey 2004).

For a disease such as measles in which infection is almost universal in the absence of immunity, small changes in the CFR result in large changes in estimates of total mortality. Increased complication and mortality rates occur in children who are

younger than five, vitamin A deficient, or infected with HIV or who have acquired measles from a household contact (Perry and Halsey 2004). Declines in CFRs in the past two decades are associated with the tendency of the disease to infect older children, decreased crowding, and improved nutritional status in many developing countries (Perry and Halsey 2004). At the same time, recent studies indicate CFRs of 0.4 to 9.7 percent in Sub-Saharan African countries with low immunization coverage (Perry forthcoming).

Considerable controversy is associated with the number of deaths resulting from measles, because of difficulty in accurately specifying the cause of death in children afflicted with measles and in separating complications of measles from those of other conditions. In addition, CFRs, which have decreased rapidly in many countries, vary significantly. The natural history model used in this chapter is based on Stein and others (2003), modified to account for the effect of supplementary immunization activities.

We derived estimates of the burden of disease in countries with high-quality surveillance data and high sustained coverage of measles vaccine by adjusting the number of reported cases by a reporting efficiency factor ranging from 5 to 40 percent. In estimating the future burden of disease, the averted burden of disease, and the burden in countries without both adequate surveillance and sustained high coverage, we assumed that the average number of cases per year is equal to the number of children in the current birth cohort who are not protected by either routine or supplemental vaccination. WHO (2005a) estimates that in 2001, 611,000 deaths (approximately 5 percent of all childhood mortality) were attributable to measles.

An alternative proportional mortality approach, which is based on retrospective verbal autopsy studies in 18 countries to derive the proportional causes of child deaths in 42 high-mortality countries, also has appeared in the literature (Morris, Black, and Tomaskovic 2003). This model suggests that measles may have accounted for approximately 3 percent of all childhood deaths in 2000.

In countries with a high disease burden, the true number of measles deaths may be somewhere between the proportional mortality and natural history estimates. WHO (2005b) uses a hybrid method that estimates that measles was responsible for an average of 4 percent of mortality among children under five between 2000 and 2003, or approximately 400,000 deaths per year. If the actual number of deaths in 2001 was 400,000, then the cost per death averted will be lower than what has been estimated for this chapter, and the effect of increasing coverage will be overestimated because fewer deaths could be prevented.

Both of the approaches described have strengths and limitations. We adopt the natural history approach for this analysis because the chapter includes deaths at all ages and the model can adapt to recent changes in CFRs and coverage rates.

However, the natural history method is sensitive to the accuracy of parameter inputs such as CFRs and may underestimate the effect of herd immunity. Further modeling efforts would need to incorporate sensitivity testing around a range of parameter estimates.

In the absence of vaccination, the measles virus would infect almost 100 percent of the population, including most of the 688 million children under five in the developing world. Using the methods described here, approximately 125 million cases and 1.8 million to 2.0 million deaths per year would be expected in the absence of vaccination.

***Haemophilus influenzae* Type b (Hib)**

Hib is transmitted through the respiratory tract and causes meningitis, pneumonia, septic arthritis, skin infections, epiglottitis, osteomyelitis, and sepsis. Deaths caused by Hib occur primarily from meningitis and pneumonia. In developed countries, approximately half of diagnosed invasive infections are meningitis (Wenger and Ward 2004). In developing countries, a larger proportion of identified cases is meningitis resulting from underdiagnosis of other clinical syndromes (Martin and others 2004; Peltola 2000). Intervention studies have demonstrated significant reductions in pneumonia in vaccinated compared with unvaccinated children (Levine and others 1998; Mulholland and others 1997). Although infections occur throughout the world, the incidence of Hib disease may be lower in some Asian countries than in Africa and the Americas (Gessner and others 2005).

We derived estimates of Hib disease burden from incidence rates and CFRs for meningitis and pneumonia. We derived country-specific estimates of the incidence of Hib meningitis from the literature on incidence in the prevaccine era (Bennett and others 2002). For countries without meningitis incidence data, we used the average incidence in countries with similar epidemiological profiles. Regional averages ranged from 219 cases per 100,000 to 3 per 100,000 population in children under one, and 1 to 15 per 100,000 population in children age one to four. The CFR for meningitis is nearly 100 percent in the absence of intensive antibiotic therapy, but it can be reduced to 5 to 8 percent when appropriate therapy is available (Swartz 2004). We derived CFRs in a manner similar to that used for incidence rates and adjusted them on the basis of country-specific data on access to care. Regional means ranged from 3 to 32 percent.

Estimating the burden of Hib pneumonia is much more complex. A rapid assessment method assumes five pneumonia cases for every meningitis case (WHO 2001). An alternative approach assumes that Hib is responsible for a fixed proportion (about 20 percent) of acute lower respiratory infection deaths in the absence of immunization (Peltola 2000). We derived pneumonia CFRs from a literature review of lower respiratory infections in children (Bennett and others 2002), with

average CFRs ranging from 1 percent among infants in developed countries to 12 percent in Sub-Saharan Africa.

Hepatitis B

In many developed countries, most transmission of hepatitis B occurs during or after adolescence, coinciding with the onset of sexual activity and of drug abuse involving unsafe reuse of needles and syringes (McQuillan and others 1999). In many African countries, transmission occurs primarily in early childhood through mucosal contact with infectious body fluids and unsafe injection practices (Margolis, Alter, and Hadler 1997). Some Asian countries have a high rate of chronic carrier states, and the primary mode of transmission is mothers to infants (Beasley 1988; Mast and others 2004). The rate of symptomatic disease is only about 1 percent in infancy and 10 percent in early childhood, but it increases to 30 to 40 percent in adults. Serosurveys for carrier states of hepatitis B are available for almost all nations (WHO 1996).

Models of hepatitis B disease burden are based on estimated ratios between infected and carriage states at various ages or estimates of the percentage of carriers that progress to hepatoma, fulminant hepatitis, or cirrhosis at later stages of life (Miller and McCann 2000). The model we used for estimating hepatitis B mortality estimates the age- and sex-specific progression of hepatitis B surface antigen infection to disease incorporating competing mortality, particularly because individuals infected with HIV are more likely to perish from HIV before the full mortality impact from hepatitis B infection (Gay and others 2001; Griffiths, Hutton, and Pascoal 2005).

Whereas most vaccine-preventable diseases that result in death occur at an early age shortly after the age of vaccination, deaths from hepatitis B occur many years into the future. Countries that introduce hepatitis B vaccines today will not reap most of the benefits for many years. In the absence of vaccination, we estimated approximately 1.4 million future deaths attributable to hepatitis B for the 2001 birth cohort after accounting for competing mortality. Global vaccination of 35 percent would prevent more than 500,000 of those future deaths. Discounting the value of future hepatitis B deaths to their equivalent value in the present to make the burden of disease prevented equivalent to that of other vaccine-preventable diseases results in approximately 87,000 deaths averted.

Yellow Fever

Yellow fever virus is transmitted by mosquitoes, primarily *Aedes aegypti*, with a three- to six-day incubation period. Patients present with intense headache, fever, chills, and myalgia, among other symptoms. Although once much more widespread, yellow fever is now limited to West and Central Africa, the northern half of South America, and Panama. In approximately

15 to 20 percent of yellow fever patients, severe disease occurs, with liver and kidney failure and cardiovascular collapse. The CFR varies, with increased severity in older adults (Monath 2004). The average CFR in patients in Africa with jaundice is 20 percent (Monath and others 1980; Nasidi and others 1989).

On the basis of surveillance data adjusted for underreporting, WHO (1992) estimates the global burden of yellow fever at 200,000 cases and 30,000 deaths in 1990. Most cases and deaths occur in 33 African countries, where 1 in 80 cases is assumed to be reported. In South American countries, 1 in 10 cases is assumed to be reported. We use the implied incidence rate and a CFR of 15 percent to project future mortality. Between 1990 and 2001, some improvement in routine coverage of yellow fever vaccine occurred, but the overall burden of yellow fever is unlikely to have declined.

ESTIMATES OF THE CURRENT BURDEN OF VACCINE-PREVENTABLE DISEASES AND OF THE BURDEN AVERTED BY VACCINATION

Table 20.2 provides WHO estimates of deaths from selected vaccine-preventable diseases for 2001, taking immunization coverage rates into account. The greatest burden of disease is in Sub-Saharan Africa, which accounts for 58 percent of pertussis deaths, 41 percent of tetanus deaths, 59 percent of measles deaths, and 80 percent of yellow fever deaths. East Asia and the Pacific has the greatest burden from hepatitis B, with 62 percent of deaths worldwide. South Asia also experienced a high disease burden, particularly for tetanus and measles.

Table 20.2 also shows the extent of mortality in the absence of immunization and the estimated number of deaths averted by vaccination. In 2001, vaccination averted up to 52 percent of yellow fever deaths, 61 percent of measles deaths, 69 percent of tetanus deaths, 78 percent of pertussis deaths, 94 percent of diphtheria deaths, and 98 percent of polio deaths that would have occurred in the absence of vaccination. These results demonstrate the significant effect that vaccination programs have had on worldwide disease burden. The figures also show that vaccination programs have been less successful in reducing the disease burden in Sub-Saharan Africa, where coverage rates are lower.

Table 20.3 reports WHO estimates of disability-adjusted life years (DALYs) lost from vaccine-preventable diseases by region for 2001, demonstrating the high burden of disease worldwide from disability associated with sequelae of hepatitis B (liver cancer and cirrhosis), pertussis, and tetanus.²

EXPANDED PROGRAM ON IMMUNIZATION

WHO initiated the EPI in 1974 to provide countries with guidance and support to improve vaccine delivery and to help make vaccines available for all children (Hadler and others 2004;

Turk 1982; WHO 1974). A standard immunization schedule was established in 1984 on the basis of a review of immunological data for the original EPI vaccines: BCG, diphtheria-tetanus-pertussis (DTP), oral polio, and measles vaccines (Halsey and Galazka 1985).

Today, national immunization programs in developing countries are responsible for improving access to the traditional EPI antigens and introducing new vaccines. In 2002, the EPI introduced the Reaching Every District strategy, which focused on achieving an 80 percent coverage rate of DTP3 in 80 percent of districts and using immunization contacts to deliver other high-priority child health interventions. In addition to delivering vaccinations, national immunization programs are concerned with the quality and safety of immunization through the adoption of safe injection technologies (autodisabled syringes, storage boxes, and incinerators) and proper cold chain and vaccine stock maintenance.

In most developing countries, immunizations are provided through a system of fixed facilities at different levels of the health system. Immunization campaigns are discrete, time-limited efforts at national or subnational levels that usually focus on specific antigens (for example, polio). Mobile strategies rely on the use of specialized vehicles to transport health professionals and vaccines to deliver services to remote or migrating populations. Outreach is a strategy by which staff members from a health facility travel to villages and surrounding areas to administer vaccines. Extended outreach refers to more targeted and intensive efforts.

In 1999, the major international development partners involved in immunization (for example, WHO, UNICEF, the World Bank, and bilateral donors) joined the Bill & Melinda Gates and Rockefeller Foundations, the vaccine industry, and nongovernmental organizations to create GAVI (<http://www.vaccinealliance.org>) to increase access to new and underused vaccines in the world's poorest countries, improve access to basic immunization services, and accelerate research and development pertaining to new vaccines and delivery technology. Through the Vaccine Fund, GAVI raised more than US\$1.3 billion to strengthen immunization systems, introduce new vaccines, and support safe injection practices. More than US\$3 billion has been pledged for the next 10 years. Between 2000 and 2003, an additional 4 million children were vaccinated with DTP3, 42 million with hepatitis B, nearly 5 million with Hib, and more than 3 million with yellow fever vaccine.

COSTS AND COST-EFFECTIVENESS OF EXISTING VACCINATION PROGRAMS

Brenzel and Claquin (1994) and GAVI (2004) estimate the cost per fully immunized child (FIC) for the traditional six EPI antigens as approximately US\$20.³ We evaluated the cost per

n.a. = not available.

Note: Totals may not add due to rounding.

a. Primarily deaths at older ages caused by delayed effect of poliomyelitis in childhood.

b. See text for discussion of uncertainty regarding measles estimates. The values shown here are an updated version of the 2001 estimates.

c. Deaths averted to date from the use of the hepatitis B vaccine in infant immunization programs are minimal, largely because of the long time period (20 to 40 years) to see mortality effects.

Note: Totals may not add due to rounding.

a. Includes all DALYs attributable to the three conditions. Hepatitis B is the underlying cause of only a portion of the liver cancer and cirrhosis of the liver DALYs.

b. Includes all DALYs attributable to meningitis, including Hib, *S. pneumococcus*, and *N. meningitides*.

c. Includes all DALYs attributable to lower respiratory infections, including Hib and *S. pneumococcus*.

FIC for the childhood EPI cluster antigens by World Bank region on the basis of published and unpublished data. These studies used a standard costing approach that estimated the costs of labor, vaccines, supplies, transportation, communication, training, maintenance, and overhead and included the annualized value of equipment, vehicles, and building space (Khaleghian 2001; USAID, Asia–Near East Region 1988; WHO 1988). The number of FICs in these studies was measured using community-based sample surveys (Henderson and Sundaresen 1982).

Our literature review found 102 estimates of total and unit immunization program costs from 27 countries between 1979 and 2003 for different immunization delivery strategies (Berman and others 1991; Beutels 1998, 2001; Brenzel 2005; Brenzel and Claquin 1994; Brinsmead, Hill, and Walker 2004; Creese 1986; Creese and Domínguez-Ugá 1987; Domínguez-Ugá 1988; Edmunds and others 2000; Griffiths and others 2004; Levin and others 2001; Pegurri, Fox-Rushby, and Walker 2005; Robertson and others 1992; Soucat and others 1997; Steinglass, Brenzel, and Percy 1993). All costs were converted to 2001 U.S. dollar equivalents. Because total and unit costs are related to population size, table 20.4 reports population-weighted results only. National immunization program refers to total national costs for all strategies.

The population-weighted mean cost per FIC for all regions and all strategies is approximately US\$17, with a range of US\$3 to US\$31. The lowest mean population-weighted cost per FIC

was for extended outreach services (US\$5.81), perhaps because the strategy is a more targeted approach. Routine facility-based strategies had lower average costs (US\$13.65 per FIC) than campaigns (US\$26.82 per FIC) or mobile strategies (US\$25.84 per FIC). Higher unit costs associated with these strategies are possibly attributable to a different mix of inputs as well as greater expenses for per diems, fuel, and social mobilization. The results also vary by World Bank region, with East Asia and the Pacific (US\$13.25) and Sub-Saharan Africa (US\$14.21) having lower estimates of cost per FIC than Europe and Central Asia (US\$24.12) and the Middle East and North Africa (US\$22.15).

The findings of our analysis are generally supported by the literature (Creese 1986; Brenzel and Claquin 1994; Khaleghian 2001), which has shown that variation in the cost per FIC is related to the mix of delivery strategies, the prices of key inputs such as vaccines, and the overall scale of programs. In addition, an analysis of 13 national financial sustainability plans for immunization reveals a wide range in the cost per FIC by region and strategy.⁴

Recurrent costs are the lion's share of total immunization costs (80 percent for fixed facility strategy and 92 percent for campaigns), which has implications for the need for continuous and predictable program financing. Labor costs account for the largest share (roughly 30 to 46 percent of total cost) for all strategies except extended outreach. Vaccine costs range from 8 percent for mobile strategies to 29 percent for extended

Table 20.4 Estimates of the Population-Weighted Annual Cost for the Traditional Vaccines per FIC, by Immunization Strategy and Region, 2001 (2001 US\$)

Strategy	East Asia and the Pacific (n = 4)	Europe and Central Asia (n = 1)	Latin America and the Caribbean (n = 1)	Middle East and North Africa (n = 1)	South Asia (n = 10)	Sub-Saharan Africa (n = 15)	All regions (n = 32)

— = not available.

Note: Mean values are used in the analysis. Ranges for estimates are reported in parentheses. Europe and Central Asia, Latin America and the Caribbean, and the Middle East and North Africa are limited to one observation for each region, which may not be indicative of the cost per FIC in each region. However, in lieu of using region-specific estimates, the overall average (US\$13.65) would be applied, which may underestimate the cost per FIC in these more developed regions, where higher unit costs for delivery of health services would be expected.

outreach strategies. Transportation costs account for the second-largest share of EPI costs for mobile strategies, while building costs account for a greater share of fixed facility strategies.

Using data from table 20.4 on costs per FIC and multiplying by the size of the population covered, we estimate US\$1.17 billion for the total cost of immunization programs in developing countries in 2001, with a range of US\$717 million to US\$1.48 billion. At US\$20 per FIC, the cost of the six traditional vaccines in developing countries would have amounted to US\$1.57 billion in 2001. Table 20.5 shows that the estimated cost per death averted ranges from US\$205 in South Asia and Sub-Saharan Africa to US\$3,540 in Europe and Central Asia. These results suggest that the cost per death averted rises with coverage rates. Europe and Central Asia, Latin America and the Caribbean, and the Middle East and North Africa had higher coverage rates in 2001, resulting in fewer deaths that could be averted. The table also shows that the cost per DALY from the traditional EPI vaccines ranges from US\$7 to US\$438, depending on region, mix of strategy, and levels of scale.

Our analysis highlights the variation in cost per FIC by region and strategy and demonstrates the value of more disaggregated results for making policy decisions. However, given the limited sample of estimates available for the regions and strategies, the results should be used as an indicative guide for policy making and not as a substitute for country-specific cost-effectiveness evaluations of strategies. In addition, our estimates do not take into account household costs, such as time spent seeking services, and other social costs. Our estimates also do not consider the direct and indirect costs of acute illnesses prevented by vaccination or the costs of long-term complications from disease and of adverse events associated with vaccination (though the latter are unlikely to have a significant impact on costs because rates of serious complications are extremely low). Furthermore, the analysis focuses on FICs and underemphasizes the benefits of partial immunization. Future economic evaluations of immunization program alternatives could consider these factors as a critical step in determining the allocation of scarce resources among high-priority health interventions.

Table 20.5 Average Cost per FIC, Total Immunization Cost, Cost per Death Averted and Cost per DALY for the Traditional Immunization Program by Region

Strategy	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa
Cost/FIC (2001 US\$) (from table 20.4)	13.25	24.12	18.10	22.15	17.11	14.21

COST-EFFECTIVENESS OF INCREASING IMMUNIZATION COVERAGE FOR THE TRADITIONAL EPI

WHO (2004) estimates that in 2001, 30 million children were inadequately immunized with DTP. Achieving higher coverage rates by improving access for remote populations, accelerating immunization delivery strategies, and introducing new vaccines will mean increasing the level of investment (Batt, Fox-Rushby, and Castillo-Riquelme 2004).

We estimated the costs of scaling up EPI coverage for a hypothetical population of 1 million in each region between 2002 and 2011. Costs were reported in 2001 dollars, and a 3 percent discount rate was applied. Brenzel (2005) provides details on the methods. The costs of scaling up coverage are based on vaccine and delivery costs per dose. We derived vaccine costs from the unit price of each vaccine (provided by WHO, UNICEF, and the Vaccine Fund); wastage rates for vaccines and injection supplies by strategy; the required injection supplies; and the number of doses per FIC. A 2 percent adjustment was made for inflation. We used data on the cost per FIC generated earlier to derive delivery costs per dose by strategy and region by subtracting the costs of vaccines, injection supplies, and fixed costs.

Fixed costs were excluded from the scaling-up exercise because they were assumed to remain constant during the projection period.

- First, the largest projected coverage increase of 9 percentage points (figure 20.1) may not require additional infrastructure investments.
- Second, how and to what extent fixed costs would change by region is uncertain, and a conservative approach would be to exclude them.
- Third, because most immunization costs are recurrent costs, the analysis focuses on these.

Source: Authors' estimation.

Figure 20.1 Coverage of FICs Projected to 2011

- Finally, because the scale factor is derived from the unit costs of a health center visit, the assumption of constant fixed costs in the short run appears reasonable.

Previous studies have found that the main cost drivers of immunization costs are the mix of strategies and the scale of immunization programs (Brenzel and Claquin 1994; Domínguez-Ugá 1988; Robertson and others 1992; Soucat and others 1997). Countries are unlikely to achieve 90 percent or more coverage relying on fixed facilities alone because of limited population access. We estimate the proportion of FICs obtained for each strategy by region.⁵ The best mix of strategies for increasing coverage will vary by country depending on the

dispersion of the population, the access to health facilities, the vaccines being delivered, and the effectiveness of various strategies in reaching target populations. Estimates are also adjusted for the level of scale by a factor derived from the unit cost per health center contact by coverage level (Mulligan and others 2003), and details are provided in Brenzel (2005).

The total additional cost of reaching higher coverage levels was divided by the number of deaths averted. Coverage projections for 2002–11 were based on statistical modeling of official WHO and UNICEF estimates for the period between 1995 and 2002 for all developing countries. The model relates coverage in future years to that in the previous year, with the relationship between past and future coverage differing for each region and economic status combination.

Figure 20.1 shows historical and projected coverage rates by region. The figure shows that coverage increased in all the regions during the late 1980s under universal childhood immunization. After 1990, when funding for universal childhood immunization waned, the figure indicates the subsequent stagnation and, in some cases, the declines in coverage rates. For the scaling-up period, we project that the coverage of FICs will increase from 78 to 79 percent in East Asia and the Pacific, from 92 to 95 percent in Europe and Central Asia, from 88 to 90 percent in Latin America and the Caribbean, from 91 to 95 percent in the Middle East and North Africa, from 70 to 79 percent in South Asia, and from 52 to 61 percent in Sub-Saharan Africa. The projections show that three of the six regions are expected to achieve 90 percent FIC by 2011. East Asia and the Pacific, South Asia, and Sub-Saharan Africa will require additional intensive efforts to achieve higher coverage rates.

Table 20.6 reports the results of the scaling-up analysis for the traditional EPI vaccines, for tetanus toxoid vaccination for women of reproductive age, and for selected new vaccines. The discounted incremental cost per child vaccinated with the traditional EPI vaccines ranges from US\$10.89 in Latin America and the Caribbean to US\$12.84 in the Middle East and North Africa. The number of discounted deaths averted because of full immunization depends on incremental coverage rates and varies from 747 in Europe and Central Asia to 14,584 in Sub-Saharan Africa, resulting in regional variations in the discounted incremental cost per death averted from US\$169 in Sub-Saharan Africa to US\$1,754 in Europe and Central Asia.⁶

DALYs were estimated indirectly based on the ratio of deaths to DALYs for each disease in 2001. This ratio is applied to the hypothetical population in each World Bank region over the projection period. Calculated this way, the number of DALYs averted will not account for changes in the average age of infection that ordinarily results from expanding immunization coverage. This method over-estimates the number of DALYs and thus under-estimates the cost/DALY. Cost-effectiveness ratios should be treated as indicative only. The cost/DALY ranges from \$2 to \$20 for scaling up traditional immunizations.

For tetanus toxoid immunization, the additional discounted cost per person vaccinated ranges from US\$3.28 to US\$4.06. The cost per death averted varies from US\$271 to more than US\$190,000. The results of this analysis fall within the range of estimates reported in the literature (Berman and others 1991; Steinglass, Brenzel, and Percy 1993). Differences in coverage levels and in protection against neonatal tetanus through skilled delivery contribute to the variation in results across regions.

The analysis shows both an increase in costs and potential benefits from scaling up immunization programs. In practice, the costs and benefits related to scaling up in any one region will be highly dependent on a few countries or subnational areas within countries. Aggregate country- or region-level data do not reveal the efficiency that could best be obtained by targeting immunization efforts on specific countries or geographic areas rather than making diffuse investments across regions. For instance, Miller and others (1998) show that India and Nigeria contribute the most to estimates of global measles deaths; therefore, reducing transmission in those countries would contribute the most to reducing the global disease burden caused by measles.

Despite its importance for policy, empirical and country-specific evidence on how immunization program costs change as coverage increases is lacking. Because scaling up immunization coverage will require more intensive efforts to find unvaccinated children, an extra cost for vaccinating each additional child is generally expected. Nevertheless, most cost-effectiveness studies assume constant returns to scale (Elbasha and Messonnier 2004; Karlsson and Johannesson 1998) even when emerging evidence suggests that the cost of vaccinating each additional child may rise with the size of delivery unit (Valdmanis, Walker, and Fox-Rushby 2003). Box 20.1, which focuses on scaling up traditional immunization coverage, and box 20.2, which focuses on new antigens, summarize the results of two studies that shed more light on this subject.

COSTS AND COST-EFFECTIVENESS OF ADDING NEW ANTIGENS TO THE CURRENT IMMUNIZATION SCHEDULE

We also estimated the additional costs per person vaccinated and cost per death averted of introducing new and underused vaccines into the traditional EPI in a hypothetical population of 1 million in each region between 2002 and 2011. The new vaccines considered protect against hepatitis B, yellow fever, Hib, measles, rubella, Japanese encephalitis, and meningococcal A, as well as inactivated polio vaccine (IPV). For comparison purposes, we assumed that new vaccines were introduced in 2002.

The additional cost of combination vaccines is net of the original cost of DTP vaccination to avoid duplication. The

Note: n.a. refers to not applicable when a specific disease is not prevalent in a specific region.

delivery cost per FIC was apportioned to individual antigens on the basis of the share of number of doses per FIC for that antigen (Brenzel 2005). Cost estimates are based on the number of doses required for full immunity (that is, hepatitis B, Hib, and IPV vaccines require three doses for full immunity, and meningococcal A requires two doses for full immunity). Results are reported in table 20.6.

The analysis also assumes that an additional visit to a health facility is required for new doses (depending on timing in the

EPI schedule). Combination vaccines may be more cost-efficient because of potential savings in supplies, syringes, and health workers' time, in addition to the overall health benefits of reducing the number of required injections. However, if the combination vaccine does not reduce the number of visits a child would ordinarily need to make to a health facility, any cost savings may be subsumed by the higher costs of increasing coverage.

The discounted incremental cost per person ranges from less than US\$1 to US\$16.23, depending on the unit price of

Box 20.1

Marginal Costs of Immunization Services in India

A study in Tamil Nadu evaluated immunization costs and coverage using a longitudinal panel dataset of immunization program costs (Brenzel 1995). Data were collected from a stratified, random sample of facilities between 1989 and 1991 for the North Arcot District Polio Control Program.^a The sample included 120 observations of 59 different health centers: 17 followed for three years (29 percent), 27 followed for two years (46 percent), and 15 with a single observation (25 percent). Total immunization costs included the cost of labor, vaccines, injection supplies, transportation, and overhead and the value of equipment, vehicles, and buildings.

During this period, coverage rates for FICs increased from 5 to 77 percent. The table shows that the cost per dose and the cost per FIC increased during this period.^b Changes in the cost per dose were highly statistically significant, whereas no statistical differences were apparent in the cost per FIC during the study period.

Comparison of Total Facility Immunization Costs, Immunization Activity, and Unit Costs by Year, North Arcot District Polio Control Program, 1989–91 (2001 US\$)

Indicator	Year 1	Year 2	Year 3	Overall
Total costs	996	1,337	980	1,104
Variable costs	697	1,260	917	958
Cost/dose	1.09	1.98	1.33	1.47
Cost/FIC	13.11	27.92	17.07	19.37

a. The program was a joint effort by the Indian Council for Medical Research, the Centre for Advanced Research in Virology at the Christian Medical Centre and Hospital in Vellore, and the governments of Tamil Nadu and India.

b. Higher costs in the second year reflect a change in the organization of the primary health care system in 1990 to improve access to basic services.

The study used data from the health facility sample to explain the determinants of immunization costs, which were modeled as a function of outputs, input prices, and other production-related variables that influence the cost function with respect to outputs. A random effects estimation was performed on the analysis sample relating the natural logarithm of health facility costs to the type of polio vaccine in use, estimated target population, and size of geographical area serviced by the health facility and natural logarithms of the number of FICs per facility, the number of hours spent by a village health nurse on immunization services per facility, and the number of small pieces of equipment used for immunization service delivery.

The analysis revealed a significant association between facility cost and the number of FICs, the hours worked by village health nurses, the area served, and the type of polio vaccine. When calculated using mean values, the marginal cost per FIC was Rs 24.43 (US\$1.30) lower than the associated average cost per FIC of Rs 183 (US\$9.80), implying that the average cost curve lies above the marginal cost curve for the sample of health facilities in India. A declining relationship is apparent between costs and coverage for this sample of facilities, calling into question assumptions of constant returns to scale. The results suggest that, in India, average cost-effectiveness ratios would overestimate total resource needs. Using a single-point estimate of average unit costs to determine the use of scarce public health resources will result in suboptimal resource allocations.

vaccine, the type of vaccine, the delivery strategy, and the coverage levels. The results lead to several conclusions:

- First, the additional incremental cost per person vaccinated is relatively small for some new vaccines.
- Second, because fixed costs are excluded, the results represent conservative estimates of additional costs.
- Third, because of price uncertainty, cost variations are greatest for newer vaccines, such as the DTP-IPV combination.

The second opportunity for measles has the lowest cost per death averted, ranging from US\$23 to US\$1,906 for fixed

facility strategies, and from US\$65 to US\$1,363 for campaigns. These results are consistent with the literature. Foster, McFarland, and John (1993) find an incremental cost per death averted ranging from US\$335 to US\$552 in urban areas and from US\$327 to US\$706 in rural areas. The Africa Measles Partnership (2004) estimates a cost per death averted of US\$131 to US\$393 in the African context, but these figures include the costs of infrastructure.

In the hypothetical populations, the incremental cost per death averted for the pentavalent vaccine ranged from US\$1,433 to more than US\$85,000, depending mostly on the number of potential deaths that could be averted. Although a

Box 20.2

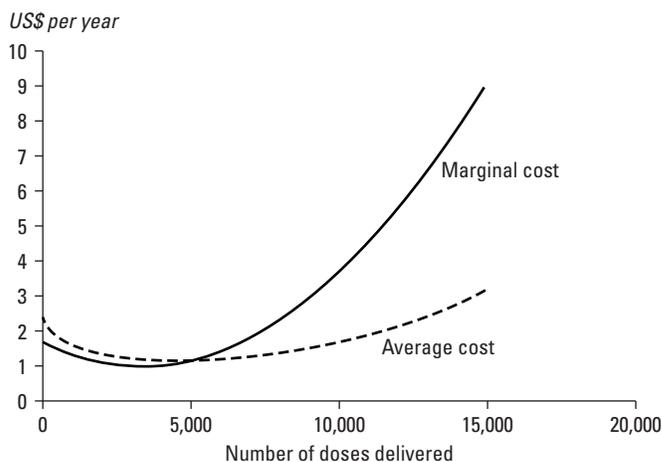

An Immunization Costing Study of Adding New Vaccines to the EPI in Peru

Data were collected from 19 government health facilities in three districts in Peru, including five hospitals and 14 health centers (Walker and others 2004). Total annual costs per center included vaccines, supplies, personnel, cold chain, overhead, and shared inputs. The average cost per dose for traditional EPI antigens plus yellow fever varied from US\$1.50 to US\$3.20 per dose as shown in the table, with vaccines and personnel accounting for the bulk of costs.

At 2,000 doses, the marginal cost of delivering one more dose is US\$1.08, increasing to US\$5.33 for 12,000 doses. Average and marginal costs are equal (US\$1.18) when 5,000 doses are provided per site. When an outlier delivering many vaccines at a high cost was removed, cost-minimizing output rose to 6,000 doses at US\$1.11.

Although each vaccination facility is likely to be associated with different average and marginal costs, considering vaccine provision across a range of providers is relevant, because targets for vaccination can be set by site. Information about marginal costs can help determine what the most efficient size for vaccination facilities is in the long run and how to minimize costs across different size units in the short run, given targets (see figure).

When hepatitis B, Hib, and the pentavalent vaccine (DTP-hepatitis B-Hib) are added to the delivery schedule, the total annual additional cost increases to US\$4,121, US\$11,886, and US\$25,261, respectively, with an average

Source: Authors' calculations.

Marginal and Average Vaccination in Sample Facilities in Peru (2001 US\$)

incremental cost per dose of vaccine of US\$0.20, US\$4.14, and US\$4.24, respectively. Adding these new vaccines increased the total cost of providing 5,100 doses from US\$5,840 to US\$9,415 and changed the minimum average cost from US\$1.18 per dose to US\$1.68. Therefore, the addition of new vaccines shifts both average and marginal costs upward.

Mean Cost per Dose by Type of Facility, Selected Districts in Peru (2001 US\$)

Cost items	Health post	Health center	Rural hospital	Provincial hospital	Department hospital (Ayacucho)	National hospital
<i>Recurrent items</i>						
Vaccines	0.59	0.87	1.39	1.03	0.60	0.31
Syringes	0.04	0.05	0.07	0.04	0.05	0.03

wide range of results was found, these estimates are supported by the literature. Miller (1998) estimated between US\$3,127 and US\$3.2 million per life saved for Hib vaccine. Brinsmead, Hill, and Walker's (2004) systematic review of the literature on the cost-effectiveness of Hib vaccine finds wide variations in results because of methodological differences and epidemiological and health system characteristics. The discounted incremental cost of introducing the pentavalent (DTP–hepatitis B–Hib) vaccine is roughly equal to the total mean cost of the traditional vaccine package estimated earlier. This finding implies that introducing this combination vaccine may double the financial requirements, an implication that is supported by data from national financial sustainability plans for immunization (Lydon 2004).

The incremental discounted cost per person vaccinated with a birth dose of hepatitis B is approximately US\$2, and that for the tetravalent vaccine was between US\$7 and US\$8. The 10-year time period for our analysis is too short to accumulate deaths averted resulting from hepatitis B vaccination because deaths from liver cancer occur at older ages. Beutels's (1998, 2001) reviews of studies of the cost-effectiveness of introducing hepatitis B vaccine indicate that results vary depending on assumptions of endemicity and the methodology used, with a cost per death averted ranging from US\$3,500 to US\$271,800.

Rubella vaccination had a low additional cost per person vaccinated, at slightly more than US\$1. Golden and Shapiro (1984) found that vaccinating all prepubertal children with rubella vaccine had the highest benefit-cost ratio (ranging from US\$1.70 to US\$1.96). Most benefits were future cost savings from long-term institutional care. When rubella was delivered in combination with measles and mumps, the benefit-cost ratios varied from US\$4.70 to US\$38.80 (Hinman and others 2002).

The additional cost per person vaccinated with one dose of Japanese encephalitis vaccine was between US\$4.37 and US\$4.56. A study in Thailand using two doses showed a cost per child ranging from US\$2.31 to US\$4.20, depending on the mode of delivery (Siraprasiri, Sawaddiwudhipong, and Rojanasuphot 1997). Ding and others (2003) estimate a cost per case averted of US\$258 and a cost per DALY averted of US\$16.80 for a five-dose inactivated Japanese encephalitis vaccine.

Our analysis suggests an additional discounted cost per person vaccinated for injectable polio vaccine of between US\$6.60 and US\$7.32, depending on coverage levels and mix of delivery strategy. The additional discounted unit cost of the combination DTP-IPV vaccine was higher, ranging from US\$13.88 to US\$15.28. These results are also sensitive to the current prices of the vaccine, which will probably decline in coming years. Brenzel (1995) finds that in India the cost per case prevented for the combination DTP-polio vaccine was much lower than for oral polio vaccine (OPV), primarily because the combination vaccine was associated with a greater reduction in the number of polio cases. Miller and others (1996) suggest that

introducing IPV into routine vaccination in the United States would cost an additional US\$15 million to US\$28 million depending on the type of schedule adopted, resulting in a cost per vaccine-associated paralytic poliomyelitis case prevented of approximately US\$3 million. Sangruee, Caceres, and Cochi (2004) found that the least costly option would be for programs to stop providing OPV after postpolio eradication and certification and that optionally introducing IPV with universal IPV had the highest costs and the lowest expected number of vaccine-associated paralytic poliomyelitis cases. If the unit price of IPV fell to US\$0.47, switching to IPV from OPV would be economically worthwhile.

FINANCIAL SUSTAINABILITY OF IMMUNIZATION PROGRAMS

Even though research has demonstrated that vaccination against childhood diseases is one of the most cost-effective health interventions, governments in many developing countries are considering how to meet the financing requirements of immunization programs, particularly as new vaccines are introduced and programs are scaled up. GAVI is working with countries to prepare for the transition from grant funding and to secure the overall financial sustainability of national programs. Approximately 55 countries have prepared national financial sustainability plans for immunization. These plans help countries evaluate the current and future costs and financing of national immunization programs and identify strategies to address future funding gaps (GAVI 2004; http://www.who.int/immunization_financing/en).

According to a recent analysis of financial sustainability plans, specific costs for immunization programs represent an average of 2 percent of total health spending and 6 percent of government health spending and are equivalent to less than 0.2 percent of gross domestic product on average. However, this profile changes after new and more expensive vaccines are introduced. In some countries, program-specific costs for immunization can reach as high as 20 percent of government health spending with introduction of combination vaccines (Lydon 2004). This share is related to the current unit price of the vaccine, which is expected to decline.

Governments and their development partners are challenged to find ways to finance and sustain immunization programs. In countries that are implementing reforms to achieve greater transparency and fiscal discipline through sectorwide approaches and medium-term expenditure frameworks, the additional financing requirements are compounded by the need to operate within a fixed budget for the health sector, so that increased funding needs for one program may necessitate budget cuts for others. This example illustrates the potential tradeoffs that exist at the country level, which create both opportunities for more open policy dialogue in relation to

priority setting for the use of scarce public funds and risks that the cost of new vaccines may not be readily integrated into national plans and budgets. Because of the financial implications of reaching higher coverage levels and simultaneously introducing new vaccines, policy makers will not only have to weigh the cost-worthiness of alternative investments but also have to understand their long-term budgetary implications.

IMPROVING THE COSTS AND COST-EFFECTIVENESS OF IMMUNIZATION PROGRAMS
