The cost-effectiveness of immunization programs could be improved by either reducing costs or improving programs' health benefits. Programs could reduce costs by using a more efficient mix of delivery strategies, reducing vaccine wastage, and using lower-cost inputs while maintaining the same quality of service. Reductions in the price of vaccines in the near future will also reduce costs. Innovations in vaccine technology may result in more widespread use of vaccine vial monitors, and increased use of heat-stable vaccines could potentially reduce the cost of the cold chain, although these innovations may themselves add to costs. The number of children and adults immunized can be increased by creating additional demand for vaccination; reducing missed opportunities; and reducing the dropout rate between the first and third doses of DTP, hepatitis B, and other vaccines. Finally, changes in the EPI schedule could affect total costs by reducing the number of doses required to achieve immunity and thereby reducing the number of visits, resulting in savings in the costs of labor, supplies, transport, and perhaps overhead.

The EPI schedule was established in 1984 based on a review of immune responses to diphtheria, tetanus, pertussis, polio, and measles vaccines starting at different ages and with varying intervals between doses (Halsey and Galazka 1985). The EPI schedule administers three doses of DTP at the shortest possible intervals to complete the immunization series as early in life as possible. However, if the primary series could be reduced to two doses with a booster dose at 12 to 15 months of age, the cost savings from reduced visits and one fewer dose of DTP in countries that administer a fourth dose of DTP would be considerable. Additional serological studies would be needed to compare the existing EPI schedule with the theoretical schedule before a new schedule could be adopted. Also, other vaccines to be introduced into immunization programs would need to be reevaluated in this schedule. Two doses of IPV administered beginning at two months of age induce protective levels of antibodies between 95 and 100 percent for each of the three polio types (Halsey and others 1997; Plotkin and Vidor 2004).

Some countries with a low incidence of tuberculosis (such as those of Eastern Europe) are considering the discontinua-

tion of routine BCG vaccination, given the low risk of acquiring tuberculosis in early childhood. If the BCG were not administered during the first month of life, program costs would be reduced by the value of one visit and by the costs associated with vaccine purchase, shipping, storage, and administration.

RESEARCH AGENDA

Private and public sector investment in research and development pertaining to new vaccines and improved use of existing vaccines is considerable. Most research and development is focusing on vaccines likely to have the greatest effect in the developed world and the best financial return; however, by means of public-private partnerships for product development, foundations have stepped in to support vaccine research and development for diseases for which the greatest burden occurs in developing countries.

New vaccines are being developed that could be incorporated into EPI schedules, including vaccines that protect against rotavirus, *S. pneumoniae*, malaria, cervical cancer associated with human papilloma virus, HIV/AIDS, and dengue. New and improved vaccines are also being developed to protect against meningococcal infections in infancy and Japanese encephalitis (NIH 2000). WHO recently created the Initiative for Vaccine Research Department to facilitate global coordination of research and development efforts for these and other vaccines.

In compiling data for this chapter, we noted a number of key gaps in knowledge that could usefully drive a research agenda and contribute to more evidence-based policy making in the future (Fox-Rushby and others 2004). First, little is currently known about how and why delivery costs change with increasing numbers of vaccinations and at higher coverage rates and whether economies of scale can be achieved. Little is known about the relative cost-effectiveness of different strategies to increase coverage given different baseline coverage rates. This issue relates to other questions of the optimal timing for introducing new vaccines and of how decisions should vary given different epidemiological and economic settings. Future research should therefore consider the extent to which cost-effectiveness analyses need to be repeated for every country or context or whether (and how) estimating and validating relationships across countries and accounting for uncertainty in estimates of costs and effects are possible.

Second, more attention needs to be given to measuring effect. For example, even though the coverage of single antigens required to reach particular levels of FICs should be accounted for, economic evaluations need to move beyond such indicators of output to measuring effect on the quantity and quality of life. In evaluating different schedules, methodological research needs to focus on how to incorporate the combined

effects of multiple vaccinations in this respect. Remarkably few studies have considered the effect on nonhealth benefits, such as economic growth and welfare. The larger the package of vaccinations considered, the more important this question becomes.

CONCLUSIONS

This chapter confirms that vaccination of children and women with the traditional EPI vaccines is a highly cost-effective public health intervention, although cost-effectiveness ratios vary by region, delivery strategy, and level of scale. Overall, vaccination has had a significant effect on reducing mortality and morbidity from childhood diseases and will be a priority intervention for achieving the child health Millennium Development Goals. Improving and sustaining measles control are among the most cost-effective interventions in high-mortality regions.

Establishing and maintaining high immunization coverage rates in many of the poorest developing countries have proven challenging for those with high population growth rates, limited infrastructure and resources, and fluctuating demand for services. According to historical coverage rate trends, Europe and Central Asia, Latin America and the Caribbean, and the Middle East and North Africa are expected to achieve 90 percent coverage of FIC by 2011, with East Asia and the Pacific, South Asia, and Sub-Saharan Africa lagging behind.

Increasing and sustaining higher immunization coverage rates will require further efforts so that disease control can be maintained, particularly when a perception exists at the community level that vaccine-preventable diseases are no longer a major public health issue. At higher coverage rates, further disease burden reductions will be smaller, which will affect relative cost-effectiveness. Targeted approaches in countries or at subnational levels could potentially yield high returns, especially in those areas with poor control of vaccine-preventable diseases.

Our analysis shows that the cost per FIC will increase as countries scale up immunization coverage and introduce new vaccines. Adding more antigens to traditional EPIs has been successfully accomplished in many countries, especially for Hib and hepatitis B vaccines. Although many of the new vaccines under consideration are more expensive than those for the original six targeted EPI diseases, they may still be relatively cost-effective compared with other interventions and with treatment costs. Our analysis shows a wide range of cost-effectiveness estimates depending on the type of vaccine, vaccine prices, coverage levels, and delivery strategy, with the additional incremental cost per person being relatively small for some new vaccines. Declines in unit prices of new vaccines also will affect cost-effectiveness results.

Financing and sustaining immunization programs are challenges that governments in developing countries and their development partners will face. The financial implications of reaching higher coverage levels and the simultaneous desire to introduce new vaccines will require policy makers to consider both the relative cost-effectiveness of interventions and the long-term budgetary implications.

Although global and regional estimates of cost-effectiveness of interventions are useful guides, further analytical work will be needed to evaluate the relative benefits (deaths and cases averted and DALYs) and costs (delivery and treatment) of vaccines for different delivery strategies and higher coverage rates, particularly at the country level.

ACKNOWLEDGMENTS

The authors thank Tina Proveaux for editorial and technical assistance and Howard Barnum, Mariam Claeson, Felicity Cutts, Tony Measham, and Philip Musgrove for reviewing drafts of the manuscript. Santiago Cornejo and Ravi Cheerukupalli provided valuable inputs.

NOTES

1. For our analysis, the preimmunization era neonatal tetanus mortality rate per 1,000 live births is used: developed countries, 0.1; East Asia and the Pacific, 4.7; Europe and Central Asia, 0.4; Latin America and the Caribbean, 4.4; Middle East and North Africa, 4.7; South Asia, 15.3; and Sub-Saharan Africa, 10.2.

2. Because disease classification does not have a one-to-one correspondence with those prevented by vaccine, according to table 20.3 is based on estimates of the proportion of these illnesses that may be preventable by specific vaccines. For example, some meningitis and acute lower respiratory infections are caused by Hib or *S. pneumoniae*, and some cirrhosis is caused by hepatitis B.

3. A *fully immunized child* is a standard term that refers to a child who has received one dose of BCG vaccine, three doses each of oral polio vaccine and DTP vaccines, and one dose of measles vaccine. The number of FICs does not include children who have been partially immunized, so this measure underestimates the total effect on the disease burden. However, the number of FICs is representative of the effectiveness of the delivery system in providing access to immunization services to children. The authors are aware that fully vaccinating a child does not correspond to full immunity.

4. The mean population-weighted cost per FIC for the financial sustainability plans for immunization was US\$21.06. The plans use DTP3 coverage as a proxy for FICs rather than coverage measured through population-based surveys (http://www.who.int/immunization_financing/en).

5. Assumptions about the relative distribution of FICs by strategy and region were based loosely on such factors as the proportion of the population with access to health services for fixed facilities and the likelihood of active mobile strategies.

6. A proxy for the total number of deaths averted is the sum of the individual deaths averted for each antigen in the traditional EPI. This figure may overestimate the actual number of deaths averted by fully immunizing children and therefore underestimate the cost per death averted. However, the values estimated by region appear to support previously reported estimates, and direct estimation of deaths averted was impossible given data and model limitations.

Chapter 21

Conquering Malaria

Joel G. Breman, Anne Mills, Robert W. Snow, Jo-Ann Mulligan, Christian Lengeler, Kamini Mendis, Brian Sharp, Chantal Morel, Paola Marchesini, Nicholas J. White, Richard W. Steketee, and Ogobara K. Doumbo

Malaria is the most important of the parasitic diseases of humans, with 107 countries and territories having areas at risk of transmission containing close to 50 percent of the world's population (Hay and others 2004; WHO 2005). More than 3 billion people live in malarious areas and the disease causes between 1 million and 3 million deaths each year (Breman, Alilio, and Mills 2004; Snow and others 2003). Recent estimates of the global falciparum malaria morbidity burden have increased the number to 515 million cases, with Africa suffering the vast majority of this toll (Snow and others 2005). In addition, almost 5 billion clinical episodes resembling malaria occur in endemic areas annually, with more than 90 percent of this burden occurring in Africa (Breman 2001; Breman, Alilio, and Mills 2004; Carter and Mendis 2002; Snow and others 1999, 2003; Snow, Trape, and Marsh 2001).

The disease has resurged in many parts of the tropics, and nonmalarious countries face continual danger from importation. Contributing to this resurgence are the increasing problems of *Plasmodium falciparum* resistance to drugs and of the *Anopheles* vectors' resistance to insecticides. The recent findings that insecticide-treated nets (ITNs) are extremely cost-effective in preventing malaria and overall deaths and that intermittent preventive therapy (IPT) (treatment doses given during periods of vulnerability) is effective for protecting pregnant women and their fetuses, along with the discovery of new drugs (artemisinins) and their use in combination with other antimalarials and promising vaccine trials, have given great impetus to the battle against this scourge (Alonso and others 2004; Armstrong-Schellenberg and others 2001; Lengeler 2004; Newman and others 2003; Yeung and others 2004).

CAUSES, EPIDEMIOLOGY, MANIFESTATIONS, AND DIAGNOSIS

Four species of the genus *Plasmodium* cause malarial infections in humans: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Virtually all deaths are caused by falciparum malaria. Human infection begins when the malaria vector, a female anopheline mosquito, inoculates plasmodial sporozoites from its salivary gland into humans during a blood meal. The sporozoites mature in the liver and are released into the bloodstream as merozoites. These invade red blood cells, causing malaria fevers. Some forms of the parasites (gametocytes) are ingested by anopheline mosquitoes during feeding and develop into sporozoites, restarting the cycle.

P. falciparum predominates in Haiti, Papua New Guinea, and Sub-Saharan Africa, while *P. vivax* is more common in Central America and the Indian subcontinent and causes more than 80 million clinical episodes of illness yearly (Mendis and others 2001). The prevalence of these two species is approximately equal in the Indian subcontinent, eastern Asia, Oceania, and South America. *P. malariae* is found in most endemic areas, especially throughout Sub-Saharan Africa, but is much less common than the other species. *P. ovale* is unusual outside Africa, and where it is found accounts for less than 1 percent of isolates.

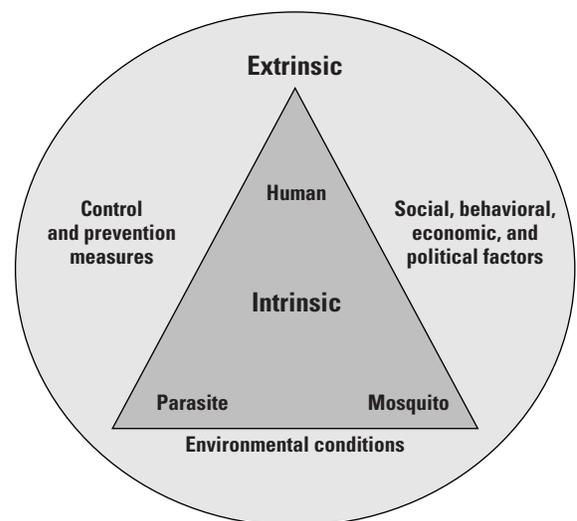

While more than 40 anophelines can transmit malaria, the most effective are those such as *Anopheles gambiae*, which are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomological inoculation rate (EIR)—that is, the number of sporozoite-positive mosquito bites per person per year—is the

most useful measure of malarial transmission and varies from less than 1 in some parts of Latin America and Southeast Asia to more than 300 in parts of tropical Africa.

The epidemiology of malaria may vary considerably within relatively small geographic areas. In tropical Africa or coastal Papua New Guinea, with *P. falciparum* transmission, more than one human bite per infected mosquito can occur per day and people are infected repeatedly throughout their lives. In such areas, morbidity and mortality during early childhood are considerable. For survivors, some immunity against disease develops in these areas, and by adulthood, most malarial infections are asymptomatic. This situation, with frequent, intense, year-round transmission, is termed *stable malaria*. In areas where transmission is low, erratic, or focal, full protective immunity is not acquired and symptomatic disease may occur at all ages. This situation is termed *unstable malaria*. An epidemic or complex emergency can develop when changes in environmental, economic, or social conditions occur, such as heavy rains following drought or migrations of refugees or workers from a nonmalarious to an endemic region. A breakdown in malaria control and prevention services intensifies epidemic conditions. Epidemics occur most often in areas with unstable malaria, such as Ethiopia, northern India, Madagascar, Sri Lanka, and southern Africa. Many other African countries situated in the Sahelian and Sub-Saharan areas are susceptible to epidemics (Djimé and others 2004; Worrall, Rietveld, and Delacollette 2004). Public health specialists have only recently begun to appreciate the considerable contribution of urban malaria, with up to 28 percent of the burden in Africa occurring in rapidly growing urban centers (Keiser and others 2004).

The determinants of malaria and of risk factors for patients and communities relate to intrinsic (human, parasite, and vector) and extrinsic (environmental, control, and socioeconomic) factors (figure 21.1) (Breman 2001). Both humoral and cellular immunity are necessary for protection.

Anemia may be quite common among young children living in areas with stable transmission, particularly where the parasite is resistant to chloroquine, sulfadoxine-pyrimethamine (SP), or other drugs. Correctly and promptly treated, uncomplicated falciparum malaria has a mortality rate of approximately 0.1 percent (Sudre and others 1992). Once vital organ dysfunction occurs or the proportion of erythrocytes infected increases to more than 3 percent, mortality rises steeply. Coma is a characteristic and ominous feature of falciparum malaria, and despite treatment it is associated with death rates of some 20 percent among adults and 15 percent among children. Convulsions, usually generalized and often repeated, occur in up to 50 percent of children with cerebral malaria (CM) (Mung'Ala-Odera, Snow, and Newton 2004). Whereas less than 3 percent of adults suffer neurological sequelae, roughly 10 to 15 percent of children surviving CM—especially those with hypoglycemia, severe malarial anemia (SMA), repeated

Source: Breman 2001.

Figure 21.1 Determinants of the Malaria Burden: Intrinsic and Extrinsic Factors

seizures, and deep coma—have some residual neurological deficit when they regain consciousness. Protein-calorie undernutrition and micronutrient deficiencies, particularly zinc and vitamin A, contribute substantially to the malaria burden (Caulfield, Richard, and Black 2004).

In areas with intense and stable transmission, falciparum malaria in primigravid and secundigravid women is associated with low birthweight (average reduction of about 170 grams) and consequently with increased infant and childhood mortality (Steketee and others 2001). HIV infection predisposes all pregnant women to more frequent and severe malaria, and the reverse may also be true (Ter Kuile and others 2004). *P. vivax* malaria in pregnancy is also associated with a reduction in birthweight (average reduction of some 100 grams), and this effect is greater in multigravid than in primigravid women (Nosten and others 1999).

The confirmatory diagnosis of clinical malaria rests on the microscopic demonstration of asexual forms of the parasite in stained peripheral blood smears. Newer diagnostic tests using antigen and nucleic acid detection methods are being evaluated. These tests are promising, but their limitations in relation to species sensitivity (except for *P. falciparum*), parasite quantitation, field feasibility, and costs necessitate further development and evaluation (Warhurst and Williams 2004).

BURDEN OF DISEASE

In 2001, the World Health Organization (WHO) ranked malaria as the eighth-highest contributor to the global disease burden as reflected in disability-adjusted life years (DALYs), and the

Table 21.1 Deaths and DALYs from Deaths Attributable to All Causes and to Malaria by WHO Region, 2000

Percentages may not add up to 100 percent because of rounding.

second highest in Africa (WHO 2002a). The DALYs attributable to malaria were estimated largely from the effects of *P. falciparum* infection as a direct cause of death and the much smaller contributions of short-duration, self-limiting, or treated mild febrile events, including malaria-specific mild anemia and neurological disability following CM (Murray and Lopez 1996, 1997). The estimate assumes that each illness event or death can be attributed only to a single cause that can be measured reliably. Table 21.1 shows deaths and DALYs from deaths attributable to malaria and to all causes by WHO region (WHO 2002a). It does not include the considerable toll caused by the burden of malaria-related moderate and severe anemia, low birthweight, and comorbid events (Snow and others 2003). Sub-Saharan African children under four represent 82 percent of all malaria-related deaths and DALYs. Malaria accounts for 2.0 percent of global deaths and 2.9 percent of global DALYs. In the African region of WHO, 9.0 percent of deaths and 10.1 percent of DALYs are attributable to malaria.

Recent analysis of falciparum malaria morbidity concludes that 515 (interquartile range 298 to 659) million cases occur yearly (table 21.2). This figure is 92 percent higher than the 278 million malaria cases estimated by WHO for 1998, which also includes those attributable to *P. vivax*, and 200 percent higher than previous estimates for areas outside of Africa (Snow and others 2005). While the malaria incidence globally is 236 episodes per 1,000 persons per year in all endemic areas, it ranges from about 400 to 2,000 (median 830) episodes per 1,000 persons per year in areas with intense, stable (hyperendemic and holoendemic) transmission; these areas represent 38 percent of all falciparum-endemic areas.

Background

Recent estimates of malaria deaths have varied from 0.5 million to 3.0 million per year (Breman 2001; Breman, Alilio, and

Table 21.2 Population at Risk for Falciparum Malaria, Cases and Attack Rates by World Health Organization Region, 2002*

Region	Population at risk in millions (percent)	Cases in millions (IQR) (percent)	Falciparum attack rate (1,000 persons at risk per year)

Mills 2004; Snow and others 2003). Of the 10.6 million yearly deaths in children younger than 5 years 8 percent are ascribed to malaria (Bryce and others 2005). In 1998, an empirical analysis of malaria mortality undertaken on behalf of WHO used malaria risk maps to capture measures of disability, morbidity, and mortality associated with *P. falciparum* prevalence rates among African populations and yielded an estimate of about 1 million (Korenromp and others 2003; Snow and Marsh 2002; Snow and others 2003; Snow, Trape, and Marsh 2001). Each malarious country must now measure its own burden and progress toward decreasing that burden (WHO 2005).

Geographic and climate-driven (mainly rainfall) models of suitability for malaria transmission characterize the diversity of malaria transmission across the African continent (Craig, Snow, and le Sueur 1999; Snow and others 1999). Four distinct areas can be identified:

- class 1, no transmission (northern and parts of southern Africa)
- class 2, marginal risk (mainly in some areas of southern Africa and in high-altitude [>1500 meters] settings)
- class 3, seasonal transmission with epidemic potential (along the Sahara fringe and in highlands)
- class 4, stable and unstable malarious areas (most areas south of the Sahara to southern Africa and below an altitude of around 1,500 meters).

Direct Consequences of *P. falciparum* Infection

Two major syndromes, CM and moderate (hemoglobin less than 11 grams per deciliter) and severe (hemoglobin less than 8 grams per deciliter) malarial anemia, contribute directly and

significantly to malaria mortality (tables 21.3 and 21.4). The differences in numbers derive from the different methods of calculating the burden. Children presenting with an acute febrile disease, peripheral parasitemia, and low hemoglobin concentrations account for the majority of inpatient admissions in

Table 21.4 Deaths from Malaria in Children Under Five, Africa, 2001

Cause of malaria-related death	Number of malaria deaths
Cerebral malaria	110,000
Severe malarial anemia	190,000–974,000
Respiratory distress	110,000
Hypoglycemia	153,000–267,000

n.a. = not applicable.

— = not available.

Note: Figures in parentheses are interquartile ranges.

a. WHO (2002b) reports 1,124,000 deaths from malaria.

areas with stable transmission. The arbitrary definition of 5 grams of hemoglobin per deciliter is prognostic for a fatal outcome and proves useful clinically as a criterion for transfusion. Lactic acidosis commonly coexists with hypoglycemia and is (with coma, repeated convulsions, shock, and hyperparasitemia) an important predictor of death from severe malaria (White and Breman 2005; WHO 2000b).

The vast majority of deaths in developing countries occur outside the formal health service, and in Africa, most government civil registration systems are incomplete (Breman 2001; Greenberg and others 1989). Newer demographic and disease-tracking systems are being used globally and should help rectify the woefully inadequate vital statistics available for malaria and other diseases (INDEPTH 2002).

Health personnel usually attribute causes of death during demographic surveillance system surveys through a verbal autopsy interview with relatives of the deceased about the symptoms and signs associated with the terminal illness. Both the specificity and the sensitivity of verbal autopsy vary considerably depending on the background spectrum of other common diseases, such as acute respiratory infection, gastroenteritis, and meningitis, which share common clinical features with malaria (Korenromp and others 2003).

In malarious Africa, some 30 to 60 percent of outpatients with fever may have parasitemia. Monthly surveillance of households will detect a quarter of the medical events that are detected through weekly surveillance, and weekly contacts with cohorts identify approximately 75 percent of events detected through daily surveillance (Snow, Menon, and Greenwood 1989). Given the predominance of fevers, malaria case management in Africa and other endemic areas usually centers on presumptive diagnosis.

Estimates of the frequency of fever among children suggest one episode every 40 days. If we assume that the perceived frequency of fever in Africa is similar across all transmission areas (and possibly all ages), African countries would witness approximately 4.9 billion febrile events each year. Estimates indicate that in areas of stable malaria risk, a minimum of 2.7 billion exposures to antimalarial treatment will occur each year for parasitemic persons, or 4.93 per person per year (Snow and others 2003). While these diagnostic, patient management, and drug delivery assumptions are debatable, they indicate the magnitude of the challenges malaria presents.

The case-fatality rates of CM are high, even with optimal management. Murphy and Breman (2001) report a mean case-fatality rate of 19.2 percent and Snow and others (2003) cite a figure of 17.5 percent. Those who succumb at home without optimal treatment will have higher case-fatality rates.

Studies of neurological sequelae after severe malaria indicated that 3 to 28 percent of survivors suffered from such sequelae, including prolonged coma and seizures (Mung' Ala-Odera, Snow, and Newton 2004). CM is associated with hemipare-

sis, quadriplegia, hearing and visual impairments, speech and language difficulties, behavioral problems, epilepsy, and other problems (table 21.3). The incidence of neurocognitive sequelae following severe malaria is only a fraction of the true residual burden, and the impact of milder illness is unknown.

Studies of children presenting to hospital with malaria and hemoglobin of less than or equal to 5 grams per deciliter indicate a median transfusion rate of 80.1 percent. Thus, 275,400 to 442,290 surviving SMA admissions, newborn through 14 years, will be exposed to blood transfusion each year in Sub-Saharan Africa. As a result, each year 5,300 to 8,500 children, age birth through 14 years, living in stable endemic areas of Africa are likely to acquire HIV infection because of exposure to blood transfusion to manage SMA (Colebunders and others 1991; Savarit and others 1992).

Indirect and Comorbid Risks

The DALY model of malaria does not sufficiently take it into account as an indirect cause of broader morbid risks. Some consider anemia to be caused indirectly unless linked to acute, high-density parasitemia. Similarly, low birthweight may also be indirectly attributable to malaria, and a child's later undernutrition and growth retardation linked to malaria infection enhances the severity of other concomitant or comorbid infectious diseases through immune suppression. Thus, malaria infection contributes to broad causes of mortality beyond the direct fatal consequences of infection and is probably underestimated (Breman, Alilio, and Mills 2004; Snow and others 2003).

In Africa, pregnant women experience few malaria-specific fever episodes but have an increased risk of anemia and placental sequestration of the parasite. Maternal clinical manifestations are more apparent in areas with less intense transmission, particularly in Asia. Estimates indicate that in Sub-Saharan Africa, malaria-associated anemia is responsible for 3.7 percent of maternal mortality, or approximately 5,300 maternal deaths annually.

Prematurity and intrauterine growth retardation resulting in low birthweight associated with maternal malaria account for 3 to 8 percent of infant mortality in Africa (Steketee and others 1996, 2001). Assuming an infant mortality rate of 105 per 1,000 live births, Snow and others (2003) calculate that in 2000, 71,000 to 190,000 infant deaths were attributable to malaria in pregnancy (table 21.3). Other studies indicate that malaria-associated low birthweight accounted for 62,000 to 363,000 infant deaths (Murphy and Breman 2001).

Anemia among African children is caused by a combination of nutritional deficiencies and iron loss through helminth infection, red cell destruction, decreased red cell production as a result of infectious diseases, and genetically determined hemoglobinopathies. Chronic or repeated infections, often associated with parasite resistance to drugs, are more likely to

involve bone marrow suppression (Menendez, Fleming, and Alonso 2000).

Murphy and Breman (2001) estimate that 190,000 to 974,000 deaths per year in Sub-Saharan Africa are attributable to SMA. Children residing in areas where the prevalence of *P. falciparum* was more than 25 percent had a 75 percent prevalence of anemia. By modeling the relationship between anemia and parasite prevalence, Snow and others (2004) found that mild anemia rose 6 percent for every 10 percent increase in the prevalence of infection. Reducing the incidence of new infections through ITNs or the prevalence of blood-stage infections through chemoprophylaxis or IPT for children halved the risk of anemia.

Caulfield, Richard, and Black (2004) report that iron, zinc, and protein-calorie deficits are responsible for a considerable amount of malaria-related mortality and morbidity and indicate that 57.3 percent of deaths of underweight children under five are attributable to nutritional deficiencies. One striking feature of the global distribution of anthropometric markers of undernutrition is its congruence with the distribution of endemic malaria. Improved growth among young children has more recently been demonstrated in The Gambia and Kenya in a comparison of those protected and unprotected by ITNs (Ter Kuile and others 2003).

Early during the HIV epidemic, Greenberg and others (1988) and Greenberg (1992) demonstrated that malaria-associated anemia treated with unscreened blood transfusions contributed to HIV transmission. At the same time, two longitudinal cohort studies in Kenya and Uganda and one hospital-based case-control study in Uganda demonstrated that HIV infection approximately doubles the risk of malaria parasitemia and clinical malaria in nonpregnant adults and that increased HIV immunosuppression is associated with higher-density parasitemias (French and others 2001; Whitworth and others 2000). In pregnant women, the presence of HIV increases the rate and intensity of parasitemia and frequency of anemia (Ter Kuile and others 2004). The increasing incidence of HIV-associated febrile illnesses may lead to increased use of antimalarials. Some believe that the recommended use of trimethoprim-sulfamethoxazole for prophylaxis of bacterial pneumonia and other infections in HIV/AIDS patients may contribute to SP resistance and that monitoring is required. Yet, evaluation of trimethoprim-sulfamethoxazole for malaria prophylaxis in Mali did not show any increases in parasite resistance mutations specific for these drugs (Thera and others 2005).

Malaria accounts for 13 to 15 percent of medical reasons for absenteeism from school, but little information is available on the performance of parasitized schoolchildren (Holding and Kitsao-Wekulo 2004). A randomized placebo control study of chloroquine prophylaxis in Sri Lankan schoolchildren demonstrated an improvement in mathematics and language scores by those who received chloroquine but found no difference in

absenteeism (Fernando and others 2003). As noted earlier, malaria may result in low birthweight, and low birthweight can lead to a range of persistent impaired outcomes, predominantly behavioral difficulties, cerebral palsy, mental retardation, blindness, and deafness. The recently launched studies of intermittent preventive treatments during infancy (IPTi) should provide a more precise means of examining the benefits of IPTi and consequences on learning and performance of infection early in life (Holding and Kitsao-Wekulo 2004; Rosen and Breman 2004; Schellenberg and others 2005).

INTERVENTIONS AND THEIR EFFECTIVENESS

Malaria will be conquered only by full coverage, access to, and use of antimalarial services by priority groups; rapid, accurate diagnosis; prompt and effective patient management (diagnosis, treatment, counseling and education, referral); judicious use of insecticides to kill and repel the mosquito vector, including the use of ITNs; and control of epidemics. Eliminating malaria from most endemic areas remains a distant, huge, but surmountable challenge because of the widespread *Anopheles* breeding sites; the large number of infected people; the use of ineffective antimalarial drugs; and the inadequacies of resources, infrastructure, and control programs. The Roll Back Malaria Partnership, which began in 1998, aims to halve the burden of malaria by 2010 and has developed strategies and targets for 2005 (box 21.1). While ambitious, the initiative is making substantial progress by means of effective and efficient deployment of currently available interventions (WHO 2003, 2005). Indeed, Brazil, Eritrea, India, and Vietnam are reporting recent successes in reducing the malaria burden (Barat 2005). Despite the enormous investment in developing a malaria vaccine administered by means of a simple schedule and recent promising results in the laboratory and in field trials in Africa, no effective, long-lasting vaccine is likely to be available for general use in the near future (Alonso and others 2004; Ballou and others 2004).

Drug Use

Proper use of drugs is essential. Early diagnosis and effective treatment of patients lends credibility to the malaria program, strengthens confidence in the health care system by families and communities, and raises the esprit of clinicians and public health workers.

Early Diagnosis and Treatment. Early diagnosis and effective treatment can cure infection, prevent further morbidity and progression to severe disease and death, and arrest transmission. This intervention requires timely and accurate diagnosis; use of efficacious drugs; education of patients and their families about the disease, home management, and

Box 21.1

Roll Back Malaria's Strategy and Goals for 2005

The goal of Roll Back Malaria Partnership is to halve the burden of malaria by 2010. The following targets for specific intervention strategies were established at the Abuja Malaria Summit in April 2000.

Strategy

- Prompt access to effective treatment
- Provision of ITNs
- Prevention and control of malaria in pregnant women
- Epidemic and emergency response

Abuja target (by 2005)

- 60 percent of those suffering with malaria should have access to and be able to use correct, affordable, and appropriate treatment within 24 hours of the onset of symptoms.
- 60 percent of those at risk for malaria, particularly children under five and pregnant women, will benefit from a suitable combination of personal and community protective measures, such as ITNs.
- 60 percent of pregnant women at risk of malaria will have access to IPT^a.
- 60 percent of epidemics are detected within two weeks of onset.
- 60 percent of epidemics are responded to within two weeks of detection.

Source: WHO 2003b, 2005.

a. The original Abuja declaration included the recommendation for chemoprophylaxis as well, but current WHO and Roll Back Malaria policy strongly recommends IPT and not chemoprophylaxis for preventing malaria during pregnancy.

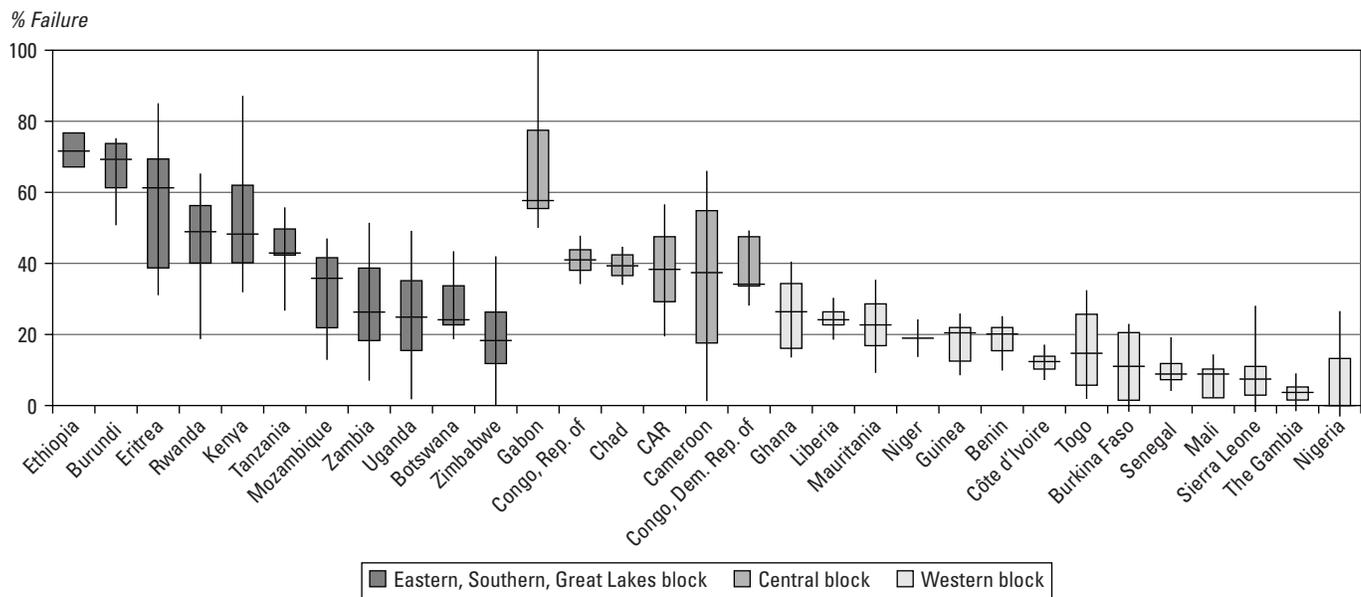

prevention; and referral to higher levels of the health system. The following are critical to the effectiveness of this intervention:

- *Timeliness.* A febrile malaria attack warrants early treatment. If left untreated, a proportion of *P. falciparum* malaria infections, perhaps 1 in 250 (and to a far lesser extent infections with other malaria species) will progress to severe disease within a few hours to a few days (Greenwood and others 2005). The globally agreed goal is that diagnosis and effective treatment should be provided within 24 hours of the onset of symptoms and signs.
- *Diagnosis and effective drug treatment.* An accurate diagnosis of malaria is based on detection of the parasite and, if laboratory diagnosis is not feasible, on clinical grounds. Health workers must monitor the therapeutic efficacy of drugs closely and change treatment policies when parasite resistance to chloroquine (figure 21.2), SP, and other drugs emerges (Baird 2005; Laxminarayan and others 2006; WHO 2002a). Concerns include unreliable and inaccurate microscopy and the disadvantages of alternative tests plus the widespread distribution and use of substandard and counterfeit drugs. The recommended treatments for malaria

in areas with resistance to single drugs are combination treatments, preferably artemisinin combination therapy (ACT) (WHO 2001a, 2001b, 2003a, 2005). While ACT is a welcome, life-saving approach, more information on the cost-effectiveness of this new strategy is needed (Arrow, Panosian, and Gellband 2004; Yeung and others 2004). Baird (2005) reports that ACT costs range from US\$2.00 (artesunate-amodiaquine, three doses in 48 hours) to US\$9.12 (artemether-lumefantrine, six doses in 48 hours) per adult treatment; WHO has obtained the latter drug for US\$2.40 per adult treatment for qualified purchasers, meaning those from low-income malarious countries.

- *Location of clinical management.* Effective management of patients requires skilled and well-equipped personnel at all levels of the health system. The two strategies for delivering antimalarials effectively are through health facilities and in or near the home when access to health facilities is limited. Given the pervasiveness of malaria infections, more information on the most effective and efficient ways to promote home treatment is urgently needed.

Evidence for the effectiveness of early diagnosis and treatment is available from two different epidemiological conditions

Source: WHO 2005.

Note: WHO has established 126 sentinel sites in 36 African countries that monitor the efficacy of locally used antimalarial drugs by following patients in clinics. The box indicates the 25th–75th percentile, the vertical line the lower and upper values, and where the lines cross the median.

Figure 21.2 Chloroquine Treatment Failure in Africa, 1997–2002

and health systems. In areas of low to moderate transmission, for example, southern Africa, the Americas, and Southeast Asia, where health care systems are relatively effective, the two major consequences of prompt and effective intervention are reduction of the period of infectivity of infected persons, and thus reduced transmission and incidence, and a lowered case-fatality rate and overall mortality. In Vietnam and the KwaZulu-Natal province of South Africa, *P. falciparum* malaria incidence and mortality rates fell when effective treatment policies (artesunate and ACT) replaced failing monotherapies (Hung and others 2002). The effective drug policies were implemented in conjunction with enhanced vector control; thus, effective treatment alone does not account for the fall in malaria incidence and mortality.

In areas with stable, high transmission of *P. falciparum* malaria—for instance, Papua New Guinea and Sub-Saharan Africa—where access to treatment is poor, little is known about the impact of early and effective treatment on malaria transmission. With a high EIR (10 to 1,000), a reduction in transmission intensity is unlikely to affect the incidence of disease until low EIRs (less than 10) are reached.

IPT in Pregnancy and Infancy. IPT is recommended in pregnancy in areas with high and stable transmission of *P. falciparum* malaria; IPT usually consists of two curative doses of antimalarial treatment. The recommended drug is SP given during the second and third trimesters of pregnancy during prenatal care visits. IPT in infancy involves giving infants treatment doses during vaccination or well-baby visits to health clinics.

In primigravid and secundigravid women, the incidence of severe maternal anemia, the incidence and density of placental parasitemia, and the incidence of low birthweight were 25 to 95 percent lower when mothers were given IPT than when they were not (Kayentao and others 2005; Steketee and others 2001). While initial studies indicate that IPT in infancy reduces anemia and febrile episodes, more research is needed. SP is becoming ineffective for IPT, and health experts are suggesting ACT as a replacement (White 2005).

Chemoprophylaxis. Chemoprophylaxis is advised by travel medicine specialists for nonresidents of endemic areas who are exposed to malaria for short periods. WHO does not recommend chemoprophylaxis for permanent residents of endemic areas because of low feasibility and compliance and high costs relative to the public health benefits (WHO 1996, 2000a, 2000b). The choice of chemoprophylaxis will depend on the drug-sensitivity profile, tolerance, side effects, costs, regimen, and compliance by patients (Baird 2005; Kain, Shanks, and Keystone 2001; White and Breman 2005). The effectiveness of chemoprophylaxis will depend mainly on patient compliance and parasite susceptibility.

Supervision and Policy Change. In relation to drug use, all control activities must be supervised and evaluated rigorously to ensure high-quality care for patients and program effectiveness and efficiency (Bryce and others 1994; Jha, Bangoura, and Ranson 1998). Studies in 37 countries indicate the need for a treatment policy change to ACT (WHO 2002a). Several

countries in Africa, Asia, and South America are now implementing ACT as the first-line treatment for uncomplicated malaria (WHO 2005). Many countries are also trying to improve the time lag before treatment. More than 83 percent of the population in the three malarious provinces in South Africa is within 10 kilometers of a health facility (Sharp and le Sueur 1996). In Burkina Faso, Ethiopia, and Uganda, where access to clinics was poor and difficult, mothers and community health workers were empowered to dispense treatment, which resulted in major reductions in mortality and morbidity in children (Kidane and Morrow 2000; Pagnoni and others 1997; Sirima and others 2003).

Insecticide-Treated Nets

The use of ITNs (bednets, curtains, and other materials) to provide personal protection by killing or repelling mosquitoes is one of the major strategies of malaria control (RBM 2002). Pyrethroids are recommended for the periodic treatment or re-treatment of the protective materials.

The effectiveness of ITNs depends on their acceptability by the population at risk and their affordability. It is contingent on the habits, biology, and susceptibility of the mosquito vector; the compliance of the human population; and the concentration of insecticide on or in the fiber, which has to be maintained by regular re-treatment or by incorporating the insecticide in the fiber for long duration.

Over 20 studies in Africa and Asia have demonstrated more than 50 percent protective efficacy for individual users of ITNs in reducing malaria episodes, 29 percent protection against severe malarial disease, and substantial protection against anemia (Lengeler 2004). Most importantly, the use of ITNs reduced child mortality by 18 percent in five sites in Sub-Saharan Africa (Lengeler 2004).

Lengeler's (2004) review demonstrates the efficacy of ITNs in both stable and unstable transmission areas. Widespread use of ITNs resulted in an overall reduction in mortality of 19 percent, protected against anemia, and had a substantial impact on mild disease episodes. One large-scale rural study in Tanzania found that ITNs and untreated nets reduced mortality of children one month to four years, with protective efficacies of 27 and 19 percent, respectively (Armstrong-Schellenberg and others 2001). Re-treating ITNs semiannually or just before the annual peak in transmission is essential for effective vector control and is proving a major logistical and financial challenge. Fortunately, new types of nets with a long-lasting insecticidal property are now available, and re-treatment will soon cease to be an issue. The salutary impact of large-scale ITN programs has been demonstrated in China (Tang 2000), Tanzania (Abdulla and others 2001; Armstrong-Schellenberg and others 2001; WHO 2005), and Vietnam (Hung and others 2002). More operational experience is

required to inform national initiatives to scale up ITN use (Lengeler and Sharp 2003); yet, recent encouraging reports show that Eritrea, Malawi, Togo, Zambia, and other countries in Africa are already scaling up nationally with high coverage.

Vector Control

The reduction of *Anopheles* breeding and biting of humans involves different methods of insecticide and repellent application, environmental management, and behavioral change of populations at risk.

Indoor Residual Spraying of Dwellings with Insecticide.

Indoor residual spraying (IRS) is the application of long-lasting insecticides (up to six months) on the walls of dwellings. Insecticides repel mosquitoes from entering houses or impart a lethal dose of the insecticide on the female mosquito when it rests on a sprayed surface, thereby preventing subsequent transmission. IRS is most effective against indoor-biting (endophilic) mosquito vectors. Vector susceptibility and post-feeding behavior are the main criteria to be considered when choosing an insecticide: organophosphates, carbamates, and pyrethroids are the main compounds used although some countries still rely on organochlorines (dichlorodiphenyl-trichloroethane, or DDT).

The effectiveness of this intervention depends on cost, toxicity, acceptability of the insecticide, its residual effects, and local political and international partnership commitment. Malaria incidence decreased sharply following the use of IRS in large-scale programs in many parts of Africa, the Americas, Asia, and Europe (Lengeler and Sharp 2003).

In southern Africa, more than 13 million people in six countries are protected from malaria (WHO 2002c). Control was initiated through the use of IRS and supported by engineering approaches, larviciding, prompt diagnosis, and effective treatment. Examples of successful and sustained malaria elimination using IRS with effective drug treatment are available from Cyprus, Greece, Portugal, Spain, and the former Yugoslavia and its successor states (Curtis and Mnzava 2000). The most successful malaria control efforts were linked closely to research and took place in many parts of Asia, where the notable example is the near eradication of malaria from Sri Lanka in the early 1960s, and in Central and South America from the late 1950s to early 1970s (Alilio, Bygbjerg, and Breman 2004; Carter and Mendis 2002; Gilles 2002).

Larviciding and Fogging. Larviciding is the application of chemical insecticides, including those of biological origin and insect growth regulators, to breeding sites. These may be applied to all mosquito breeding sites or targeted to the breeding sites of specific vectors. Recommended compounds, formulations, and dosages for larviciding are available through the WHO Pesticides Evaluation Scheme. Fogging or space spraying

with insecticides requires specialized equipment, because the particle size of the insecticide determines its suspension qualities in the air, the number of droplets, and the penetration of space. The insecticide is not effective for as long as with IRS or ITNs, and application must occur during periods of peak target mosquito activity, generally at night.

Larviciding is not generally indicated for large-scale vector control in rural endemic areas because of the difficulty of locating all breeding sites, their often temporary nature, and the required frequency of application. Thus, larviciding is usually limited to urban areas, refugee camps, and industrial and development projects. Despite its impact on mosquito density and its contribution to reducing transmission, larviciding is not as effective as IRS and ITNs in reducing mosquito longevity (Najera and Zaim 2002).

Civil Engineering. Draining and filling larval breeding sites is one of the oldest methods of mosquito control and must be targeted to the breeding sites of locally important malaria vectors. Civil engineering strategies can require costly heavy equipment and materials and are useful for eliminating permanent breeding sites in urban areas, which are increasing globally, and at development project sites where earth removal has occurred.

Home Repellents and Insecticide Use

Commercially available mosquito repellents are applied directly on the skin or clothing as aerosols, lotions, or creams and contain active ingredients that protect the individual from mosquito bites. Commercially available mosquito coils containing pyrethroids can be burnt to repel mosquitoes, and electrically heated dispensers serve a similar function. Some communities in endemic regions use smoke, burning herbs, or plants to deter mosquitoes from entering the home.

N,N-diethyl-meta-toluamide (DEET) is the most widely used and effective ingredient in commercially available repellents (Curtis and others 1991). While several studies have shown that mosquito coils are effective at repelling mosquitoes, they are not as effective as ITNs (Charlwood and Jolly 1984).

Health Education and Counseling

Health education is the provision of information via newspapers, radio, or television, and health counseling is interactive, is individual, and involves the transfer of skills. The provision of information to households on ways to prevent malaria is needed in all endemic communities. It should cover the importance of early treatment and where to access it, the use of referral services, and the significance of full compliance with treatment and other interventions. The necessary information can be provided by community and voluntary health workers.

These persons are an extension of the health system and work under the direct supervision of health facility staff or non-governmental organizations and in conformity with standards and norms established by the national government (Gilles 2002). Such information can help to increase the standard of patient care and prevention programs by promoting citizen and community advocacy and demand for control.

ECONOMICS OF MALARIA CONTROL INTERVENTIONS

Goodman, Coleman, and Mills's (2000) study represents the most thorough attempt to compare the cost-effectiveness of a wide range of malaria control interventions. They find that in a very low-income country, the cost-effectiveness range per DALY averted was US\$19 to US\$85 for ITNs (nets plus insecticide), US\$32 to US\$58 for residual spraying (two rounds per year), US\$3 to US\$12 for chemoprophylaxis for children (assuming an existing delivery system), US\$4 to US\$29 for IPT for pregnant women, and US\$1 to US\$8 for case-management improvements. Goodman, Coleman, and Mills (2000) find that even though some interventions are relatively cheap, achieving high coverage may require a level of expenditure currently out of reach for many African countries and that overcoming operational barriers to achieving widespread coverage is likely to require substantial assistance from external donors.

Analysis

The following analysis incorporates new knowledge on the effects of interventions and on their costs for a low-income, Sub-Saharan African population living in an area of high, stable transmission. The modeling draws on a wide range of sources on the costs and effects of each intervention, extrapolated across settings and operational conditions. The approach allows for changing cost-effectiveness over time, for example, as resistance to antimalarial drugs or insecticides increases. To address problems of uncertainty in relation to many of the parameters, we used probabilistic sensitivity analysis, which allows for multivariate uncertainty by assigning ranges rather than point estimates to input variables. We assumed that cost and effectiveness input variables follow uniform triangular or normal continuous probability distributions (Mulligan, Morel, and Mills 2005).

We consider the cost-effectiveness of a limited subset of interventions: ITNs, IRS, IPT during pregnancy, and patient management with a change of the first-line drug. We include costs to the provider and the community and incremental out-of-pocket expenses for households, but because of major valuation and measurement problems, we do not include the indirect costs of patients' time to seek care and of the lost

productivity resulting from morbidity. We consider only gross costs for all interventions except patient management, given the uncertainty inherent in estimating savings.

Insecticide-Treated Nets. We based our analysis of ITNs on the delivery mechanism used in the WHO Special Programme for Research and Training in Tropical Diseases (WHO/TDR) trials, where householders, community health workers, and program staff worked together to treat the nets. In relation to insecticide, we considered permethrin and deltamethrin. Deltamethrin is effective for a year; thus, re-treatment is annual. Permethrin lasts for six months; thus, we assumed two treatments per year if the transmission season is longer than six months. The activities undertaken were the training of staff and community health workers, a campaign to inform the community about the intervention, the procurement and transport of the insecticide and nets, and the initial treatment and the re-treatment of the nets. We calculated cost-effectiveness for each intervention for two scenarios: one whereby nets were distributed to households and the second whereby treatment was arranged for existing nets. We drew estimates of the effectiveness of ITNS from a recent meta-analysis of WHO/TDR-sponsored trials conducted in Sub-Saharan Africa (Lengeler 2004). We adjusted the key parameter and effectiveness estimates to account for the proportion of children sleeping and not sleeping under a recently treated net.

With one treatment per year using deltamethrin, the mean cost per DALY averted was US\$11 (90 percent range of US\$5 to US\$21). With one treatment of permethrin per year the cost-effectiveness ratio (CER) increased slightly to a mean of US\$12 (90 percent range of US\$6 to US\$20). Two treatments of permethrin per year increased the mean CER to US\$17 (90 percent range of US\$9 to US\$31). Even if net coverage is low and nets have to be distributed and treated, the intervention remains an extremely attractive use of resources. Moreover, the model includes health benefits only for children under five. If we included benefits for other household members, the CERs would be lower.

Insecticide Residual Spraying. We considered four insecticides for our analysis of the cost-effectiveness of IRS: DDT; malathion; and two pyrethroids, deltamethrin and lambda-cyhalothrin. We used the results of the Cochrane Review meta-analysis of ITN trials conducted in Africa to approximate the results of spraying on morbidity and mortality and adjusted effectiveness estimates to account for noncompliance (Lengeler 2004).

We found little difference between the CERs for the four insecticides when one round of spraying was done per year: they ranged from US\$5 to US\$18. With two rounds per year, costs increased, but we assumed that effectiveness remained the same, so all the CERs approximately doubled to US\$11 to

US\$34. These results should be interpreted with caution because of uncertainty in relation to the estimates of effectiveness in children under five. The model was based on one round of spraying per year in areas of seasonal transmission and two rounds per year in areas of high, intense (perennial) transmission. Effectiveness will depend on the length of the transmission seasons and on the insecticide. DDT lasts for six months or more, lambda-cyhalothrin for three to six months, and malathion and deltamethrin for only two to three months (Lengeler 2004; Lengeler and Sharp 2003).

IPT during Pregnancy. We analyzed the cost-effectiveness of IPT assuming that primigravid women are given two or three doses of SP at a prenatal clinic. We analyzed benefits to the child by decreased mortality and benefits to the mother resulting from changes in the incidence of severe anemia. We estimated the effect of IPT on the neonatal mortality rate as a function of increased birthweight based on the Cochrane meta-analysis of malaria prevention in pregnancy (Gülmezoglu and Garner 1998). The model allowed for level of drug resistance, probability of initial attendance at a prenatal clinic, probability of returning for a second visit, probability of returning for a third visit, and compliance with the drug regimen. We estimated both incremental and average costs.

The incremental CER for IPT in pregnancy using SP had a 90 percent range from US\$9 to US\$21 with a mean of US\$13. Average total cost-effectiveness had a mean of US\$24 (90 percent range of US\$16 to US\$35).

Change in First-Line Drug. We analyzed the cost-effectiveness of changing first-line therapies to SP and to ACT using a patient-management model with a decision-tree framework in which a patient presents with uncomplicated malaria at an outpatient facility and progresses to full recovery, recovery with neurological sequelae, or death. Three potential drug policy changes were considered (see table 21.5). For current drug policies we assumed either chloroquine or SP as the first-line drug, with SP or amodiaquine as a second-line drug and quinine as the third-line drug. We then examined the cost-effectiveness of policy switches to either SP or ACT as first-line drug (with amodiaquine as second line and quinine as third line).

Amodiaquine was chosen as the second-line drug in the new drug policy because, like chloroquine and SP, it is relatively cheap. Low compliance, adverse effects, and potential cross-resistance between amodiaquine and chloroquine excluded it from first-line selection. We omitted other potential drugs to limit the scope of analysis.

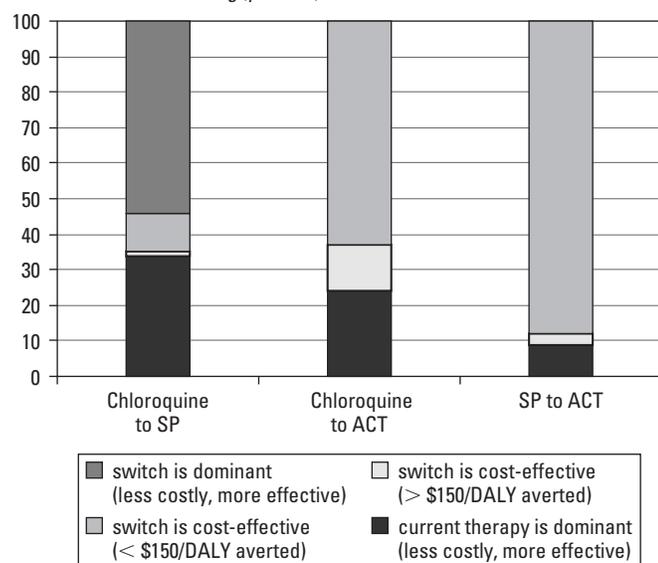

We used commonly found levels of drug resistance to create likely ranges. When used as second-line treatment, we assumed that a drug faced half the level of resistance than when it was used as a first-line drug. We estimated the growth rate of resistance to each drug based on its expected current location along

Table 21.5 Change in First-Line Drug

Scenario	Current drug policy			New drug policy		
	First-line drug	Second-line drug	Third-line drug	First-line drug	Second-line drug	Third-line drug
A	Chloroquine	SP	Quinine	SP	Amodiaquine	Quinine
B	Chloroquine	SP	Quinine	ACT	Amodiaquine	Quinine
C	SP	Amodiaquine	Quinine	ACT	Amodiaquine	Quinine

Resistance to current drug (percent)

Source: Authors.

Figure 21.3 Cost-Effectiveness of Switching the First-Line Drug

a sigmoid growth curve. We assessed compliance with each drug based on the length and complexity of each regimen. We gave the widest range (20 to 70 percent) to compliance with ACT, which usually requires a three-day treatment, to account for the different lengths of regimen and variety of formulations.

Figure 21.3 shows that a switch from chloroquine to SP is cost-effective (less than \$150 per DALY averted) when chloroquine resistance is above 35 percent. Switching from chloroquine to ACT becomes cost-effective as chloroquine resistance reaches around 37 percent. Switching from SP to ACT becomes cost-effective as SP resistance reaches 12 percent. This low threshold is due to the high growth rate of resistance to SP when it is used as a first-line therapy.

Results and Interpretation. Table 21.6 presents the average CERs for the interventions reviewed. All interventions can be considered attractive using a cutoff of US\$150 per DALY averted. For the childhood preventive interventions, the level of existing infrastructure is a key factor in influencing cost-effectiveness. ITNs are an even better use of resources if

Table 21.6 CERs for ITNs, IRS, and IPT (2001 US\$)

Intervention	Mean cost per DALY averted	90 percent range
<i>ITNs (net + insecticide treatment)</i>		
Deltamethrin	11	5–21
Permethrin (1 treatment)	12	6–20
Permethrin (2 treatments)	17	9–31
<i>ITNs (without provision of nets)</i>		
Deltamethrin	5	2–7
Permethrin (1 treatment)	6	3–9
Permethrin (2 treatments)	11	6–17
<i>IRS (1 round)</i>		
Melathion	12	8–18
DDT	9	5–13
Deltamethrin	10	6–14
Lambda-cyhalothrin	10	6–14
<i>IRS (2 rounds)</i>		
Malathion	24	15–34
DDT	17	11–24
Deltamethrin	18	12–27
Lambda-cyhalothrin	19	12–28
<i>IPT</i>		
Incremental costs	13	9–21
Average costs	24	16–35

Source: Authors' calculations.

net coverage is already high, and IPT is even more cost-effective if prenatal care coverage is good. However, even if levels of infrastructure are poor, these interventions are still attractive based on cost-effectiveness criteria.

Curtis and Mnzava's (2000) review comparing worldwide trials of ITNs and IRS for malaria control suggests that they were of equivalent effectiveness. Lengeler and Sharp (2003 21,) also conclude that choosing between IRS and ITNs is "largely a matter of operational feasibility and availability of local resources, rather than one of malaria epidemiology or cost-effectiveness." DDT is the cheapest insecticide but is

seldom used because of concerns about its environmental impact. An updated systematic review of the health effects of IRS as well as a full economic comparison between spraying with DDT and other insecticides and ITNs is urgently required. Such reviews should include the environmental benefits of reducing DDT levels and the costs of alternative interventions.

As effective patient management, IPT, and other approaches toward drug use become more widespread, drug resistance will increase, which will affect cost-effectiveness. In terms of first-line treatment, while a switch from chloroquine to SP is unlikely to be costly, cost-effectiveness depends on the initial level of severe resistance to each drug. A switch from chloroquine to ACT is likely to be costly but more effective, given that resistance to ACT is essentially nonexistent and the growth rate of resistance to ACT is likely to be low (Yeung and others 2004). Given the high growth rate of resistance to SP, switching to ACT becomes cost-effective when SP resistance surpasses 12 percent, a relatively low threshold. A switch from chloroquine to ACT appears to be highly cost-effective at all initial levels of chloroquine resistance above 37 percent. Recent studies indicate the remarkable effectiveness of the ACT artemether-lumefantrine in East African areas of chloroquine, amodiaquine, and SP resistance (Mutabingwa and others 2005; Piola and others 2005); it is expected that the availability of ACTs will increase and the costs will decrease in the near future.

Affordability and Scaling Up

Cost-effectiveness analyses can identify which interventions are the most efficient to implement, but information is also needed on affordability. Some interventions are cheap, such as prevention in pregnancy. Achievement of high coverage with an intervention to prevent childhood malaria (for example, ITNs) has a high total cost, which needs to be borne in part by external funding. For example, full coverage of children (assuming 22 percent of the population is under five years of age) would cost US\$2.81 million per 1 million persons of the general population covered (assuming the provision of nets plus two rounds of permethrin). The same coverage with IRS would cost about US\$4.01 million using deltamethrin (two rounds).

In addition to the difficulties of financial feasibility, the implementation of ITN interventions poses operational and logistical challenges. A number of strategic approaches are available for national ITN upscaling (RBM 2002). The main ones are social marketing (for example, in Malawi and Kenya), assisted commercial sector development (Senegal, Mali, Tanzania), and totally free distribution (Togo). An important feature of all the approaches is that their cost per net distributed decreases significantly as the scale of the undertaking increases, so it is hard to use available estimates to project cost in national programs.

Independent of the main ITN distribution strategy, a number of countries are implementing additional actions targeted

at the main high-risk groups. For example, a national voucher scheme is currently being implemented in Tanzania to provide every pregnant woman in the country with a free ITN, and a net is being distributed to children at the time of measles vaccination in Togo.

Re-treatment of ITNs on a large-scale remains a formidable operational issue, and free distribution of insecticide in the way it is done in Vietnam and China is probably the best way forward. This should occur while waiting the availability of long-lasting insecticidal nets that do not require retreatment.

Curtis and Maxwell (2002) point to the successful experience of Vietnam, where ITNs now protect 10 million people and the public health service provides free insecticide. This approach in Africa would require a substantial commitment by donors and governments given that most African governments spend only around US\$4 per capita per year on health (World Bank 2003). Eritrea, with 65 percent ITN coverage, and other African countries are beginning to make great strides in getting ITNs to their populations (Barat 2006; WHO 2005; World Bank 2005).

The move toward ACT poses the most difficult questions in relation to the long-term affordability of malaria control interventions. After scale-up, estimates indicate that the additional annual costs of ACT versus current failing drugs range from US\$300 million to US\$500 million globally (Arrow, Panosian, and Gellband 2004), with the precise amount depending on the extent to which all fevers are treated. This figure does not include drugs for nonmalaria fevers in endemic areas and the costs for the substantial health system strengthening required to make the most effective use of ACT. These include the costs of improved drug regulation, pharmacovigilance, diagnostics, and implementation of different drug policies for different population groups. The introduction of ACT has permanently changed the economic landscape of malaria control. Innovative funding solutions at the global level are required to ensure that effective drugs are made available to the most vulnerable groups. The Global Fund to Fight AIDS, Tuberculosis, and Malaria is providing the major leadership and resources for securing ACTs and other commodities, and many other agencies and organizations are joining coalitions to combat malaria through control, research, training, funding, and advocacy activities (Bremen, Alilio, and Mills 2004; Feacham 2004: <http://www.theglobalfund.org/en>).

Economic Benefits of Malaria Control

Given the substantial total costs of several malaria control interventions, the case for introducing them can be strengthened by evidence on non-health-related benefits, especially evidence of income gains or prevention of income losses. Three different approaches to measuring such benefits are assessing the direct and indirect costs of malaria, studying the relationship between

malaria and the output of agricultural or industrial activities, and exploring the macroeconomic impact of malaria. Only the third approach sheds much light on the benefits of control as opposed to the burden of the disease in the absence of control. This point is important, because in places facing the most severe malaria problems, direct information on the economic benefits of control is largely unavailable.

Direct and Indirect Costs of Malaria. The standard approach has been to view the two key determinants of the economic costs of malaria as the direct costs of expenditure on prevention and treatment and the indirect costs of productive labor time lost because of malaria morbidity and mortality, and to estimate the total economic impact by adding the direct and indirect costs (Mills 1992). Households use a range of preventive measures (mosquito coils, aerosol sprays, bednets, and mosquito repellents) to differing degrees. A review of evidence for Sub-Saharan Africa found that monthly per capita household expenditures ranged from US\$0.05 per person in rural Malawi to US\$2.10 in urban Cameroon, equivalent to US\$0.24 and US\$15 per household in 1999 U.S. dollars (Chima, Goodman, and Mills 2003). The costs of treatment for malaria include out-of-pocket expenditures for consultation fees, drugs, transport, and subsistence at a distant health facility. For Sub-Saharan Africa, these costs ranged between US\$0.41 and US\$3.88 per person, equivalent to between US\$1.88 and US\$26 per household per year. Household expenditure on treatment is usually highly regressive, consuming a much larger proportion of income in the poorest households.

Computations of public expenditures on malaria prevention and treatment are imprecise because most fall within general health service expenditures. About 20 to 40 percent of outpatient visits in malarious Africa are for fever, and suspected malaria among inpatients ranges from 0.5 to 50.0 percent of admissions. Kirigia and others (1998) found that inpatient treatment for pediatric malaria absorbed 15 percent of the annual recurrent costs of inpatient care in one Kenyan hospital and 9 percent in another. Ettlting and Shepard (1991) estimated that Rwanda's Ministry of Health spent 19 percent of its operating budget on malaria treatment. Because of the dominance of out-of-pocket spending by households, public expenditures on malaria generally account for a minority of total malaria expenditure.

The methods used to measure and value time lost and a day's work vary considerably between studies; the average time lost per episode for a sick adult and for an adult caring for sick children ranged from one to five days. The average indirect cost per episode ranged from US\$0.68 for children under 10 years of age in Malawi to US\$23 per adult episode in Ethiopia. Authors have concluded that aggregate productivity losses can be significant for households and for the economy as a whole. In Malawi, the indirect costs of malaria were equiv-

alent to 2.6 percent of annual household income (Ettlting and others 1994), and Russell (2004) reports that malaria generally consumes less than 10 percent of family income. Leighton and Foster (1993) estimate that the total annual value of malaria-related production losses was 2 to 6 percent of gross domestic product in Kenya and 1 to 5 percent in Nigeria. The productivity consequences of mortality have received relatively little attention.

The direct and indirect cost approach involves two methodological problems. First, calculations are based mainly on days of illness and neglect mortality, debility (usually from anemia), and neurological and other long-term sequelae. Second, households' coping strategies are likely to reduce the immediate impact of illness, although in the long term they may impose costs through the sale of assets such as livestock, which jeopardizes a household's asset base.

Relationship between Malaria and Output. With the exception of a study of cotton production in Côte d'Ivoire, where the prevalence of parasitemia above a cutoff density had a major impact on labor efficiency (Audibert, Mathonnat, and Henry 2003), studies have not succeeded in identifying impacts on output. One possibility is that the risk of malaria may discourage the planting of crops that require intensive cultivation, the settlement and cultivation of fertile land, or the development of tourism and industry in suitable locations, but good evidence is lacking.

Macroeconomic Impact of Malaria. Recent empirical cross-country comparisons of economic growth indicate that eliminating malaria would have a strong positive impact on economic development. Gallup and Sachs (2001) use cross-country regression analysis to relate the growth in gross domestic product per capita between 1965 and 1990 to initial income levels, initial human capital stock, policy variables, geographical variables, and a malaria index calculated as the product of the fraction of land area with endemic malaria in 1965 and the fraction of malaria cases that were due to *P. falciparum* in 1990. Their results suggest that countries with a substantial amount of malaria grew 1.3 percent per year less than countries with little or no malaria between 1965 and 1990 (controlling for other influences on growth) and that a 10 percent reduction in malaria was associated with 0.3 percent higher growth per year. McCarthy, Wolf, and Wu (2000) employ a similar approach to explore the impact of malaria on average per capita growth rates during three five-year periods. They find a significant negative association between malaria and economic growth, although the estimated impact differed sharply across countries. The impact was smaller than that found by Gallup and Sachs (2001), exceeding 0.25 percent per year in only a quarter of the sample countries and averaging 0.55 percent for those in Sub-Saharan Africa.

Benefit-Cost Ratios

Mills and Shillcutt 2004 related the evidence on the macroeconomic benefits of malaria control to information on the costs of reducing malaria to calculate a benefit-cost ratio (Mills and Shillcutt 2004). Depending on the assumptions, the benefit-cost ratio ranged between 1.9 and 4.7 (using a 3 percent discount rate). In terms of economic growth alone malaria control is extremely cost beneficial.

RESEARCH PRIORITIES

Current interventions to combat malaria remain inadequate for achieving the increased levels of successful patient management and prevention to which all malarious countries aspire and for which ambitious targets have been set (box 21.1). Greatly increased support for malaria research and for developing institutional capacity must occur to make advances and to bring them to populations in need. The WHO Scientific Working Group on Malaria and others have identified four major areas of research as follows (Remme and others 2002; WHO 1996, 2003c).

Patient Management

Patient management, including treatment, should address the following:

- evaluation of treatment effectiveness and of access to treatment for uncomplicated malaria in children and during pregnancy, with an emphasis on home management and evaluation of alternative delivery systems
- investigation of the pathogenesis of malaria, in particular anemia and immune response mechanisms
- evaluation of new approaches, for example, rectal drug administration, for managing severe illness
- evaluation of ACT, including delivery approaches via the public and private sectors
- development of new drugs with novel targets; the Medicines for Malaria Ventura (MMV) is spearheading this activity.

Prevention Research

Prevention research should focus on the following:

- new approaches to drug-based malaria prevention, including IPT in children and during pregnancy
- strategies for scaling up the use of ITNs.

Innovative Approaches

Innovative approaches should use new technologies, including recent advances in sequencing the DNA of *P. falciparum* and *A. gambiae*, to achieve the following:

- discover and develop drugs, diagnostics, vaccines, insecticides, and antiparasite effector molecules using genomics

- carry out strategic and basic research on vector-parasite-host interactions
- assess mechanisms for addressing drug and insecticide resistance
- develop and carry out field evaluations of transgenic methods for interrupting malaria transmission.

Policy Research

Social, economic, and policy research should focus on the following:

- developing and applying a common methodology for measuring socioeconomic status
- carrying out policy and operational research on the impact, viability, sustainability, and optimal balance of public-private partnerships
- investigating ethical, legal, and social issues pertaining to new malaria-related tools.

Capacity strengthening for research and operations (including clinical trials) is urgently needed. This strengthening will result in the ability to better evaluate new drugs and vaccines and existing malaria control tools (ITNs, IPT) and to tackle the scaling up of malaria strategies.

A classification of research priorities by time frame includes the three-year, five-year, and ten-year targeting.

Three-year completion targeting includes the following:

- apply to the U.S. Food and Drug Administration (FDA) with evidence for two separate fixed-dose artemisinin combinations at a target adult treatment price of US\$1.00, or US\$0.60 or less for children; two combinations are necessary, as one may fail in testing or have other unforeseen problems
- evaluate the two best candidate ACT drugs for IPT in pregnant women and in infancy and early childhood (IPTi)
- launch studies to reach an evidence-based conclusion on the costs and benefits of long-lasting ITNs versus IRS in Sub-Saharan Africa and other endemic areas
- carry out operational studies to determine the best methods of deploying ACT through the public and private sectors so that first-level patient management can occur at the home and at the village levels; this involves studying packaging and distribution networks, assessing adherence, and addressing how to deploy and supervise use of artesunate rectal suppositories
- conduct economic reviews and predictive modeling to make an economic case for increased international investment in malaria control, including collecting detailed data from several scaled-up, national, fully supported control programs employing the best available strategies and interventions

- conduct in Africa and other endemic continents a maximum number of FDA-compliant phase I and phase II malaria vaccine trials to select candidates for clinical trials.

The five-year completion target is as follows:

- develop and deploy more sensitive, specific, and predictive diagnostic tests that are inexpensive and practical
- carry out operational studies on how to deploy diagnostics in areas of low, intermediate, and high transmission.

The ten-year completion target has these focuses:

- develop an inexpensive, safe, and synthetic trioxane anti-malarial drug
- develop another new drug with a target and resistance mechanism that is unrelated to existing drugs
- carry out basic insecticide research to develop new approaches to both personal protection and residual house spraying
- launch successful phase III and phase IV field testing of malaria vaccines to prevent clinical illness and transmission with licensure by regulatory bodies
- use genomic, proteomic, and bioinformatic tools to better understand the pathogenesis of malaria, to design new drugs and vaccine candidates for training scientists, and to transfer technologies
- train a critical mass of leaders in science and operations to carry out the required research in support of control.

CONCLUSION

Given the heavy burden of malaria, the need to use existing strategies and interventions in scaled-up programs more effectively and to deploy them more widely is urgent and merits the highest priority, especially in Africa. While existing tools can be improved, newer tools are required. The history of malaria research and control shows that they are synergistic. Integrating research and control activities has resulted in success in several areas of the world, and will result in vanquishing malaria early in the 21st century.

Tropical Diseases Targeted for Elimination: Chagas Disease, Lymphatic Filariasis, Onchocerciasis, and Leprosy

Jan H. F. Remme, Piet Feenstra, P. R. Lever, André Médiçi, Carlos Morel, Mounkaila Noma, K. D. Ramaiah, Frank Richards, A. Seketeli, Gabriel Schmunis, W. H. van Brakel, and Anna Vassall

Tropical diseases are infectious diseases that are found predominantly in the tropics, where ecological and socioeconomic conditions facilitate their propagation. Climatic, social, and economic factors create environmental conditions that facilitate transmission, and the lack of resources prevents affected populations from obtaining effective prevention and adequate care. Tropical diseases are diseases of the poor, and investments in control and research to develop more effective intervention tools and strategies have been minimal (Gwatkin, Guillot, and Heuveline 1999; Remme and others 2002). For some, however, effective intervention methods have been developed, and successful control has been achieved.

This chapter focuses on four tropical diseases—Chagas disease, lymphatic filariasis (LF), onchocerciasis, and leprosy—for which effective means of control are available. All four diseases are targeted for elimination as a public health problem. Control strategies are being implemented at scale and have already achieved a major reduction in the burden of disease, and the causative agent has even been eliminated in some previously endemic areas. Those successes have not come easily, and much remains to be done to ensure complete and sustained control of the diseases.

DISEASE CHARACTERISTICS AND TRANSMISSION

Chagas disease, LF, onchocerciasis, and leprosy are all parasitic infections, but their causative agents, modes of transmission,

and geographic distribution differ. Chagas disease is caused by infection with a protozoan, leprosy by a mycobacterium, and LF and onchocerciasis by filarial nematodes. Three are vector-borne diseases, but leprosy is transmitted directly from person to person. Chagas disease occurs only in the Americas, onchocerciasis is found predominantly in Africa, and LF and leprosy occur in all tropical regions.

Chagas Disease

Chagas disease—also known as American trypanosomiasis—is a zoonotic disease caused by the protozoan hemoflagellate *Trypanosoma cruzi* that is mainly transmitted by large, blood-sucking, reduviid bugs of the subfamily *Triatominae* (known as *kissing bugs*). Infection with this blood parasite has been recorded in more than 150 species of 24 families of domestic and wild mammals as well as in humans. In the vertebrate host, *T. cruzi* usually infects macrophage, muscle, and nerve cells.

Human infection with *T. cruzi* most commonly originates through contact of broken skin or mucosa with the excretion of infected insect vectors. The incubation period ranges from 7 to 15 days, leading to the acute phase of infection—characterized by patent parasitemia—which may last up to four weeks. The acute phase may be without obvious symptoms. Romaña's sign—that is, unioocular, bipalpebral edema with regional lymphadenopathy—is diagnostic of the acute infection but occurs in less than 5 percent of infections.

If a recent infection is untreated, the individual will remain infected for life. After an asymptomatic period of 10 years or more, some 10 to 40 percent of those infected will develop cardiac or digestive complications that are characteristic of the chronic stage of the disease. In chagasic myocardopathy the most common symptoms are dyspnea and arrhythmias. Electrocardiographic alterations can occur, such as right bundle branch block, left anterior hemiblock, or both, which may require a pacemaker implant. Apical aneurisms are also typical of advanced chagasic cardiopathy, which may rupture on excessive exercise, leading to sudden death. Chagas disease can also involve intestinal complications characterized by severe dilations of parts of the digestive tract known as megasyndromes. Megaesophagus and megacolon are the most common. Symptoms of megaesophagus are dysphagia and odinophagia and subsequent malnutrition. Chagasic megacolon is characterized by constipation and meteorism. As a result of colon distension and contractions, abdominal pain is frequent, and fecalomas are a complication.

More than 120 species of *Triatominae* and three transmission cycles are recognized. The domestic cycle, responsible for maintaining infection in humans, occurs mostly in rural or periurban areas where houses have adobe walls and thatched roofs. Humans, dogs, cats, and in some countries guinea pigs are the main parasite reservoirs in this cycle. The vector lives and multiplies in cracks in the walls, holes in the roof, under and behind furniture and pictures, and so on. The sylvatic cycle involves sylvatic triatomine bugs that become infected and in turn infect rodents, marsupials, and other wild animals. The third is the peridomestic cycle in which mammals participate (domestic rodents, marsupials, livestock, cats, dogs) by moving freely in and out of human dwellings, and sylvatic bugs are attracted to lights in houses and to food. This peridomestic cycle acts as a link between the domestic and sylvatic cycles. Occasionally, infected sylvatic species of *Triatominae* fly into houses and contribute to transmission either by feeding and defecating on the people or their domestic animals or (indirectly) by contaminating food and drink in which the parasites can survive. In the Amazon region, cases of acute Chagas disease have been associated with sylvatic *Triatominae* contaminating sugarcane or fruit juice.

Transmission by blood transfusion is the second-most common way of acquiring *T. cruzi* infection. The true incidence of infection through blood transfusion is unknown, because most cases are not recognized. In transfusionally acquired *T. cruzi* infection, the incubation period is 30 or more days, and the most common symptoms are fever, general lymph node enlargement, and splenomegaly (Schmunis and others 2001).

Transplacental transmission of *T. cruzi* can occur, and estimates indicate that 5 percent of newborns born to chagasic mothers will become infected. Less common routes of transmission are by transplantation with an infected organ or,

more rarely, through contaminated food or infection in the laboratory (WHO 2002a).

Lymphatic Filariasis

LF is caused by species of nematode parasites—*Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*—and is transmitted by mosquitoes (WHO 2002c). The adult filarial parasites live in the lymphatics of humans. After mating, each female worm produces several thousand offspring, microfilariae, during its lifetime. The microfilariae are found in humans' internal organs and appear in peripheral blood at times that coincide with the vector's biting activity. The biting mosquito ingests the microfilariae along with the blood meal, and they develop into infective-stage larvae in 10 to 12 days. When an infective mosquito bites a human, the infective-stage larvae are transmitted to the human host and develop into the adult stage in about one year. The adult parasites live 5 to 10 years, of which the fecund life span is 4 to 6 years. Several hundreds to thousands of infective mosquito bites are necessary to establish infection.

Of the three parasite species, *W. bancrofti* accounts for nearly 90 percent of LF infections worldwide. *B. malayi* is prevalent only in some parts of South and Southeast Asia, and *B. timori* is found only in Indonesia. Several species of *Culex*, *Anopheles*, *Aedes*, and *Mansonia* mosquitoes are involved in the transmission of LF. *C. quinquefasciatus* is the major vector in Africa, Asia, and South America and transmits nocturnally periodic *W. bancrofti*. Among anophelines, *An. gambiae* and *An. funestus* play a significant role in Africa. Several *Aedes* species, particularly *Ae. polynesiensis*, are the major vectors in the South Pacific islands, where diurnally subperiodic *W. bancrofti* is common. *B. malayi* is primarily transmitted by *Mansonia* and *Anopheles* species.

Infected people can harbor microfilaremia without overt clinical manifestations. The disease process is determined primarily by living adult worms, inflammatory responses caused by the death of adult worms, and secondary bacterial infections. The inflammatory response begins with the death of or damage to adult worms, which leads to host reaction and acute filarial lymphangitis. A heavy worm burden and the presence of worms in the scrotal area precipitate the development of hydrocele, chyluria, chylocele, and lymph scrotum. Lymphatic dysfunction caused by dilatation of the lymphatic vessels makes the patient more prone to repeated secondary bacterial infection, which precipitates lymphedema and elephantiasis. Microfilariae play an important role in the pathogenesis of tropical pulmonary eosinophilia (Dreyer and others 2000).

Onchocerciasis

Onchocerciasis is an infection with the filarial parasite *Onchocerca volvulus*. The main complications are severe eye disease that can lead to blindness and severe skin disease with

unsightly lesions and intense itching (WHO 1995a). *O. volvulus* is transmitted by vector blackflies of the genus *Simulium*, whose larvae and pupae develop in rapidly flowing, well-oxygenated streams and rivers. As a result, onchocerciasis is often known as *river blindness*. The most important vectors are members of the *S. damnosum* complex in Africa and the Middle East and *S. neavei* in parts of East Africa. Of the many vectors in the Americas, the most important are *S. ochraceum*, *S. metallicum*, *S. oyapockense*, *S. guianense*, and *S. exiguum*.

When taking a blood meal, infected *Simulium* vectors deposit one or more infective (third-stage) *O. volvulus* larvae, which reach adulthood in the human host after about a year but may live as long as 14 years. The adult worms typically entwine in nodules where they mate, producing microfilariae that migrate into the skin, eyes, and other organs. These microfilariae are unable to develop into adult worms without first being ingested in the blood meal of a blackfly vector. The microfilariae transform in the vector over a period of 6 to 12 days to produce the third-stage larvae that are infective to humans.

The thousands of microfilariae that do not succeed in reaching a blackfly vector die in the human body, provoking inflammatory reactions in tissues. Inflammation in the eyes leads to irreversible ocular lesions, resulting first in impaired vision and finally in total blindness (WHO 1995a). The death of microfilariae in the skin gives rise to intense itching, dermatitis, depigmentation, and atrophy of the skin (Murdoch and others 2002). A less common complication is lymphadenitis, which may lead to hanging groin and elephantiasis of the genitals, and increasing evidence indicates that onchocerciasis is a risk factor for epilepsy and hyposexual dwarfism in certain areas (Boussinesq and others 2002). The greater is the body load of adult worms and microfilariae, the greater is the risk of developing skin and eye disease.

The disease pattern of onchocerciasis—in particular the severity of ocular disease—varies considerably between geographic zones. Onchocercal blindness can be extensive in hyperendemic communities of the West African savannas, whereas in forest villages with a comparable intensity of infection, the skin manifestations tend to be the main complications of the disease (Dadzie and others 1989; Murdoch and others 2002). These differences may reflect the existence of different vector-parasite complexes, with strains of *O. volvulus* that differ in pathogenicity (Zimmerman and others 1992). The vector-parasite complex in the West African savanna is responsible for the most severe form of ocular onchocerciasis in the world: in the most affected villages, more than 10 percent of the population may be blind because of onchocerciasis.

Leprosy

Leprosy is caused by *Mycobacterium leprae*, a gram-positive, strongly acid-fast bacterium. *M. leprae* is an obligate,

intracellular parasite that resides predominantly in macrophages. It is the only bacterium that infects peripheral nerves, showing a preference for Schwann cells, particularly of unmyelinated fibers.

The disease spectrum of leprosy ranges from a single self-healing, hypopigmented macule to a generalized illness causing widespread peripheral nerve damage and affecting even bones and internal organs. Skin lesions may be well- or ill-defined hypopigmented macules, plaques, or nodules that are localized or distributed over the whole skin. They may be hypaesthetic, anesthetic, hyperaesthetic, or have normal sensibility. Nerve lesions occur in dermal nerves as well as in superficial sensory nerves and mixed nerve trunks. One or more nerves may be enlarged on palpation. Signs such as clawing of fingers and toes, “absorption” of digits caused by repeated injury, and dry skin are secondary to impairment of motor, sensory, and autonomic nerve function.

A diagnosis of leprosy is based on finding at least one of three so-called cardinal signs (ILA 2002):

- diminished sensibility in a typical macule or plaque in the skin
- palpable enlargement of one or more peripheral nerve trunks at specific sites
- demonstration of acid-fast mycobacteria in a slit skin smear.

Currently, patients are classified based on clinical signs only, but skin smear results are taken into account when available. Patients who have more than five skin lesions or who have a positive skin smear are classified as *multibacillary*; others are classified as *paucibacillary*.

The skin signs of leprosy are relatively harmless, but complications of the disease may lead to severe consequences, such as blindness, infertility, disfigurement, and severe sensory and motor disability. Reactions—that is, episodes of acute inflammation caused by hypersensitivity to bacterial antigens—can be particularly severe. Patients can develop nerve damage without any obvious sign of these reactions, but after neuropathy has become irreversible, it may lead to secondary impairments, such as wounds, contractures, and shortening of digits. As a result of visible impairments or activity limitations—or simply because of the diagnosis of leprosy—many people experience psychosocial problems (van Brakel 2000).

The exact mode of transmission of *M. leprae* is still not fully understood, but the respiratory tract seems to play an important role. The primary reservoir of infection is the human host. Untreated multibacillary leprosy patients are able to shed large amounts of *M. leprae* from the nose, and household and social contacts of such patients are at a higher risk of developing leprosy than the general population (van Beers, Hatta, and Klatser 1999). *M. leprae*-specific DNA sequences have been isolated from the noses of apparently healthy individuals, and

widespread seropositivity against *M. leprae*-specific antigens has been demonstrated in endemic areas, although the role of these individuals in transmitting leprosy is not fully understood. Effective antileprosy treatment usually renders a patient noninfectious within a few days.

DISEASE BURDEN

Information on the number of people infected is often difficult to obtain for tropical diseases. Many infected people may be without obvious symptoms, those with symptoms may not seek care at public health facilities, and those who do may not be reported. Routine health information systems provide little information on the number of people infected in the population. Surveys are more informative but are rarely done. A better picture emerges only when control programs need to map the distribution of the disease as a basis for targeting large-scale interventions. Hence, the apparent paradox is that intensification of disease control may result in a significant initial increase in estimates of the burden of disease through better epidemiological data.

Chagas Disease

Chagas disease is an important public health problem in 17 countries in Latin America. Estimates from the 1980s indicated that some 16 million to 18 million individuals were infected (WHO 1991), and in the 1990s, a series of multinational control initiatives was launched that was designed to interrupt transmission by eliminating domestic insect vectors and improving the serological screening of blood donors. As a result, estimates of the number of infected people were revised to 9.8 million in 2001 (Schmunis 2000). The estimated burden of disease in terms of disability-adjusted life years (DALYs) declined from 2.7 million in 1990 (World Bank 1993) to 586,000 in 2001 (Mathers, Murray, and Lopez 2006). Because of migration, *T. cruzi*-infected individuals can be found outside Latin America (for example, in Spain or the United States).

Estimates from the 1980s suggested that 5 million people in the Americas had symptoms of Chagas disease (WHO 1991). These estimates decreased to 1.2 million to 2.8 million in the 1990s. The World Health Organization (WHO) attributed 45,000 yearly deaths to Chagas disease (WHO 1991). WHO decreased its mortality estimates to 13,000 in 2001 (WHO 2002d).

In all affected countries, Chagas disease has been responsible for a high burden of disease and significant direct and indirect costs. Reports from Brazil in the late 1980s suggested that the aggregate costs for pacemakers and intestinal surgeries for Chagas disease were US\$250 million per year, excluding the costs of consultations, care, and supportive treatment for chronic chagasic patients, which amounted to US\$1,000 per

year per patient, and disability awards, which in one state accounted for US\$399,600 (Dias 1987; Schofield and Dias 1991). In Bolivia, in 1992, aggregate treatment costs were estimated at US\$21 million. In Chile, in 1997, aggregate treatment costs for Chagas disease were estimated at US\$14 million to US\$19 million (Schenone 1998), and in Uruguay, in 1996, costs were estimated at US\$15 million (Salvatella and Vignolo 1996).

Lymphatic Filariasis

LF is endemic in 83 countries, with 1.1 billion people living in known endemic areas. In 1992, the WHO Expert Committee estimated that 78 million people were infected (WHO 2002c). This estimate was later revised to 119 million, and current estimates indicate that LF is responsible for the loss of 4.6 million DALYs per year. Many endemic areas lack reliable data on the prevalence of LF, and estimates of the number infected may increase when more precise data become available from epidemiological mapping. Nationwide mapping in four neighboring countries in West Africa showed that LF was endemic in a much wider area than expected, and the findings resulted in a dramatic increase in the estimated number infected (Gyapong and others 2002).

Epidemiological trends have varied widely among different regions in recent decades. LF was controlled or eliminated from several islands in the Pacific, and China has seen a dramatic reduction in infection levels. Unfortunately, in India and Africa, the most endemic areas of the world, recent decades have witnessed little change (WHO 2002c).

The acute form of the disease is common and causes severe hardship in endemic communities. Infected individuals suffer from one to eight acute episodes per year, and during each episode, affected patients are bedridden for three to five days.

Morbidity caused by chronic LF is mostly lifelong, and the disease is considered the second leading cause of disability in the world (WHO 1995b). Patients affected by elephantiasis or hydrocele are often victims of societal discrimination, and the disease impairs their educational and employment opportunities, marriage prospects, and sexual life. Case-control studies in India revealed that affected individuals are 27 percent less productive than their uninfected counterparts (Ramu and others 1996). The patients work less and often switch to lighter jobs, leading to a loss of more than 1 billion person-days per year in India alone (Ramaiah and others 2000), which translates into an annual economic loss equivalent to 0.63 percent of gross national product.

Onchocerciasis

More than 99 percent of those infected with *O. volvulus* reside in 30 endemic countries in Africa, with the remainder living in the Republic of Yemen and six countries of the Americas.

In 1995, the WHO Expert Committee on Onchocerciasis estimated that 17.7 million people were infected, of whom about 270,000 were blind and another 500,000 were severely visually impaired (WHO 1995a). However, more recent information from rapid epidemiological mapping of onchocerciasis (Noma and others 2002) by the African Programme for Onchocerciasis Control (APOC) indicates that the number of those infected is twice as high and that some 37 million people were infected in 1995. This revised estimate corresponds to an estimated 1.99 million DALYs lost because of onchocerciasis in 1995.

Using the most recent rapid epidemiological mapping data and the latest APOC data on treatment coverage and assuming that four rounds of ivermectin treatment will reduce the prevalence of troublesome itching by 85 percent and the burden of visual impairment and blindness by 35 percent give a DALY estimate of 1.49 million DALYS lost for 2003 (see table 22.1).

In addition to the burden of blindness and severe itching, onchocerciasis has important socioeconomic consequences. In the West African savanna, fear of blindness has resulted in the depopulation of fertile river valleys, severely affecting agricultural production. It was this socioeconomic impact, and not just the health impact, that led to the creation of the Onchocerciasis Control Program (OCP) in West Africa in 1975 (Remme 2004b).

Even though the importance of onchocercal blindness has long been recognized, only in 1995 did research demonstrate that the public health importance of onchocercal skin disease was even greater. Troublesome itching associated with dermal onchocerciasis makes working, studying, or interacting socially difficult (Murdoch and others 2002; Vlassoff and others 2000). Onchocercal itching now accounts for 60 percent of DALYs lost (Remme 2004a). Other skin manifestations, such as reactive skin lesions, are not included in the DALY estimates, even though they are highly prevalent and have major psychosocial and economic impacts. Onchocercal skin disease also diminishes people's income-generating capacity, and the school dropout rate is twice as high among children from households in which the head of household is affected by onchocercal skin disease (Benton 1998).

Leprosy

In May 2001, 10 years after the World Health Assembly had adopted a resolution to eliminate leprosy by the end of the millennium, the target—a prevalence rate of less than 1 per 10,000—had been achieved at the global level. The number of cases registered for treatment worldwide fell from 5.4 million in 1985 to 460,000 by the end of 2003 (WHO 2004a); however, this trend should not be taken at face value because the reduction is attributable mainly to such factors as the shortening of

treatment duration for multibacillary patients and the cleaning up of patient registers.

Leprosy is reported from all regions of the world, but the burden of disease, which is estimated at 192,000 DALYs, is concentrated in a few countries. During 2003, 513,798 new cases were detected, of which more than 80 percent were in Brazil, India, Madagascar, Mozambique, Nepal, and Tanzania (WHO 2004a). India alone accounted for about 75 percent of the new cases. Case detection has remained remarkably stable over the past decade. Trends in case detection rates should be analyzed in conjunction with the proportion of new patients with grade 2 impairment (an indicator of the delay between onset of the disease and diagnosis) and the proportion of children among new cases (an indicator of recent transmission).

Virtually all published data on leprosy-related disability concern impairments. In 1997, WHO estimated the global prevalence of patients with visible impairments (disability grade 2) as 2 million. A similar number may have sensory impairment without deformity. Sensory and motor impairment that are already present at diagnosis are important risk factors for developing additional impairment and disability. Evidence indicates that sensory impairment itself causes significant functional disability.

The prevalence of activity limitations among people affected by leprosy is unknown. Van Brakel and Anderson's (1998) survey in Nepal finds that among those with any impairment, about 20 percent had limitations in relation to one or more indoor activities and up to 34 percent had significant limitations in relation to common outdoor activities. Even less is known about the prevalence of restrictions on social and economic participation. Surveys are urgently needed to assess the extent of patients with leprosy-related disabilities who require intervention.

Two difficulties affect the validity of DALY estimates for leprosy. The first is the lack of data, particularly on the burden of functional and psychosocial disability caused by leprosy. The second is that the effect of leprosy often goes well beyond the affected individual; the psychosocial consequences may affect the whole family. People without any visible signs of leprosy may be stigmatized simply because they are known to be a leprosy patient. Even after completing treatment, people may remain stigmatized.

Summary of DALY Estimates

Table 22.1 summarizes the DALY estimates for each of the four diseases by World Bank region. The high estimate for LF reflects not only its wider distribution and the larger number of people affected, but also the reduction in the burden for the other three diseases as a result of control efforts. For those diseases for which there has been significant progress toward elimination, public health officials should remain aware of the

Table 22.1 DALYs Lost, by Disease and World Bank Region (thousands)

Disease (date of information)	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa	High-income countries	Total
Chagas disease (2001)	0	1	583	0	0	0	1	585
LF (2001)	373	1	9	4	2,412	1,656	212	4,667
Onchocerciasis (2003)	0	0	2	0.4	0	481	0	484
Onchocerciasis (latest APOC data)	0	0	2	0.4	0	1,487	0	1,490
Leprosy (2001)	34	0	18	2	113	24	1	192

burden of disease that is currently averted but that might return if control were not to be sustained before transmission has been completely eliminated.

INTERVENTIONS AND THEIR EFFECTIVENESS

For each of the four diseases in this chapter, effective interventions are available.

Chagas Disease

The primary approaches to control of Chagas disease are halting transmission and providing adequate treatment for those infected. The two most important routes of transmission are insect vectors and blood transfusion from infected donors; thus, control programs focus on eliminating domestic vector populations and improving the serological screening of blood donors.

Vector Control. *Triatoma infestans* lives only inside houses and in the peridomestic area. Work during the late 1940s suggested that spraying houses with residual insecticides could eliminate vectors' domestic populations. The effect and sustainability of such vector control programs can be enhanced when they are combined with improved housing and when communities are well informed and closely involved in vector surveillance activities.

Argentina and Brazil initiated programs for nationwide vector control in the 1960s, and Chile and Uruguay did so in the 1970s. These programs were strengthened in 1991 by the Southern Cone Initiative, a multinational effort to eliminate infestation by *T. infestans* launched by the ministries of health of Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay and coordinated by the WHO Regional Office for the Americas. Similar regional initiatives for Central America and the Andean

Pact regions, targeted primarily against *Rhodnius prolixus*, followed in 1997.

The results in the Southern Cone region have been impressive, with vast areas now free of domestic infestation with *T. infestans* and other vector species. In Argentina, seroprevalence rates among men age 18 to 20 drafted for military service decreased from 5.8 percent in 1981 to 1.2 percent in 1993. The number of cases of Chagasic cardiomyopathy, when compared with the number expected in the absence of control, indicates a decrease of 81 percent in the population up to 18 years of age. In 2001, a WHO commission certified that 4 of the 18 endemic provinces were free of vectorial transmission. In Brazil, domestic infestation rates decreased by 98.3 percent between 1991 and 2000. Of the 11 Brazilian states that were originally endemic for *T. infestans*, 9 have been certified as free of vectorial transmission. In Chile, house infestation rates decreased from 28.80 percent in 1982 to less than 0.01 percent in 1999, when the country was certified free of vectorial transmission. Uruguay also achieved a dramatic reduction in house infestation rates, from 5.7 percent in 1983 to 0.3 percent in 1997, when it too was certified as free of vectorial transmission. Bolivia and Paraguay have not yet eliminated transmission, but thousands of houses have been sprayed since 1991.

Blood Transfusion Control. The purpose of screening for *T. cruzi* in blood banks is to eliminate all units of potentially infected blood. Argentina and Brazil require screening to be done using two serological tests to reduce the risk of false negatives; however, the cost-benefit ratio of the two-test approach may be questionable in countries where prevalence is low and the reagents used for diagnosis are highly sensitive.

In 1993, the national coverage of blood donor screening was analyzed in four Central American and six South American countries (Schmunis and others 1998). At that time, only Honduras, Uruguay, and República Bolivariana de Venezuela screened 100 percent of donors, and even in those countries

infected transfusions were possible because of the lack of sensitivity of the reagents used. Since then, the sensitivity and specificity of serological tests have improved, and more countries have passed legislation requiring the screening of all blood donors. By 2001, seven endemic countries were screening 100 percent of blood donors for *T. cruzi*, four were screening more than 99 percent of donors, and two were screening about 90 percent; but four countries were still screening fewer than 25 percent of donors. In countries with a high number of immigrants from Latin America, such as Spain and the United States, thousands of individuals are potentially infected, and screening of blood donors for *T. cruzi* infection may be indicated in these countries.

Treatment. If untreated, most individuals infected with *T. cruzi* will remain infected for life. Spontaneous cure is rare. Only two drugs, nifurtimox and benznidazole, are effective for treating *T. cruzi*. Both are highly effective for acute infections and can be used in cases of congenital Chagas disease. Their effectiveness for treating chronic cases remains unclear, but increasing evidence indicates that they are effective in clearing parasitemia when administered to young cases, which may impede the development of chronic lesions. Both drugs may cause serious side effects and should be administered under medical supervision.

Lymphatic Filariasis

In recent years, new control tools and strategies have become available for LF (Ottesen and others 1997), and the World Health Assembly has adopted a resolution on the global elimination of LF. The Global Programme for the Elimination of Lymphatic Filariasis was launched in 2000 with the primary goals of interrupting transmission and preventing suffering and disability caused by the disease (Ottesen 2000).

The core strategy for interrupting transmission is annual mass drug administration (MDA) to treat the entire at-risk population for a period long enough to ensure that levels of blood microfilariae remain below those necessary to sustain transmission. Two annual, single-dose, two-drug regimens are recommended for MDA: ivermectin plus albendazole in African countries that are coendemic for onchocerciasis, and diethylcarbamazine plus albendazole for all other endemic countries. Where feasible, diethylcarbamazine-fortified salt as the only source of domestic salt for a period of at least six months would be an alternative strategy to MDA.

The principal strategy for alleviating suffering and decreasing the disability caused by LF focuses on decreasing secondary bacterial and fungal infection of limbs or genitals whose lymphatic function has already been compromised by filarial infection. Operationally, a regimen of meticulous local hygiene of affected areas and the creation of hope and understanding

among patients and their communities are the principal strategic approaches (Dreyer, Dreyer, and Noroes 2002).

Mass Treatment. It is not yet known how many years of MDA are needed to eliminate LF transmission, but empirical evidence on the effect of MDA on transmission is progressively becoming available. In *Anopheles*-transmitted *W. bancrofti* in Papua New Guinea, four rounds of MDA with diethylcarbamazine or diethylcarbamazine plus ivermectin that reached about 88 percent of the target population reduced the annual transmission potential (the estimated number of infective-stage larvae inoculated per person per year) by 97 percent and 84 percent in low- and high-transmission areas, respectively. In India, where *W. bancrofti* is transmitted by *C. quinquefasciatus*, six rounds of MDA that reached 54 to 75 percent of the target population reduced the annual transmission potential by 95 and 80 percent in diethylcarbamazine- and ivermectin-treated villages, respectively (Ramaiah and others 2003). Modeling studies indicate that the required duration of treatment will depend largely on the treatment coverage achieved and the extent of systematic noncompliance to treatment—that is, noncompliance by the same individuals during successive treatment rounds (Stolk and others 2003). The physiology of the vectors also plays a role, because with *Culex*-transmitted LF, the critical microfilariae density required to interrupt transmission is thought to be lower than in areas where *Anopheles* is the vector.

The addition of albendazole to the two established antifilarial drugs—diethylcarbamazine and ivermectin—is based on clinical trials indicating that the combination therapy is as good as or better than single-drug therapy and that albendazole may enhance the macrofilaricidal action of diethylcarbamazine. Albendazole is also effective and safe against intestinal helminth infections, and its inclusion may enhance compliance with MDA. However, clinical trials have not yet been conclusive, and more robust evidence on the advantages of combination therapy is needed (Addiss and others 2004; Gyapong and others 2005). Community trials are ongoing in India and Africa, and preliminary results of a trial in south India suggest that the combination of diethylcarbamazine and albendazole may indeed achieve greater reduction in the prevalence of antigenemia than diethylcarbamazine alone (Rajendran and others 2002). A study in Nigeria showed that the addition of albendazole to ivermectin had an additive effect on reducing LF mosquito infection rates. (Richards and others 2005).

Vector Control. Vector control has sometimes been extremely effective against LF. In the Solomon Islands, 9 to 10 years of vector control virtually eliminated LF. In India, five years of integrated vector control in an urban area reduced the overall prevalence of microfilariae by 28 percent and the prevalence in children by 92 percent. Studies suggest that 11 to 12 years of

effective vector control may eliminate LF (Ramaiah, Das, and Dhanda 1994). Vector control combined with chemotherapy produced the best results. The introduction of polystyrene beads in vector breeding habitats and treatment with diethylcarbamazine reduced the annual infective biting rate in Tanzania by 99.7 percent (Maxwell and others 1990). In India, vector control combined with single-dose treatment with diethylcarbamazine plus ivermectin reduced the annual transmission potential by 96 percent, compared with 60 percent using chemotherapy alone (Reuben and others 2001).

Such results, along with the limitations of MDA for completely eliminating microfilariae in some situations, have reactivated the debate on the role of vector control in LF elimination (Burkot and Ichimori 2002). However, few endemic countries have an adequate vector control infrastructure.

In some African countries, the same vector species transmit both LF and malaria. In such situations, the effect of malaria control measures, particularly insecticide-treated bednets, on LF vector densities and transmission needs further evaluation. A review of the role and feasibility of community-based vector control strategies and large-scale application of biological control agents is also needed.

Morbidity Management. The second objective of the Global Programme for the Elimination of Lymphatic Filariasis is to decrease the disability caused by LF. Simple and cheap methods have been developed for managing lymphedema, using water and soap occasionally supplemented with antibiotics. Studies in India, Africa, and the Americas have shown that such methods can significantly improve the quality of life of those affected, but implementation of this strategy has greatly lagged behind the MDA campaigns.

Onchocerciasis

Onchocerciasis control is based on vector control and large-scale ivermectin treatment.

Vector Control. Vector control used to be the only feasible intervention when available drugs were too toxic for large-scale use. Following success with vector control in Kenya, where the application of larvicides resulted in local elimination of the vector *S. neavei*, and in selected locations in West Africa, where the application of larvicides effectively stopped local vector breeding but could not prevent reinvasion of infective vectors from elsewhere, vector control was considered feasible in the West African savanna if carried out on a large scale. In 1975, the OCP started large-scale vector control operations using helicopters for weekly spraying of larvicides over the vector breeding sites in river rapids (Molyneux 1995). The operation ultimately covered some 50,000 kilometers of rivers over a geographic area of 1,235,000 square kilometers. The OCP's strategy was to maintain vector control for at least 14 years to

interrupt transmission and eliminate the parasite reservoir. Despite initial problems with reinvasion by infective flies, the strategy proved effective, eliminating onchocerciasis as a public health problem throughout the OCP area. The OCP was successfully concluded in 2002, but concerns remain about the possible recrudescence of onchocerciasis through reinvasion by infected blackflies or migration of infected persons into OCP areas. The OCP countries, therefore, need to maintain effective surveillance to identify any recurrences of infection (Richards and others 2001).

Treatment with Ivermectin. In 1987, Merck & Co., the manufacturer of ivermectin, agreed to donate the drug for onchocerciasis control for as long as needed (Peters and Phillips 2004). Clinical and community trials involving more than 70,000 people showed that annual ivermectin treatment was safe, prevented ocular and dermal morbidity, and significantly reduced transmission; however, ivermectin is a microfilaricide and does not kill the adult worms, and long-term treatment is needed to sustain suppression of the microfilarial load (Remme 2004b). Additional research is needed to determine the extent to which repeated treatments reduce the reproductive capacity of the adult worm population over time.

The introduction of ivermectin allowed the OCP to achieve its objective in 12 years instead of 14 by combining vector control with ivermectin treatment, but most important, it also provided an opportunity to control onchocerciasis in endemic areas outside the OCP where vector control was not feasible. This ability led to the creation of two other regional programs for controlling onchocerciasis in endemic areas of Africa and the Americas: APOC (Remme 1995) and the Onchocerciasis Elimination Program for the Americas (OEPA) (Richards and others 2001).

The World Bank and WHO launched APOC in 1995 to serve 19 onchocerciasis-endemic countries outside the OCP. APOC's principal strategy is to establish annual ivermectin distribution in highly endemic areas to prevent eye and skin morbidity. In partnership with ministries of health and non-governmental organizations, APOC currently provides more than 35 million ivermectin treatments per year and aims to reach 65 million treatments per year before its scheduled termination in 2010. APOC uses an approach referred to as *community-directed treatment with ivermectin*, whereby local communities rather than health services direct the treatment process (Amazigo and others 2002). A community decides collectively whether it wants ivermectin treatment, how it will collect ivermectin tablets from the medical supply entity, when and how the tablets will be distributed, who will be responsible for distribution and recordkeeping, and how the community will monitor the process. Health workers provide only the necessary training and supervision. To date, communities have responded enthusiastically to this approach (Seketeli and

others 2002), and interest is now growing in exploring this strategy for interventions against other diseases (Homeida and others 2002).

In the Americas, *O. volvulus* transmission occurs only in a few small areas in six endemic countries. Accordingly, OEPA's strategy is based on intense ivermectin treatment twice a year that should allow eventual cessation of ivermectin delivery without the risk of recrudescence (Richards and others 2001). OEPA was launched in 1992 and is currently reaching more than 85 percent of its intended target population.

Leprosy

The objectives of leprosy control are to interrupt transmission, to cure patients, to prevent the development of associated deformities, and to rehabilitate those patients already afflicted with deformities. The strategy involves early case detection and the provision of adequate chemotherapy and comprehensive patient care (ILA 2002).

Multidrug Therapy. Dapsone therapy for leprosy was introduced in the late 1940s and successfully used as monotherapy for two decades. In the 1970s, resistance to dapsone emerged, and WHO introduced multidrug therapy (MDT) in 1982. Paucibacillary patients were to be given a six-month regimen of daily dapsone and supervised monthly rifampicin. Multibacillary patients were to be treated with a three-drug regimen for two years or, where feasible, until the skin smear had become negative. This regimen followed the paucibacillary regimen, adding a smaller daily dose of clofazimine and a larger supervised dose once a month.

These regimens have had good results, with a relapse incidence of less than 0.1 percent per year (ILA 2002). No multidrug-resistant leprosy has been reported so far, and reports of rifampicin-resistant *M. leprae* have been few. In 1998, the standard multibacillary MDT regimen was shortened to 12 months. Long-term relapse rates for the 12-month regimen are not yet available.

Public health specialists expected that wide application of MDT together with earlier diagnosis resulting from the upgrading of leprosy services would have a considerable effect on transmission; however, by 2002, clear evidence of a reduction in transmission had not been seen.

Immunoprophylaxis and Chemoprophylaxis. Several randomized trials have shown that vaccination with the bacillus Calmette-Guérin (BCG) vaccine reduces the risk of developing leprosy (Fine and Smith 1996), with the level of protection varying from 20 to 80 percent. Chemoprophylaxis based on dapsone or intramuscular acedapsonone conferred overall protection against leprosy of about 60 percent (Smith and Smith 2000). Two large trials are currently under way in Bangladesh and Indonesia to investigate the efficacy of one or two doses

of rifampicin in preventing leprosy, with preliminary results from the Indonesian trial indicating a significant protective effect.

Prevention of Disabilities. As concerns primary prevention, leprosy-related disability is preventable, but when peripheral neuropathy has become established, it is irreversible and leads to lifelong morbidity and disability (Bekri and others 1998; Meima and others 1999). Early case detection and treatment are therefore likely to be the most effective interventions in relation to preventing disability. When detected and treated in time with corticosteroids, primary impairments may be reversible, but because many patients present late, some 11 to 51 percent do not recover or get worse.

In relation to secondary prevention, the main strategy is self-care to prevent worsening of impairments in people who already have irreversible neural impairment or secondary impairments such as wounds and contractures. The role of health care workers is to educate patients so that they can be responsible for the daily management of the effects of nerve function impairment. An essential part of secondary prevention is the use of protective footwear by people with anesthetic feet. Several studies have shown that the use of locally acceptable, appropriate footwear is a cost-effective intervention for those with a loss of plantar sensation (ILA 2002). Reconstructive surgery, protective footwear for people with insensitive feet, and assistive devices to correct or prevent activity limitations are also used in secondary prevention.

As concerns tertiary prevention, the stigma attached to leprosy often prevents patients from participating in normal community activities. Strategies include counseling of those affected and their families, neighbors, and communities; vocational training; and advocacy work.

Rehabilitation. Impairments often lead to activity limitations and restrictions on social participation, which can be prevented by correcting the underlying impairment if it is not yet irreversible. After impairment is established, activity limitations can still be minimized with the help of reconstructive surgery or appropriate assistive devices, such as orthoses, grip aids, calipers, or prostheses. A large but unknown percentage of people succeed in overcoming activity limitations by themselves. Some require rehabilitation interventions, such as physical or occupational therapy, reconstructive surgery, or temporary socioeconomic assistance.

Intervention Effectiveness

For all four diseases covered in this chapter, interventions are available that are effective under routine control conditions. The feasibility of eliminating these diseases as public health problems from most endemic areas is therefore not in doubt; however, questions remain about the effectiveness and

sustainability of control under specific conditions and about the feasibility of eliminating the parasites and transmission. The vector control strategy for Chagas disease worked well in the Southern Cone countries, but the sylvatic reservoir of *T. cruzi* remains unaffected, and continued surveillance will be essential. Vector control is more challenging in the Andean and Central American countries, where some of the vectors are not domiciliated. For LF, the number of years of MDA and the treatment coverage required to interrupt transmission remain unknown, just as the epidemiological conditions and the number of rounds of ivermectin treatment required to achieve the same for onchocerciasis are not yet known. For leprosy, the key questions remain how much effect MDT has on transmission and when the incidence of new cases can be expected to decline significantly. Hence, the sustainability of control remains a critical issue.

The control programs for three of the diseases depend on drug donations. To date, the pharmaceutical companies donating the drugs and the donors supporting drug distribution have shown impressive commitment to the programs, but if their commitment were to lapse, the control programs would collapse and the diseases would return as public health problems. Another risk is drug resistance. The control programs rely on just a few drugs, and even though drug resistance is not currently apparent, if it were to emerge, the essential tools for control would be lost. Hence, although elimination is in sight, the battle has not yet been won, and research to develop new and improved interventions and strategies for these tropical diseases remains important.

COSTS AND COST-EFFECTIVENESS OF INTERVENTIONS

The published information on cost-effectiveness of interventions for the four diseases is incomplete, and this section provides some new data on the cost per DALY averted that is not available in the literature.

Chagas Disease

For the Southern Cone countries, investment in the control of Chagas disease since 1991 has been about US\$320 million, well within the original estimates of US\$190 million to US\$350 million (Schofield and Dias 1991). Initial predictions of cost-effectiveness suggested an internal rate of return (IRR) for the initiative of about 14 percent, but point studies during the course of the interventions suggest actual IRRs of about 30 percent for Brazil (Akhavan 1998) and more than 60 percent for the province of Salta, Argentina (Basombrio and others 1998).

Brazil had an estimated 2 million infected individuals in 1995. Annual follow-up of the 1.6 million asymptomatic cases

would have cost US\$98 million. Diagnosis of megasyndromes for 6 percent of infected individuals at an average cost of US\$141 each would add US\$16.9 million, and corrective surgery for 3 percent of the latter would add US\$60 million. Cardiac pacemakers for 5 percent of infected individuals at US\$3,000 each would add another US\$30 million, so that the partial direct costs for medical attention in Brazil in 1995–96 would have been US\$205 million.

In Argentina, the costs for medical attention in 1992 were US\$435 for acute cases, US\$122 per patient for asymptomatic cases, US\$336 for moderate cardiopathy, and US\$1,135 for severe cardiopathy. Given that Argentina had 2 million infected individuals, and assuming that 85 percent of them would have been asymptomatic, 9 percent would have had mild cardiopathy, 4 percent would have had moderate cardiopathy, and 2 percent would have had severe cardiopathy, then total expenditures for medical attention would have amounted to US\$457 million.

In Chile, aggregate treatment costs were estimated at US\$37 million in 1991. New estimates in 1997 using the government payment schedule and an estimate of 142,000 people infected, including 26,545 with myocardiopathy of which 9,652 were severe cases, resulted in an estimated cost of US\$14 million to US\$19 million. In Uruguay, annual costs for treatment were estimated at US\$15 million for 1996.

These treatment costs are significantly higher than the costs of vector control, which for 1996 were US\$13 million in Argentina, US\$28 million in Brazil, US\$650,000 in Chile, and US\$4,000 in Uruguay. Akhavan's (1998) study in Brazil estimates a cost of US\$260 per DALY prevented, and Robles's (1997) study in Bolivia indicated a cost of US\$362 to prevent one year of life lost.

Data on the cost-effectiveness of treating those infected are sparse; however, Robles's (1997) study in Bolivia estimates the costs of treating infected children under the age of five, coming up with a cost of US\$3,009 per death averted or about US\$100 per DALY averted.

Lymphatic Filariasis

The most widely used interventions for LF control are MDA, vector control, and administration of diethylcarbamazine-fortified salt. We estimate the cost-effectiveness of those strategies in terms of DALYs averted from studies in India on the costs and effectiveness of control and for different scenarios for the minimum duration of control required to achieve sustained interruption of transmission. These scenarios assume that all three strategies are implemented in areas with similar levels of endemicity of *Culex*-transmitted Bancroftian filariasis and that the available cost data for India apply.

We consider three scenarios (table 22.2). *Elim1* is an optimistic elimination scenario under which sustained interruption of transmission is achieved after a relatively short period

Table 22.2 Costs per DALY Averted for LF

Scenario	Mass drug administration			Vector control			Diethylcarbamazine-fortified salt		
	Elim1	Elim2	Control	Elim1	Elim2	Control	Elim1	Elim2	Control
Duration (years)	6	10	30	10	5	30	2	4	30
Costs of control operations per capita (US\$)	0.35	0.65	2.22	2.92	6.64	22.74	0.09	0.29	3.56
Cost per DALY averted (US\$)	4.40	8.10	29.00	47.50	84.30	302.50	1.10	3.62	46.48

Source: Authors' calculations.

of intervention (six annual rounds of MDA, 10 years of vector control, and 2 years of diethylcarbamazine-fortified salt). *Elim2* is a conservative elimination scenario under which sustained interruption is achieved only after a longer period of intervention (10 years of MDA, 15 years of vector control, and 4 years of diethylcarbamazine-fortified salt). *Control* is a scenario under which transmission is brought to low levels but not interrupted and where control efforts will have to continue.

Because of the slow dynamics of filariasis transmission and disease, the prevalence of the chronic disease manifestations (lymphedema and hydrocele) on which the DALY estimates are based will not fully reflect the effect of control for many years. We have therefore tried to predict the trend in chronic disease over a 30-year period. Recent findings from a longitudinal study (Ramaiah and others 2003) of the effect of MDA in Pondicherry, India, showed that the prevalence of hydrocele and lymphedema had declined by 58 percent after seven annual treatment rounds with diethylcarbamazine. We assumed that from the seventh year of intervention, any further reduction in disease prevalence was attributable exclusively to reduced incidence as a result of reduced transmission, and that 30 years after the initiation of the intervention, the prevalence of disease would have fallen by 90 percent. We assumed that the effect of diethylcarbamazine-fortified salt was similar to that of MDA, whereas for vector control we assumed that prevalence would decline with a delay of seven years.

The predicted costs per DALY averted (table 22.3) indicate that MDA and diethylcarbamazine-fortified salt are extremely cost-effective. Elimination with MDA costs about US\$4 to US\$8 per DALY averted, and even if transmission were not interrupted and MDA would have to be continued for 30 years (control scenario), the cost would be still only be around US\$29 per DALY averted. Diethylcarbamazine-fortified salt would be the cheapest intervention, but governments rarely favor it, and compliance can be difficult to ensure. Vector control is at least 10 times more expensive in terms of DALYs averted, but it offers additional benefits in terms of malaria and dengue control and significant relief from mosquito nuisance.

The effect of MDA on hydrocele and lymphedema is not yet well established and the results of the Indian trial on which

the previous calculations are based may be too optimistic. However, even under much less favorable assumptions that the prevalence of hydrocele and lymphedema declines by 20 percent after 7 years of MDA and by 75 percent after 30 years, the estimated cost per DALY averted would be only 50 percent higher than those given in table 22.3, and the interventions would still be very cost-effective.

The prevention of chronic disease also has direct economic benefits (Ramaiah and Das 2004). The cost of preventing one case of chronic disease through six rounds of MDA in India has been estimated at US\$8.41. The economic benefits include savings of 58.24 working days per year per case, yielding wages of US\$39.39 and treatment costs of US\$1.44. On average, chronic patients lose 11 years of productive life; thus, the average economic benefits total US\$449.13 per chronic case averted. This figure gives a benefit-cost ratio of 52.6, perhaps one of the highest for any disease control program.

Onchocerciasis

Investment in onchocerciasis control has included about US\$570 million provided by donors to the OCP during 1975–2002, US\$140 million provided and earmarked for APOC for 1996–2010, and US\$10 million for OEPA for 1991–2003. The African onchocerciasis control programs are considered highly cost-effective. No cost-benefit analysis has yet been published for OEPA.

The OCP has been highly successful. More than 40 million people in the program's 11 countries are now considered free from infection and eye lesions, more than 1.5 million people are no longer infected, and more than 200,000 cases of blindness have been prevented. Sixteen million children born since the program began are free of onchocerciasis. The socioeconomic effect has also been dramatic: 25 million hectares of fertile land in the river valleys were made available for resettlement and agriculture. A cost-benefit analysis of the OCP has estimated the net present value for the OCP over a 39-year project horizon from 1974 to 2002 as US\$485 million (Kim and Benton 1995). This figure corresponds to an IRR of 20 percent, resulting mainly from increased labor because of prevention

of blindness (25 percent of benefits) and increased land use (75 percent of benefits).

A similar cost-benefit analysis for APOC also considered benefits in terms of additional labor resulting from blindness prevention (Benton 1998). It did not consider land use because depopulation of river valleys is rarely seen in APOC countries, where the forest type of onchocerciasis predominates. Nevertheless, the estimated IRR for APOC remained almost as high as that for the OCP (17 percent), because the cost is lower but the number of people served is far greater.

The estimated rates of return for the OCP and APOC did not include the effects of control on onchocercal skin disease. Hence, these rates underestimate the benefits, because troublesome itching accounts for more than 50 percent of the DALYs attributable to onchocerciasis. The cost of ivermectin, which is donated by Merck, was not included in our analyses.

To estimate the approximate cost per DALY averted, we considered the burden of disease and treatment with ivermectin in APOC countries. Using the latest epidemiological mapping data, we estimate that, in 1995, 34.6 million people were infected in APOC countries and that 1.86 million DALYs were lost. Currently more than 44 percent of those infected are covered by community-directed treatment with ivermectin, and expectations are that treatment will be expanded to cover most of the remainder before the end of APOC in 2010. Information from areas where ivermectin treatment has been in effect for more than 15 years shows that the prevalence and intensity of onchocerciasis infection have fallen to low levels (Borsboom and others 2003), and computer simulations predict that the disease could not become a public health problem again for at least another 10 to 20 years if treatment were halted (Remme, Alley, and Plaisier 1995). We therefore estimate that 15 years of ivermectin treatment at 65 percent coverage will prevent at least 25 years of onchocercal disease. If we assume that 70 percent of endemic communities will ultimately be covered by community-directed treatment with ivermectin and that 80 percent of those communities will maintain annual treatment at 65 percent coverage for at least 15 years, at least 26 million DALYs would be prevented over a 25-year period.

The predicted cost of community-directed treatment with ivermectin in APOC countries is US\$145 million by the international donor community plus US\$64 million by ministries of health and collaborating nongovernmental organizations, giving a total of US\$209 million. Therefore we estimate that the cost of community-directed treatment is approximately US\$7 per DALY averted.

The ultimate cost-benefit of onchocerciasis control will depend on how long effective control programs will need to be maintained to keep the disease under control. National governments and ministries of health should plan to invest in ivermectin distribution and in surveillance activities for the foreseeable future. Thus, a case must continually be made with

national decision makers that if investments do not continue, recrudescence of infection is likely. One strategy for sustaining national investment is to show that ivermectin distribution systems can be made polyfunctional. Treatment programs based on MDA for intestinal parasites, schistosomiasis, and LF and on vitamin A distribution can be integrated with ivermectin distribution programs and thereby further improve cost-benefit ratios. The use of community-directed treatment with ivermectin is also envisaged as a way of strengthening peripheral and district health systems (Homeida and others 2002).

Leprosy

Costs associated with leprosy control include case detection, treatment, prevention of disability, and rehabilitation. We calculate the incremental health service cost to arrive at the average cost of curing a patient with leprosy. Our estimates are based on the limited published cost data available, program expenditure data, and expert opinion, although costs are likely to differ substantially by country.

As case-detection rates decrease, the average cost of detecting one case increases. The previous edition of this volume estimated a cost of US\$2 per case detected based on a case-detection rate of about 300 per 100,000; however, case-detection rates are now considerably lower in most countries (Dharmshaktu and others 1999; Ganapati and others 2001; Smith 1999). Many leprosy control programs now rely on voluntary case finding supported by information, education, and communication activities to raise or maintain people's awareness of the early signs and symptoms of leprosy. We estimate the cost of this approach to be about US\$1 per case detected. Nevertheless, if active methods are still used in areas where case-detection rates are low, the cost of case detection may be as high as US\$108.

The costs of diagnosing and treating leprosy have fallen in the past decade, and diagnosis by clinical examination only is now recommended. We therefore exclude the cost of skin smears. In addition, a shortening of the treatment regimen has lowered drug costs to about US\$12 for a multibacillary case and US\$1 for a paucibacillary case. Globally, almost 40 percent of leprosy cases are classified as multibacillary cases, with the remaining 60 percent being paucibacillary cases. Thus, we estimate the average drug cost as US\$5.40 per case.

The cost of treatment, however, is more than the cost of drugs alone. WHO guidelines recommend that a multibacillary case receive supervised treatment for 12 months and that a paucibacillary patient receive treatment for 6 months. Using cost data from Ethiopia and Pakistan, we estimate these treatment costs at US\$20 to US\$30 in low-income countries. Data from studies of tuberculosis interventions show that community-supervised treatment may reduce costs by up to 50 percent (Khan and others 2002), and this approach is being

advocated as part of “flexible MDT delivery” (ILA 2002) and “accompanied MDT” (WHO 2002b). Reducing the nondrug costs of treating leprosy to about US\$10 to US\$20 per patient may, therefore, be possible. We thus estimate the costs of treating a case of leprosy with MDT to be between US\$15.40 and US\$35.40 per case, depending on the strategy used.

About 10 to 20 percent of new leprosy cases are likely to suffer a reaction during or after MDT. We estimate treatment of those reactions to cost US\$25 per patient. Of these patients, 1 percent may develop severe complications requiring hospitalization, at an estimated cost of US\$480 per patient. In addition, 10 percent of new cases will develop neural or secondary impairments and may require footwear and education about wound management. We estimate the lifetime cost of protective footwear at US\$300 per patient (Seboka, Saunderson, and Currie 1998) and education at US\$10 per patient. In 1 percent of cases, reconstructive surgery may be required at about US\$455 per patient. We therefore estimate the average incremental cost of interventions for prevention of disability to be US\$44.15 per new case of disability. Because about 3 percent of new patients will need rehabilitation, we estimate the average cost at under US\$1 for each new case of leprosy detected (Jagannathan and others 1993). However, a backlog of old cases exists. Although data in this area are weak, up to a third of the 4 million people living with leprosy globally (2 million with grade 1 disability and 2 million with grade 2 disability) could require rehabilitation.

Few data are available on the program costs associated with leprosy. A review of expenditure in Asia found that up to 40 percent of the total costs could be classified as programmatic costs, although this amount may now be less because leprosy programs have increasingly been integrated into general health services. Data from Indonesia demonstrate that program costs can be reduced by up to 35 percent by integrating them with tuberculosis programs (Plag 1995). We therefore estimate the average cost of finding, treating, and preventing disabilities and rehabilitating a new case of leprosy at US\$76 to US\$264.

In practice, many leprosy programs will also be providing disability prevention and rehabilitation interventions to a large backlog of patients, so the average cost per new case will be higher than here. Programs that face a high proportion of multibacillary cases and cases presenting with high levels of disability are also likely to have higher costs.

Assuming a cure rate of around 85 percent, we estimate the costs of curing one patient of leprosy to be about US\$93 per new case. Using data from India (25 percent of those with leprosy will self-cure, an average age of onset of 27, a disability weighting of 0.152, and a life expectancy at age 25 to 29 of 44.75), we estimate the cost per DALY of detecting and treating a new case of leprosy to be US\$38.

In addition, assuming a 90 percent success rate, we calculate a cost per DALY of US\$7 for patients needing treatment for

Table 22.3 Cost-Effectiveness Estimates for the Main Interventions for Each Disease

Intervention	Cost per DALY averted (US\$)	Internal rate of return (percent)
<i>Chagas disease</i>		
Vector control	260	30–60
Treatment (children under five)	100	—
<i>LF</i>		
MDA	4–29	—
Diethylcarbamazine-fortified salt	1–46	—
Vector control	48–303	—
<i>Onchocerciasis</i>		
MDA	7	17 (APOC)
Vector control	—	20 (OCP)
<i>Leprosy</i>		
Case detection and treatment	38	—
Prevention of disability	1–110	—

Source: Authors' calculations.

MDA = mass drug administration, — = not available.

reactions and ulcers, US\$75 for those needing footwear and self-care education, and US\$110 for those needing reconstructive surgery. These estimates provide only a broad indication because data on the effectiveness of these interventions are scarce, and the application of the disability weight of 0.152 to all interventions may overestimate their benefits.

Data on the economic effect of leprosy at the national level are not available. However, leprosy affects those who are economically active, with a peak in incidence at 10 to 20 years of age and again at 30 to 50 years of age. Studies of the impact of leprosy on productivity show that deformity from leprosy can reduce the probability of obtaining employment and can reduce household income and expenditure on food (Diffey and others 2000; Kopparty 1995). In addition, leprosy can have a significant social impact because participation in the community may be restricted. This impact continues well beyond the actual treatment period because leprosy-related impairments have a tendency to get worse over time even after the infection has been arrested.

Summary

Available information indicates that interventions for the four diseases are highly cost-effective and that the benefit-cost ratio of control is high (table 22.3).

RESEARCH NEEDS AND PRIORITIES

Because the diseases in this chapter are targeted for elimination as public health problems, it is sometimes assumed that research for these diseases is no longer necessary and that all

Table 22.4 Control Strategies, Major Challenges, and Research Needs for Each Disease

Disease	Principal control strategy	Major problems and challenges	Major research needs
Chagas disease	Interruption of transmission through domestic vector control and improved blood transfusion	Control of nondomiciliated vectors Sustained vector control Millions of those infected still at risk of disease	Strategies for surveillance of nondomiciliated vectors Better drugs and diagnostics
LF	Interruption of transmission through periodic mass treatment Disability alleviation by local hygiene measures	Need for high treatment coverage Unknowns in elimination strategy Limited effect of current drugs	Strategies for high treatment coverage Evidence base for elimination strategies Drug that kills or sterilizes adult worms
Onchocerciasis	Periodic mass treatment to eliminate the disease as a public health problem	Need to sustain high coverage for decades Risk of ivermectin resistance Eradication not possible with current tools	Strategies for sustained high treatment coverage Feasibility of elimination with ivermectin Drug that kills or sterilizes adult worms
Leprosy	Case finding and multidrug treatment Rehabilitation and prevention of disability	Incomplete MDT coverage Need to integrate and sustain control Impact on transmission not known	Integration and sustainability of control Improved diagnosis of infection Prevention and management of nerve damage

Source: Remme and others 2002.

available resources should be allocated to elimination efforts. However, research remains critical to address questions pertaining to how to achieve elimination with currently available tools and especially to how to optimize implementation in different epidemiological, sociocultural, and health system settings. Epidemiological questions on the required intervention coverage, frequency, and duration need to be answered to guide elimination strategies, and research on the risk, prevention, and control of recrudescence is crucial to ensure sustained success.

The Special Programme for Research and Training in Tropical Diseases, a joint project of the United Nations Children's Fund, United Nations Development Programme, World Bank, and WHO, recently undertook a systematic analysis of research needs for each of the 10 tropical diseases in its portfolio (Remme and others 2002). This analysis involved assessing the burden of disease and recent epidemiological trends, reviewing current control strategies, and identifying the major problems and challenges for disease control and the research needed to address these challenges. Table 22.4 summarizes the results of this analysis for the four diseases discussed in this chapter.

Chagas disease has two main research priorities. The first is the development of new vector control strategies that will allow the successful elimination campaign used in the Southern Cone countries to be extended to the Central American and Andean countries, where the vectors are often not domiciliated. The second is the development of effective and affordable treatment for the millions of people already infected and the prevention of chronic complications.

For onchocerciasis and LF, the main research priorities are similar: implementation research to improve MDA; epidemiological research to determine if, when, and with what treatment coverage the parasite reservoir can be locally eliminated for different vector-parasite complexes; and research to develop a macrofilaricide and improved diagnostics that would facilitate elimination.

For leprosy, the research needs were further reviewed during a Scientific Working Group (Special Programme for Research and Training in Tropical Diseases 2003). The meeting arrived at a clear consensus of three top priorities for leprosy research: implementation research on sustainable and integrated residual leprosy control activities, improved diagnosis of infection, and improved approaches for preventing and managing nerve damage.

These are the current main priorities for research in support of elimination. Eradication is not currently anticipated for any of the diseases; thus, research on better tools and strategies that will allow a permanent solution for these infectious diseases is also needed. Furthermore, currently available control tools may be lost because of factors such as resistance, and research to develop replacement tools is essential now.

CONCLUSION

Tropical diseases are often viewed as neglected, because the investments made to fight them appear negligible compared with the massive amounts expended globally on the health

problems of developed countries. Tropical diseases are truly diseases of the poor, but despite the limited resources available for research and control, simple and effective interventions have been developed and delivered to populations in need for the four tropical diseases discussed in this chapter. Thus, experience with these four diseases sends a powerful message: success is possible, even for neglected tropical diseases of poor populations in developing countries. Elimination of these diseases as public health problems can be achieved, and investments in tropical disease research and control can make a significant contribution to poverty reduction.

An important reason for the success was that the interventions were extremely cost-effective. The available cost-effectiveness data, though limited, show convincingly that intervention against these diseases is a good investment, and the argument for investment gets better when other economic benefits, not reflected in DALYs, are taken into account, such as increased food production when fertile land along river valleys became available for agriculture after the control of onchocerciasis in West Africa and increased labor productivity after effective filariasis control in India.

The pharmaceutical industry also played a major role through large drug donations, and the creation of intercountry control programs provided effective mechanisms for implementing interventions, technical support, and coordination. Another reason for the success was a focused research program that ensured the development of interventions based on simple and sustainable approaches that use cheap and “appropriate” technology and that are potentially multifunctional.

Chagas disease, LF, onchocerciasis, and leprosy are now on target for elimination as public health problems from large parts of the world. However, these diseases cannot be eradicated using current tools, and much remains to be done to expand and sustain the control efforts and undertake the necessary research to improve the control efforts as well as to develop more definite solutions. It will be essential, therefore, that donors and ministries of health not abandon these programs because of their success.

Tropical Diseases Lacking Adequate Control Measures: Dengue, Leishmaniasis, and African Trypanosomiasis

Pierre Cattand, Phillippe Desjeux, M. G. Guzmán, Jean Jannin, A. Kroeger, André Médecin, Philip Musgrove, Mike B. Nathan, Alexandra Shaw, and C. J. Schofield

Dengue, leishmaniasis, and African trypanosomiasis (sleeping sickness) are serious diseases that the World Health Organization (WHO) characterizes as lacking effective control measures. They are transmitted by insect vectors and can result in epidemic outbreaks. Specific treatment is unavailable for dengue, although good supportive treatment can drastically reduce mortality. For the leishmaniasis and for sleeping sickness, treatment relies largely on antiquated drugs based on antimony and arsenic, respectively. Sustained control of the insect vectors is difficult for dengue and leishmaniasis because their high reproductive potential allows the vector populations to recover quickly after intervention wherever adequate breeding conditions exist. By contrast, tsetse flies, the vectors for sleeping sickness, have a much lower reproductive potential and could be eliminated over large areas, given adequate organization and surveillance. Through the African Union, African nations are developing a large-scale initiative for areawide elimination of tsetse flies, partly because of sleeping sickness, but also because of their importance as vectors of animal trypanosomiasis, which poses a serious constraint to livestock development and agriculture.

DISEASE CHARACTERISTICS AND TRANSMISSION

Dengue

Dengue is a mosquito-borne viral disease with a high capacity for epidemic outbreaks. Infection can be asymptomatic or can

present with symptoms ranging from mild, self-limiting, febrile illness to severe, life-threatening disease. Two clinical pictures are recognized: (a) dengue fever (DF) and (b) dengue hemorrhagic fever (DHF) or dengue shock syndrome (DSS).

The four dengue serotypes, known as dengue 1, 2, 3, and 4, constitute a complex of the flaviviridae transmitted by *Aedes* mosquitoes, particularly *Ae. aegypti*. Infection by any of the four serotypes induces lifelong immunity against reinfection by the same serotype, but only partial and transient protection against the others. Sequential infection by different serotypes seems to be the main trigger for DHF/DSS.

Disease Manifestations. The incubation period is four to six days. Infants and young children usually develop fever, sometimes accompanied by a rash. Older children and adults may develop either a mild febrile syndrome or classic DF with fever, headache, myalgias, arthralgia, nausea, vomiting, and rash. Skin bleeding, petechiae, or ecchymosis are observed in some patients. Bleeding from the nose, gums, and gastrointestinal tract; hematuria; or hypermenorrhea can accompany the clinical picture. Leukopenia is common and thrombocytopenia is sometimes observed. DF can be incapacitating, but the prognosis is favorable and the case-fatality rate is low.

By contrast, DHF/DSS can be life threatening. It is characterized by high fever, bleeding, thrombocytopenia, and hemoconcentration (Nimmanitya 1993; PAHO 1994). Plasma leakage differentiates DHF/DSS from classic DF. Severity is classified as mild (grades I and II) or severe (grades III and IV), with the

main difference being shock in the latter. In some epidemics, hepatomegaly has been prominent. As with DF, DHF generally begins with a sudden temperature rise accompanied by facial flush and other nonspecific manifestations, such as anorexia, vomiting, headache, and muscle or joint pains. The most common hemorrhagic manifestation is a positive tourniquet test, although petechiae, ecchymosis, epistaxis, and gingival or gastrointestinal bleeding may also be observed. After three or four days, when the temperature returns to normal or below, the patient's condition can suddenly deteriorate with signs of circulatory disturbance. The patient may sweat, be restless, have cool extremities, and show changes in pulse rate and blood pressure. Many recover spontaneously or after brief fluid therapy, but some proceed to shock with typical signs of circulatory failure. Initially patients may be lethargic but become restless and rapidly enter a critical stage of shock. Some patients evolve to severe circulatory failure (DSS), presenting a rapid and weak pulse, a narrow pulse pressure or hypotension, cold and clammy skin, and an altered mental state. DSS is fatal in 5 to 10 percent of cases if fluid management is inadequate or delayed.

Transmission and Epidemiological Trends. The dengue virus is transmitted from humans to humans by *Aedes* mosquitoes, of which the most important is *Ae. aegypti* (Bennett and others 2002; Gubler 1979; Tardieux and others 1990). Female mosquitoes ingest the virus while feeding on viremic individuals, and after an 8- to 12-day incubation period they can transmit the virus to other humans during blood feeding (Watts and others 1987). Thereafter, the female mosquito remains infective for life. Transmission of the virus from infected females to their progeny has been documented, but its epidemiological significance is not well understood (Hull and others 1984; Rosen and others 1983).

Although believed to be of African origin, *Ae. aegypti* is now established throughout the tropics and subtropics, exploiting almost any water-filled container as larval habitat. *Ae. aegypti* is also the urban vector of yellow fever. *Ae. albopictus* also transmits dengue and is an important secondary vector in parts of Southeast Asia and the Pacific. This species is of Asian origin but has spread to parts of Africa, the Americas, and Europe by depositing egg masses in used car tires, which are traded around the world.

Major epidemics of denguelike illness were documented in the 18th and 19th centuries in Africa, the Americas, and Asia, and clinical descriptions of illness compatible with dengue in China date from about 265. During 1900–50, dengue epidemics occurred in Australia, China, Greece, India, Japan, Malaysia, Thailand, and Vietnam and in the Caribbean (Gubler and Kuno 1997). DHF was first recognized in the 1950s, although a similar hemorrhagic fever was reported in Philadelphia in 1780, in Australia in 1897, and in Greece in 1928. Dengue is now endemic in Africa, the Americas, the

Eastern Mediterranean, Southeast Asia, and the Western Pacific. According to WHO, it occurs in more than 100 countries and an estimated 2.5 billion people are at risk.

The increase in dengue epidemics can be attributed to rising levels of urbanization, which promote contact between humans and *Ae. aegypti*; inadequate domestic water supplies; and increasing international travel, migration, and trade, which help disseminate vectors and the virus. Epidemiological changes in the Americas since the 1970s illustrate this process. During the 1940s through the 1960s, the *Ae. aegypti* control program was successful in most of the region, with several countries declaring complete eradication. However, after some years, reinfestation with *Ae. aegypti* was apparent, and by 1995 it had returned to most of the previously infested countries. Reinvasion by the vector was followed by increased circulation of the virus, and the region evolved from nonendemic to hypoendemic (sporadic epidemics caused by a single serotype) to hyperendemic (simultaneous circulation of multiple serotypes resulting in frequent epidemics). DHF became a major public health problem. Before 1981, 5 countries in the region reported only a few cases of DHF, but by 2002, 21 countries reported more than 14,000 cases and 250 deaths (Gubler 2002; Guzmán and Kouri 2002, 2003; Guzmán and others 2002).

Leishmaniasis

Leishmaniasis (or the leishmaniasis) refers to infections caused by protozoan parasites of the genus *Leishmania* transmitted by female sandflies (*Phlebotominae*). More than 20 *Leishmania* species are pathogenic to humans, and more than 30 species of sandflies are proven vectors. The disease tends to be focal in distribution. In anthroponotic foci, sandflies transmit parasites from human to human, and in zoonotic foci, sandflies transmit the parasites between mammal hosts and from them to humans.

Disease Manifestations. The different species of *Leishmania* cause illness of differing severity. Visceral leishmaniasis (VL), caused by species of the *L. donovani* complex, is usually fatal if untreated. Mucocutaneous leishmaniasis, caused by the *L. braziliensis* complex, is highly disfiguring and mutilating, and it can be fatal because of secondary complications. Cutaneous leishmaniasis (CL), caused by the *L. major*, *L. donovani*, and *L. braziliensis* complexes, may be a simple, self-limiting skin ulcer, but it can be disabling when numerous lesions occur. Diffuse cutaneous leishmaniasis, caused by the *L. mexicana* and *L. aethiopica* complexes, is longer lasting because of deficient immune responses.

Epidemiological Trends. Leishmaniasis is found in 88 countries worldwide. VL occurs in 62 of those countries, with most of the estimated 500,000 annual cases occurring in poorer rural and suburban areas of Bangladesh, Brazil, India, Nepal, and

Sudan. Mucocutaneous leishmaniasis is mainly limited to South and Central America, whereas most of the estimated 1 million to 1.5 million annual CL cases occur in the Middle East (Afghanistan, Algeria, the Islamic Republic of Iran, Saudi Arabia, and the Syrian Arab Republic) and in Brazil and Peru (Desjeux 1996). Reliable data on incidence and prevalence are scarce because only 33 endemic countries provide official notification of infection.

Leishmaniasis transmission is increasing in several areas. For example, the number of cases of CL in Kabul, Afghanistan, increased from 14,200 in 1994 to 65,000 in 2002, and the number of cases of VL in northeastern Brazil increased from 1,840 in 1998 to 6,000 in 2002. Such increases reflect the following environmental, land-use, and behavioral changes that increase exposure to the sandflies:

- Rural-urban migration seems to have contributed to urbanizing VL in Brazil, whereas in East Africa, VL seems to be more closely associated with migrations of seasonal workers and refugees. Transborder migrations between Bangladesh, India, and Nepal are also a risk factor for VL.
- New settlements in high-risk endemic areas, such as those established by people migrating from high plateaus to tropical plains in some Andean countries, increase their exposure to vectors.
- Development in areas of zoonotic transmission, such as road building, mining, oil prospecting, forestry, and ecotourism, and military activity increase risks for those involved (Desjeux 2001).
- Deteriorating social and economic conditions in the poorer suburbs of some cities may contribute to increasing transmission, especially of VL.

Leishmaniasis can be an opportunistic infection in people with HIV/AIDS, and coinfections have been reported in 34 countries (Desjeux and Alvar 2003). Malnutrition or HIV/AIDS coinfection can also increase disease severity by impairing the immune response.

African Trypanosomiasis

African trypanosomiasis is caused by parasites transmitted by tsetse flies (*Glossinidae*). The most important are forms of *Trypanosoma brucei* that infect humans and livestock, and *T. congolense* and *T. vivax* that infect only livestock. Human infection causes severe disease known as sleeping sickness, which is acute in the case of infection with *T. brucei rhodesiense* but more chronic with *T. b. gambiense*. Both forms lead to central nervous involvement and are fatal without appropriate treatment.

Disease Manifestations. Parasites are transmitted by the bite of infected tsetse flies. They multiply locally in extracellular spaces,

producing a characteristic lesion or chancre. The parasites circulate in blood and lymph, resulting in waves of parasitemia with episodes of fever, often accompanied by chills, rigor, malaise, prostration, and weight loss. These symptoms may occur within days of development of the chancre and constitute the hemolymphatic early stage. Febrile episodes become less severe as the disease progresses, and after a variable period the parasites invade the central nervous system and cerebrospinal fluid, leading to the late stage, with meningoencephalitis typically accompanied by severe and protracted headache, apathy, sleep disorders, irritability, and antisocial behavior.

The clinical features of late-stage sleeping sickness can resemble AIDS. With *T. b. rhodesiense*, meningoencephalitis typically occurs within weeks of initial infection, whereas with *T. b. gambiense*, this syndrome occurs later, sometimes after several years. Untreated disease causes relentless deterioration in cerebral function, with patients becoming increasingly difficult to rouse and passing into coma and death. Infection does not seem to confer immunity, so reinfection can occur after treatment.

Transmission and Vectors. Male and female tsetse flies are obligate bloodsuckers and can transmit trypanosomes, which undergo cyclical development in the infected flies. With *T. b. gambiense*, the main reservoir host is people, so tsetse flies mainly transmit from person to person, although increasing evidence suggests that pigs and some other animals are also important reservoirs. With *T. b. rhodesiense*, the main reservoir hosts are cattle and related animals, so transmission occurs mainly from animals to humans, although transmission from human to human also occurs (Okoth 1986). Mechanical (Frézil 1983), sexual (Rochas and others 2004), and transplacental (De Raadt 1985; Libala, Wery, and Ruppel 1978; Traub and others 1978) transmission have been described but are believed to be insignificant.

Thirty-one species and subspecies of *Glossina* are recognized. All probably can transmit trypanosomes, but only eight are known vectors for human infection. Animal trypanosomiasis can be found wherever wild tsetse flies occur, but human trypanosomiasis is usually associated with historic foci with strong epidemic potential. Most *T. b. gambiense* transmission is attributed to *G. palpalis* species occupying riverine and forest habitats in West and Central Africa, whereas *T. b. rhodesiense* transmission is mainly attributed to *G. morsitans* species in East African savannas. *G. fusca* species, although important vectors of animal trypanosomiasis, are considered insignificant for human forms.

Tsetse flies have an unusual life cycle. An inseminated female nurtures the egg and larva in her uterus, depositing the mature larva on the ground, where it burrows and pupates. Thus, each female produces only one offspring at a time. She produces up to 12 during her two- to three-month adult life span. The

intrinsic population growth rate is low. Even small increases in average daily mortality rates can cause population decline, even to extinction.

Epidemiological Trends. Tsetse flies occur in parts of 37 countries in Sub-Saharan Africa. Animal trypanosomiasis is widespread throughout this region, but human disease is focused in areas of 20 countries. Over the entire tsetse-fly belt, WHO estimates that 60 million people are at risk of infection, with a standing prevalence of about 300,000 infections. Of these, probably fewer than 15 percent are diagnosed and treated (Cattand, Jannin, and Lucas 2001). For *T.b. rhodesiense*, epidemiological work in Uganda estimated that for every individual correctly diagnosed and treated, a further 12 cases are undiagnosed and unreported (Odiit 2003). The incidence of sleeping sickness has been increasing steadily since the 1970s, with epidemics in several areas, particularly the Democratic Republic of Congo (DRC) and northern Angola. In 1998–99, some 45,000 new cases were reported each year, representing a 10-fold increase since the 1960s. Most current epidemics are due to *T.b. gambiense*, although major epidemics of *T.b. rhodesiense* occurred in Uganda in 1978, 1980, and 1988.

The apparent increase is largely attributable to a decline in tsetse and trypanosomiasis control operations, which are influenced both by changing political priorities and by civil unrest and war. In the DRC, some 10,000 cases were diagnosed annually during the 1980s, but after four years with little or no control, the number of reported cases rose to 30,000 per year. In Angola, cases rose sixfold following the interruption of control operations because of war. Transmission is also occurring in new locations. In 1999, urban and periurban transmission was reported in Kinshasa, DRC, and in Luanda, Angola, and a new focus was reported in Soroti, Uganda, where an epidemic of *T.b. rhodesiense* disease followed the introduction of infected cattle (Fèvre and others 2001).

DISEASE BURDEN

All three diseases affect substantial populations. Globally, WHO estimates that 500,000 cases of DHF occur annually. Assuming that DHF cases constitute 6 percent of all clinical dengue cases (that is, all other cases are classical DF) implies a total of almost 8 million new infections per year. For leishmaniasis, current estimates suggest an overall prevalence of 12 million people infected in an at-risk population of 350 million, suggesting more than 2 million new infections each year. The prevalence of sleeping sickness is estimated at 300,000 people, with 60 million people considered to be at risk. Uncertainty about the true number of cases makes all these estimates approximate, particularly because incidence is increasing. In terms of disability-adjusted life years (DALYs) lost to these diseases (table 23.1), a dengue or trypanosomiasis death accounts for 27 to 28 DALYs lost. Leishmaniasis kills less often than trypanosomiasis, but each death is responsible for a loss of 34 DALYs.

Dengue

In hyperendemic areas of Southeast Asia, where multiple virus serotypes are circulating, DF and DHF are mainly childhood diseases and in some countries are leading causes of pediatric hospitalization and death, particularly in Cambodia, Myanmar, and Vietnam. Worldwide, 80 to 90 percent of deaths occur before age 15. In recent years in the Americas, DHF in adults in endemic form has been reported frequently (Diaz and others 1988; Guzmán and others 1999; Harris and others 2000; Zagne and others 1994). In some countries, the disease is more frequent among females, and in Cuba, significantly more severe cases occur among Caucasians than among those of African descent (Kouri, Guzmán, and Bravo 1987). Dengue causes relatively few deaths, estimated at 19,000 in 2001, corresponding to a case-fatality rate of 3.8 percent for DHF. Nonetheless, it can cause a substantial burden: in Puerto Rico during 1984–94, the

Table 23.1 Number of Deaths and DALYs Caused by Dengue, Leishmaniasis, and African Trypanosomiasis, by World Bank Region, 2001 (thousands)

Region	Dengue		Leishmaniasis		African trypanosomiasis		Total	
	Deaths	DALYs	Deaths	DALYs	Deaths	DALYs	Deaths	DALYs
East Asia and the Pacific	8	217	2	48	0	0	10	265
Europe and Central Asia	0	0	0	6	0	0	0	6
Latin America and the Caribbean	2	59	0	37	0	0	2	96
Middle East and North Africa	0	8	1	48	1	22	2	78
South Asia	9	240	40	1,306	0	0	49	1,546
Sub-Saharan Africa	0	4	8	312	48	1,310	56	1,626
Total	19	528	51	1,757	49	1,332	119	3,617

DALY loss per million population was similar to that for the entire Latin America and Caribbean region from malaria, tuberculosis, intestinal helminths, and the childhood disease cluster (Meltzer and others 1998).

Economic Impact. Studies in Thailand estimated the economic impact of dengue as equivalent to US\$12.6 million in 1994, of which patients and their families incurred 45 percent (Okanurak, Sornmani, and Indaratna 1997). Kouri and others (1989) estimate the cost of the 1981 DHF epidemic in Cuba at US\$103 million, constituting US\$41 million in medical care, US\$5 million in social security disability payments, US\$14 million in lost production, and US\$43 million for vector control. For Southeast Asia, Shepard and others (2004) estimate individual treatment costs of US\$139 for DHF and US\$4.29 for DF (including health clinic visits, hospitalization, medications, travel expenses, and parents' time seeking treatment for their children). This estimate implies annual costs in the region of US\$105 million—US\$69.5 million for DHF and US\$35.5 million for DF. Extrapolating from current trends (on the basis of cases reported to WHO since 1960), this figure will increase to an average of US\$118 million each year through the first decade of the 21st century. Using the Thailand study to add the value of productive work lost doubles this figure to US\$236 million. Thus, during the next decade, Southeast Asian economies could lose a total of US\$2.36 billion because of DF and DHF. Additional economic losses are expected because of the impact of dengue outbreaks on tourism.

Social Impact. During the transmission season, parents familiar with DHF are anxious about their children's survival and the financial consequences of emergency medical care. In Cambodia, even relatively modest out-of-pocket health expenditures can lead to debt and poverty (Van Damme and others 2004). The psychological burden is poorly understood and warrants further study.

Even though dengue affects all strata of society, it may selectively affect the poorest. Most larval habitats in dengue-endemic communities are artificial: water storage containers, flower vases, discarded food containers, used tires, and habitats created by poor design of roof gutters and drains. Local vector ecology is largely determined by community social and cultural practices and infrastructure, and increasing urbanization typically attracts the poor to periurban settlements with deficient water supplies. Studies in the República Bolivariana de Venezuela (Barrera, Avila, and Gonzalez-Teller 1993; Barrera and others 1995) and in Thailand (Nagao and others 2003) have shown higher *Ae. aegypti* infestations where water distribution systems are deficient or unreliable. Along the border between Mexico and the United States, Reiter and others (2003) attribute the low dengue seroprevalence reported in Laredo, Texas, to factors such as air conditioning that limited

human-vector contact, whereas in contiguous Nuevo Laredo on the Mexican side, where per capita income was one-seventh of that in Laredo, seroprevalence was much higher despite lower vector densities.

In countries with weak or unprepared health services, epidemics of dengue can be extremely disruptive and health services can be rapidly overwhelmed. Frequently, governments declare states of emergency to mobilize additional resources against dengue outbreaks, sometimes deploying the army to eliminate or apply larvicides to larval habitats. These responses are often launched at or after the peak of the epidemic, and the decline in transmission is unjustifiably attributed to the intervention rather than to the natural epidemic decline.

Leishmaniasis

In 2001, leishmaniasis killed an estimated 51,000 people, including 40,000 in South Asia and 8,000 in Sub-Saharan Africa, representing 0.3 percent and less than 0.1 percent, respectively, of all deaths (table 23.1). Nearly all deaths occurred at ages 5 to 29. Males were more affected than females, especially in Sub-Saharan Africa, where the ratio was three to one.

Economic Impact. Treatment for leishmaniasis is expensive, especially for VL. For many countries, the cost of treating all leishmaniasis patients would far exceed their total health budgets. For a WHO-recommended course of pentavalent antimonials, current drug costs per patient are US\$150 for sodium stibogluconate, US\$120 for meglumine antimoniate, and US\$30 for generic sodium stibogluconate. Cases not responding to antimonials may require second-line, more toxic drugs, such as amphotericin B at a cost of US\$60 or pentamidine at a cost of US\$70. Less toxic amphotericin in liposomes is effective, but costs US\$1,500 per patient. The first oral drug for VL, miltefosine, currently costs US\$120 per patient.

In addition to drug costs, the additional costs of drug delivery can be high, especially for patients in remote areas. Patients often live far from a treatment center, and the expense of hospitalization may lead to interrupted treatment, facilitating resistance and requiring additional therapy. Without treatment, severe leishmaniasis can become chronic and debilitating, incapacitating patients and making them unable to work and vulnerable to poverty, malnutrition, and secondary infections.

Social Impact. Even self-limiting CL can leave disfiguring scars, which have associated stigma and may affect marriage prospects. CL can be disabling when lesions are numerous, and the most severe form, recidivans leishmaniasis, is difficult to treat, long-lasting, and disfiguring. In individuals with a defective cell-mediated immune response, the disseminated lesions of diffuse cutaneous leishmaniasis resemble those of leprosy. They do not heal spontaneously and frequently recur after

treatment. Diffuse cutaneous leishmaniasis is recognized as a special public health problem, both clinically and because of its severe emotional consequences.

The lesions of mucocutaneous leishmaniasis can cause extensive destruction and distortion of oronasal and pharyngeal cavities, leading to mutilation of the face. Patients may be shunned and, in severe cases, even incarcerated. Although mainly associated with *L. braziliensis* and *L. guyanensis* in the Americas, mucocutaneous leishmaniasis has been reported in Africa, Asia, and Europe as a complication of *L. donovani* and *L. major* infections and, in immunosuppressed patients, of *L. infantum*.

Untreated VL is usually fatal. Even after recovery, patients may develop a chronic form of CL that usually requires prolonged and expensive therapy.

African Trypanosomiasis

WHO estimates the number of deaths caused by sleeping sickness as 48,000 in 2001 (table 23.1), although current estimates are in the range of 50,000 to 100,000 per year. Men are affected at nearly twice the rate of women. In relation to mortality, of all parasitic diseases in Sub-Saharan Africa, trypanosomiasis ranks behind only malaria. As concerns DALYs, the health burden is similar to that of schistosomiasis. In Sudan, 33 DALYs on average are lost because of each premature death from sleeping sickness (McFarland 2003). In Uganda, 23 DALYs were lost per death, but only 0.21 DALYs per successfully treated individual (Odiit and others 2004). Underreporting makes deriving estimates for the whole continent difficult: 100,000 deaths per year would imply more than 2 million DALYs lost, compared with the WHO estimate of 1.31 million (830,000 for males and 480,000 for females) (table 23.1).

Economic Impact. Information on age at death indicates that sleeping sickness mainly affects economically active adults. Data from Uganda show nearly 25 percent of cases occurring in those age 20 to 29 and more than 60 percent in those age 10 to 39 (Odiit 2003). Thus, when people become ill, their families not only become burdened with the care of seriously ill individuals but also often lose their breadwinners. Poor diagnostic support in many areas means that families often invest in a number of treatments that have no effect on the disease. In a *T. b. rhodesiense* area of Uganda, Odiit and others (2004) find that some patients made up to seven visits to health facilities before being correctly diagnosed, with just under three-quarters initially being diagnosed with malaria. For the 11 of 12 who were never diagnosed or were told that they had a different fatal disease, the costs to and burdens on their families can only be imagined.

In addition to the economic losses caused by interruption of their work, sleeping sickness patients face direct financial

costs. Even though WHO now provides specific first-line drugs at no cost in excess of delivery and administration, hospitalization and treatment are expensive. In the DRC, Gouteux and others (1987) estimate that total costs are equivalent to at least 25 percent of a year's income from agriculture.

Social Impact. The importance of sleeping sickness lies not only in the number of new cases reported, but also in its potential for epidemic outbreaks causing thousands of deaths: during recent epidemics in the DRC, in some villages up to 70 percent of the population became infected. Because of the severity of the disease, one case can affect all family members, placing a burden on the whole community, reducing the labor force, interrupting agricultural activities, and jeopardizing food security. Although untreated trypanosomiasis is lethal, treated patients often remain incapacitated, perpetuating the cycle of poverty, malnutrition, and disease. DALYs do not take into account the psychosocial impact and the "minor" disabilities. In adults, loss of memory and ability to concentrate is common. Such disabilities are often accompanied by reading and writing difficulties and occasionally by extreme incoherence. These disabilities greatly affect everyday life, particularly for those school-age children who, even after successful treatment, do not recover fully and cannot pursue their studies (Frézil 1983).

Burden of Animal Trypanosomiasis. Animal trypanosomiasis constrains agricultural production—in particular, the use of draft power. Cattle infected with *T. b. brucei*, *T. vivax*, or *T. congolense* quickly succumb to a wasting form of anemia. In many areas with a high tsetse challenge, such as Central Africa, cattle are few or not present at all. Elsewhere, countries invest an estimated total of US\$30 million to US\$50 million per year in some 35 million doses of veterinary trypanocides to prevent the disease in livestock (Geerts and Holmes 1998). About 60 percent of the cattle at risk are not treated, and the disease is thought to kill about 1 million a year. Current drugs are more than 40 years old, and drug resistance is increasing, as are problems of drug availability and accessibility, counterfeit drugs, and drug mismanagement (Geerts and Holmes 1998). Constraints on draft power mean that farmers can till only small plots, making subsistence farmers extremely vulnerable to food shortages. Milk yields are lower in infected cows, and animal trypanosomiasis lowers fertility and increases mortality, thereby constraining the overall growth rate of the number of livestock (Swallow 2000). Kristjanson and others (1999) estimate annual direct losses of US\$1.3 billion per year as a result of lowered production of milk and meat, with aggregate agricultural losses attributable to trypanosomiasis estimated at US\$4.5 billion per year.

MANAGEMENT AND CONTROL STRATEGIES

Dengue

Patient Management and Treatment. Classic dengue fever is generally self-limiting. No specific treatment is available, but supportive treatment must be given, including fluid replacement when necessary. Early recognition of DHF cases—indicated by intense, continuous abdominal pain; persistent vomiting; and restlessness or lethargy—and early supportive treatment are of utmost importance to reduce case-fatality rates (Martinez 1992). For differential diagnosis, a wide spectrum of viral and bacterial infections should be considered, especially leptospirosis, malaria, yellow fever, chikungunya virus, rubella, and influenza.

Vector Control. Although good patient management can be effective for individual cases, currently no alternative to vector control is available for the prevention of dengue. Most endemic countries have a vector control component in their programs; however, the application of vector control measures is frequently insufficient, ineffective, or both and is currently failing to reduce the public health burden to an acceptable level.

Most *Aedes* control programs rely on the application of larvicides and adulticidal insecticide space sprays (Zaim and Jambulingham 2004). Because *Ae. aegypti* characteristically breeds in water that does not contain high levels of organic pollutants, control measures typically must be applied to water stored for household purposes, including drinking water. WHO currently approves five insecticides for application to potable water (FAO 1999; WHO 1991). Since the early 1970s, the organophosphate temephos has been the most widely used, but increasing levels of resistance to this insecticide are reducing the duration of effectiveness of treatments in some countries (Bregues and others 2003; Lima and others 2003; Rodriguez and others 2001). An additional challenge is the growing objection among householders, particularly in Latin America, to the application of chemicals to drinking water.

Biological control agents, including larvivorous fish and copepods, have had a demonstrable role in integrated control of *Ae. aegypti*, but operational difficulties—particularly a lack of facilities and of expertise in mass rearing and the need for repeated introduction of these agents into some container habitats—have largely precluded their widespread use. One encouraging exception is Vietnam, where indigenous species of predatory copepods are increasingly used to control semipermanent larval habitats of *Ae. aegypti* (Kay and others 2002; Nam and others 2000). However, some communities have strong cultural objections to the introduction of live animals into household water storage containers—for example, in Thailand, where bathing with water that contains small fish or other creatures is widely regarded as unacceptable.

Environmental management is generally considered the core component of dengue prevention and control, including cleanup campaigns, regular emptying and cleaning of containers, installation of water supply systems, solid waste management, and urban planning. However, huge investments in infrastructure are needed to increase access to safe and reliable water supplies, to provide solid waste management services, and to dispose of liquid waste. In addition to overall health gains, such provision would have a major effect on vector ecology, although the relationship is not invariably an inverse one. Cost-recovery mechanisms, such as the introduction of metered water, may encourage household collection and storage of roof catchment rainwater that can be harvested at no cost. Although unproven, the installation of community water services in rural townships and villages may be contributing to the rural spread of dengue in Southeast Asia and elsewhere.

At the household and community levels, where most vector control efforts are centered, increasing attention is given to such activities as covering or frequently cleaning water storage vessels, removing discarded food and beverage containers, and storing or disposing of used tires in such a way that they do not collect rainwater. Such tasks would seem to be simple and well suited to engagement by communities, but with a few exceptions, achievements to date have been unspectacular. Nevertheless, such community-based interventions are widely seen as the most promising way of achieving sustainable control through behavior change (Parks and Lloyd 2004).

Leishmaniasis

Leishmaniasis control is based primarily on finding and treating cases, combined where feasible with vector control and, in some zoonotic foci, control of animal reservoirs.

Diagnosis and Treatment. For VL, serological diagnosis is usually based on the enzyme-linked immunosorbent assay (ELISA), indirect fluorescent antibody tests, and direct agglutination tests, including a new direct agglutination test kit using lyophilized antigen, which avoids the need for refrigeration (Schallig and others 2001). A dipstick test based on a highly specific recombinant antigen is also available, together with a latex agglutination test that can be used to detect antigens in urine (Attar and others 2001; Sundar and others 1998). Parasitological diagnosis relies on microscopy of aspirates of the spleen, bone marrow, and lymph nodes.

Specific treatment includes the first-line drugs, which are pentavalent antimonials (sodium stibogluconate and meglumine antimoniate), and the second-line drugs, which are amphotericin B and AmBisome (amphotericin B in liposomes). Miltefosine for VL was registered in India in 2002, and aminosidine (paromomycin) has just completed phase 3 clinical trials and follow-up. For CL, parasitological diagnosis is

made from skin smears followed by treatment with pentavalent antimonials. Treatment is given locally if lesions are few and relatively small, or systemically if lesions are more numerous. For mucocutaneous leishmaniasis, diagnosis relies on serology because patients generally develop a strong humoral response.

Vector and Reservoir Control. In foci of peridomestic or intradomestic transmission, vector control can be carried out by indoor residual spraying using pyrethroid insecticides. Individual protection using pyrethroid-impregnated bednets is also used in some areas. In zoonotic foci of VL, control has also included culling stray dogs—and pet dogs if found to be infected—although this practice is often poorly accepted by communities and is probably of limited effectiveness. Trials with insecticide-treated dog collars are showing some promise as an alternative way to reduce the peridomestic reservoir of infection (Mazlumi Gavvani and others 2002). For zoonotic CL, rodent reservoirs can be controlled using poisoned bait and environmental management, including physical destruction of rodents' burrows.

African Trypanosomiasis

For human trypanosomiasis, control consists primarily of active and passive case finding and treatment, occasionally associated with vector control operations. Dissemination of sleeping sickness can be prevented by regular surveillance of the population at risk, including diagnosis and treatment; control of the tsetse-fly population can affect the transmission of sleeping sickness as well as of animal trypanosomiasis. In *T.b. rhodesiense* foci, where cattle are reservoirs of the disease, treating cattle with trypanocides is being investigated as an additional approach to controlling outbreaks.

Case Finding and Treatment. No single clinical sign is regarded as pathognomonic for sleeping sickness. Tests have been developed to detect antibodies, circulating antigens, or trypanosomal DNA, but all require parasitological confirmation. For mass screening, infection can be confirmed by the card agglutination trypanosomiasis test, which is easy to perform and relatively inexpensive. Parasitological confirmation is by microscopy of lymph node aspirates and of thin or thick blood films. Concentration methods increase sensitivity. The most sensitive is the miniature anion exchange centrifugation technique. The capillary tube centrifugation technique is less sensitive but is commonly used in the field because of its ease and rapidity of use and its low cost.

Determining the stage of disease is essential, because early- and late-stage infections require different treatments. The criteria for late-stage infection are based on cerebrospinal fluid analysis.

Sleeping sickness is fatal if untreated. No vaccination exists. Specific drugs are currently available free through WHO. Pentamidine is used to treat early-stage *T.b. gambiense* infection, and suramine is used for early-stage *T.b. rhodesiense*. The organoarsenical compound melarsoprol (Arsobal) is used for the late stages of both. Eflornithine has been introduced to treat late-stage *T.b. gambiense* but is difficult to administer. Nifurtimox, although not yet registered for the treatment of sleeping sickness, has been used on compassionate grounds to treat patients unresponsive to melarsoprol.

Vector Control. A wide range of techniques for tsetse control is available (Maudlin, Holmes, and Miles 2004). Most current approaches exploit the acute susceptibility of tsetse flies to biodegradable pyrethroid insecticides. Spraying can be applied from the ground to known fly resting sites or at ultra-low volume from the air. Spraying is carried out sequentially to kill all flies initially present and thereafter to kill each generation of newly emerging flies. The sequential aerosol technique uses extremely low levels of insecticide and has been effective in Botswana, Somalia, South Africa, and Zambia. It is also useful against epidemic outbreaks of sleeping sickness, where a rapid cessation in contact between humans and tsetse flies is needed.

Tsetse flies can also be controlled using traps and targets. Targets are combinations of cloth and netting baited with an odor attractant and impregnated with a pyrethroid insecticide. Traps work on the same principle, but the fly is encouraged to enter a net or plastic chamber where it remains trapped. Live bait techniques are also used. Cattle are treated with a veterinary formulation of pyrethroid insecticides applied as sprays or pour-ons, which kill both tsetse flies and ticks. This technique has been successfully used in Burkina Faso, Ethiopia, Kenya, Tanzania, Zambia, and Zimbabwe (Kuzoe and Schofield 2005).

The sterile insect technique involves mass release of sterilized male tsetse flies, which compete with local males to mate with females. Because female tsetse flies generally mate only once, the result is infertile offspring and a decline of the wild tsetse population. This technique is expensive, because it requires large-scale rearing of flies, and it is only recommended for use once the wild tsetse population has been suppressed to low levels using other techniques. A combination of insecticide spraying and trap deployment followed by the sterile insect technique has been successfully used to eliminate *G. austeni* from Zanzibar (Vreysen and others 2000).

Degrees of resistance to trypanosome infection are found in the N'dama, Dwarf, and Savannah Shorthorn breeds in West Africa and, to a lesser extent, in some Orma Boran breeds in East Africa. However, even though these cattle show tolerance, can control parasitemia, and resist development of anemia, they can ultimately succumb to the disease.

COSTS AND COST-EFFECTIVENESS OF INTERVENTIONS

Dengue

Few studies are available on the cost-effectiveness of vector control for reducing dengue transmission. One of the difficulties is that the level of vector population control needed to reduce transmission is influenced by the human population's past exposure to the circulating virus serotype. A direct relationship is apparent between seroprevalence rates and levels of vector abundance needed for epidemic transmission. Thus, the paradox is that, as herd immunity declines over time in response to effective vector control, progressively lower vector densities can maintain the same level of transmission.

Modeling of the dynamics of dengue transmission is helping to improve understanding of the interrelationships between virus, vector, and host (Ferguson, Donnelly, and Anderson 1999; Focks and others 1995; Newton and Reiter 1992; Shepard 2001), but the absence of epidemiologically defined target levels for vector control has hindered calculations of cost-effectiveness. According to Shepard and others (2004), average annual costs for dengue vector control per 1,000 population were US\$15 in 1998 in Indonesia, US\$81 in 1994 and US\$188 in 1998 in Thailand, US\$240 in 2002 in Malaysia, and US\$2,400 in 2000 in Singapore. In 1997, spending on dengue control in 14 Latin American countries ranged from US\$20 to US\$3,560 per 1,000 population, with a median of US\$260. For 17 Caribbean islands in 1990, the corresponding expenditures ranged from US\$140 to US\$8,490, with a median of US\$1,340 (Nathan 1993). By contrast, McConnell and Gubler's (2003) study in Puerto Rico concludes that larval control programs that achieve a 50 percent reduction in dengue transmission and cost less than US\$2.50 per person would be cost-effective in that setting. From research based on analytical models (Shepard 2001) and primary data from Singapore, we estimate the cost of using environmental management for control at US\$3,139 per DALY averted and the cost of using insecticides at US\$1,992 per DALY averted.

Dengue case management depends on the severity of the illness. Despite the lack of information about cost-effective interventions to treat dengue cases, Shepard (2001) estimates an average cost of US\$587 per DALY averted by appropriate case management. Were a dengue vaccine to become available, the Shepard model estimates that immunization would cost US\$3,040 per DALY averted.

Leishmaniasis

Case Finding and Treatment. For leishmaniasis, diagnosis represents a small proportion of the cost of case finding and treatment, with diagnostic tests becoming available at approximately US\$1.50 for the dipstick, US\$3.00 for the direct

agglutination test using freeze-dried antigen, and US\$1.50 for the urine latex agglutination test. These tests can be used in the field. A study in Nepal (Pokhrel 1999) comparing outreach case detection using serology (the dipstick) with parasitological diagnosis at health centers (bone marrow aspirate) concluded that the median cost per VL case detected was US\$25 in the outreach program, compared with US\$145 at health centers (of which more than 50 percent was due to absence from work). Treatment costs increased these figures to US\$131 and US\$200 per patient, respectively.

In India, an examination of the costs of drugs and hospitalization and of the evolution of the disease under treatment (cure, relapse, failure, intolerance) indicated that the final cost of successful treatment depends largely on the basic drug cost, which averaged US\$86 per patient successfully treated with miltefosine (using reduced pricing because of the large number of patients), US\$467 for treatment with amphotericin B, and US\$1,613 for treatment with AmBisome. Given current estimates of about 100,000 cases of VL each year in the state of Bihar, India, the estimated total cost of treatment using miltefosine as a first-line drug and amphotericin B as a second-line drug would be about US\$11 million, or approximately US\$110 per patient (personal communication with P. Olliaro and S. Sundar on treatment options for kalaazar [visceral leishmaniasis], 2003). By contrast, analysis of humanitarian relief interventions by Médecins sans Frontières–Holland that combined case finding with treatment after a VL epidemic in southern Sudan indicated total costs of US\$394 per patient, or an average cost of US\$595 per life saved (Griekspoor, Sondorp, and Vos 1999). Thus, the average cost per DALY averted was US\$18.40.

Vector Control. Vector control is rarely carried out as a specific approach to leishmaniasis control, and cost-effectiveness estimates are not available. In general, domestic and peridomestic sandfly vectors are more susceptible to indoor residual spraying than are other domestic vectors, such as anopheline mosquitoes or triatomine bugs, so that transient suppression of sandfly populations is seen as an additional benefit of malaria or Chagas disease vector control in areas where these vectors coincide. However, insecticide-treated bednets, which are becoming widely deployed against malaria transmission, may also become cost-effective for reducing leishmaniasis in areas of domestic transmission. In Yenice, Turkey, the use of impregnated bednets reduced the incidence of CL from 1.90 percent to 0.04 percent between 2000 and 2001 (Alten and others 2003).

African Trypanosomiasis

Case Finding and Treatment. WHO (1986, 1998) has analyzed the costs of *T.b. gambiense* control by means of case finding and treatment based on practice in Côte d'Ivoire and

Uganda. This work and other studies indicate that, at current prices, the cost of active detection using the card agglutination trypanosomiasis test with parasitological confirmation varies around US\$1 per person screened or slightly more for mobile teams. However, mobile teams are more effective in screening a high proportion of the population and are also more successful in ensuring that a high proportion of patients receive treatment. Unit costs are currently US\$0.33 per person for the card agglutination trypanosomiasis test and US\$2.20 for the miniature anion exchange centrifugation technique. Less sensitive parasitological techniques, such as examination of lymph node aspirate or blood smears, cost only a few cents but may miss a third to half of patients.

By contrast, treatment is expensive despite the availability of free drugs. Treatment of early-stage disease incurs costs of more than US\$100 per person, rising to more than US\$250 for late-stage treatment with melarsoprol and about US\$700 with eflornithine (WHO 1998). The long hospitalization period is a major component of costs during the second stage, although work undertaken by Burri and others (2000) on a shorter melarsoprol regimen offers opportunities for reducing these costs.

Despite the costs and the risk of complications, treating sleeping sickness patients in the second stage of the disease is cost-effective. In Uganda, costs were less than US\$10 per DALY averted for melarsoprol treatment and less than US\$20 per person for eflornithine (Politi and others 1995). Similarly, in southern Sudan, the cost per DALY averted ranged from US\$4 to US\$22 (Trowbridge and others 2001). Shaw and Cattand (2001) considered the costs of case finding and treatment for *T.b. gambiense* infection for three delivery options and a wide range of prevalences. Given the limited information available on DALYs gained or on the effect on transmission of reducing the size of the human reservoir, they estimate that under different scenarios the costs per DALY averted tend to converge. For most assumptions, the cost per DALY averted fell below a US\$25 threshold at prevalences of 0.5 to 1.0 percent but rose sharply at low prevalences, which explains the reluctance of control programs to invest in screening operations when prevalence is less than 0.2 percent. With better quantitative understanding of the effects of screening and removing patients from the reservoir in preventing future epidemics, investigators could demonstrate that even at low prevalences screening for sleeping sickness is highly cost-effective.

Vector Control. Several countries have undertaken community-based programs to trap tsetse flies, notably Côte d'Ivoire, where costs came to US\$2.30 per person protected per year (Laveissière and others 1994), and Uganda, which achieved a cost of US\$0.50 per person protected per year (Lancien and Obayi 1993). Vector control costs have been

studied in more detail in the context of livestock disease (Maudlin, Holmes, and Miles 2004). These costs vary according to the technique used and the environmental context, often ignoring overheads for organizing and planning. With that caveat in mind, the figures per square kilometer cited for local tsetse-fly eradication range from about US\$250 to US\$550 at current prices for aerial spraying (based on experience in Somalia, South Africa, Zambia, and Zimbabwe); US\$250 to US\$400 per square kilometer for ground spraying; and US\$200 to US\$400 per square kilometer for targets. However, the cost of traps and targets falls to US\$25 to US\$60 per square kilometer for control or suppression operations alone. Projects treating cattle with insecticides have been implemented at costs of US\$50 to US\$60 per square kilometer. Use of the sterile insect technique is much more expensive because it relies on prior suppression of fly populations using another technique. The overall costs of the experimental eradication of *G. austeni* from Zanzibar using the sterile insect and other techniques were about US\$3,000 per square kilometer, although the International Atomic Energy Agency (IAEA) envisages that the cost of the sterile insect technique component could be reduced to less than US\$800 per square kilometer as the technology is developed and applied on a sufficiently large scale (Dr. Udo Feldmann, IAEA, Vienna, personal communication).

PROBLEMS AND CHALLENGES FOR DISEASE CONTROL

Dengue

Potential for Vaccine Development. The occurrence of DHF in children and adults with previous dengue antibodies, acquired passively or actively, has been the most important challenge for the development of a dengue vaccine. Lack of a suitable animal model, insufficient knowledge of disease pathogenesis, and limited research funding have also had a negative influence. Researchers generally agree that a dengue vaccine must confer long-lasting protection against the four dengue serotypes. Currently, they are following different strategies in the development of several vaccine candidates. Some vaccines are currently undergoing human clinical trials—for example, live attenuated dengue and yellow fever chimeric vaccines. The conventional live attenuated vaccines are entering phase 3 trials, while the chimeric vaccines are presently in phase 1 and phase 2 trials. Others are in the preclinical phase of development. To accelerate the development of a dengue vaccine, a new initiative—the pediatric dengue vaccine initiative—has been launched, with the major objective of mobilizing resources to accelerate the development of a safe and effective pediatric dengue vaccine (Almond and others 2002; Halstead and Deen 2002; Pang 2003).

Vector Control. Without a vaccine, vector control remains the only available strategy against dengue. Selective, integrated vector control with community and intersectoral participation, active disease surveillance based on a strong health information system, emergency preparedness, capacity building and training, and vector control research constitute the major elements of WHO's global strategy for dengue prevention and control. Since the eradication era, few examples of successful dengue prevention and control on a national scale are available. Exceptions include Cuba and Singapore, both island states. Cuba, with approximately 11 million inhabitants, has been able to interrupt dengue transmission. Despite being in an endemic area, the country has maintained low vector densities and has successfully controlled epidemics in recent years (Arias 2002). Critical factors contributing to this achievement are the strong dengue surveillance system, which integrates environmental, entomological, epidemiological, clinical, and virological surveillance in conjunction with the public health infrastructure, and a strong vector control program, along with good intersectoral coordination, active community involvement, and strong political commitment.

A limited array of tools is available for vector control interventions, any one of which can control at least part of the vector population or provide personal protection. However, approaches are converging, at least at the policy level, toward application of vector control tools through social or community mobilization. Consensus is growing that community-based approaches are desirable and necessary, and many believe that only through such approaches can a degree of sustainability be accomplished in relation to dengue vector control. Even though few such interventions have expanded beyond the pilot stage, the decentralization of budgetary and operational responsibilities for program delivery appears to offer opportunities for strengthening and expanding this integrated vector management approach.

Increasing levels of resistance of *Ae. aegypti* to temephos imply shorter intervals between treatments. This situation is already a reality in some countries, including Brazil and several Caribbean islands (Carvalho and da Silva 1999; Rawlins 1998). Resistance of adult mosquitoes to malathion and to pyrethroids has been reported in the Americas and in Asia (WHO 1992) and is likely to reduce the efficacy of space spraying. Given the peridomestic ecology of *Ae. aegypti* in most regions and the widespread use of pyrethroids for public health purposes and in household insecticide products, the rate of development of pyrethroid resistance is likely to accelerate. At the same time, few new insecticide products are becoming available in the public health market because of the costs involved in development and registration compared with the returns on investment from the relatively small commercial market. The high cost of re-registration of existing products is also contributing to the withdrawal of some insecticides from the market.

New Risk Factors. Environmental changes, particularly those related to climate, directly affect the incidence and prevalence of vectorborne diseases. However, social factors, such as lifestyles and population density, particularly in the case of dengue, are also important. Using an empirical model of the effect of population and climate change on the global distribution of dengue fever, Hales and others (2002) conclude that predicted changes in humidity will increase the areas with a climate suitable for dengue transmission.

The world is also becoming increasingly urbanized: during 2000–25, Asia's urban population is expected to double, and that of Latin America and the Caribbean is expected to increase by almost 50 percent. The resulting high human population densities, coupled with lifestyles that increasingly contribute to the proliferation of larval habitats and infrastructural deficiencies in relation to water supply and sanitation, are such that effective delivery of vector control on the scale needed is beyond the reach of many governments. The increasing global trend in international travel also facilitates the dissemination of virus serotypes and strains between vulnerable populations.

Genetic variability is another element to be considered. The genetic diversity of the viruses is increasing, with some genotypes associated with severe disease (Cologna and Rico-Hesse 2003; Leitmeyer and others 1999; Rico-Hesse and others 1997). Recombination has been demonstrated in all four serotypes, but the implications in terms of pathogenesis are unknown. In addition to recombination, mutations, gene flow, and other factors could further influence the genetic diversity and selection of virulent strains (Holmes and Burch 2000). At the same time, in addition to initial observations of the higher risk of DHF in Caucasian than in those of African descent, a few reports associate some human leukocyte antigen alleles with disease severity (Bravo, Guzmán, and Kouri 1987; LaFleur and others 2002; Loke and others 2001; Paradoa, Trujillo, and Basanta 1987; Stephens and others 2002). The sequence of infecting viruses and, more recently, the longer interval between primary and secondary infection as a risk factor for DHF, add a new perspective to the problem (Guzmán and others 2002; Nisalak and others 2003).

Leishmaniasis

Because the primary control strategy against leishmaniasis is based on case finding and treatment, the priority for control is developing and implementing improved diagnostic methods and better treatments that are more amenable to field use. A parallel requirement is for the development of more cost-effective drug delivery systems, especially ones that take advantage of new oral drugs, such as miltefosine, and the planned registration and local production of aminosidine in India.

Improved Diagnostics and Treatment. Even though the new serological tests, such as the dipstick, lyophilized direct agglutination test kit, and latex agglutination urine test, represent major improvements, they are not yet widely used in endemic countries. Moreover, they are indirect tests that cannot provide direct parasitological confirmation of infection or of cure immediately following treatment. Current parasitological tests tend to be highly invasive and can be costly to perform; therefore, simple molecular-based tests would be an advantage.

For leishmaniasis treatment, development of the oral VL drug, miltefosine, represents a substantial improvement, but it remains expensive and with a long treatment regimen and cannot be administered to pregnant women because of the risk of teratogenicity. Further clinical evaluation is required to establish the possibility of shorter treatment regimens and the potential of combination therapy to inhibit the development and spread of drug resistance. Another oral drug, sitamaquine, is currently under development and will require similar clinical and implementation studies. Clinical trials of aminosidine (paromomycin) are proceeding, and use of this drug against VL may become widespread. An improved understanding of disease pathogenesis would be helpful in refining the criteria for cure and in improving patients' prognosis.

Vaccine Development. The leishmaniasis offer substantial opportunities for vaccine development, and a crude vaccine against CL has been widely used in parts of the Middle East. Trials of a second-generation vaccine that includes three *Leishmania* antigens are currently in progress.

Vector Control. Control of domestic and peridomestic sandfly vectors will probably continue as an additional benefit accruing to programs against other insect vectors using indoor residual spraying or insecticide-treated bednets. However, in areas where dogs are among the main reservoir hosts, increased use of insecticide-treated dog collars would merit further appraisal. Such collars not only would reduce the likelihood of new infections in dogs, but also could reduce the risk of transmission from dogs to humans.

African Trypanosomiasis

Improved Diagnostics. Serological diagnosis is reliable for verifying infection; however, most district hospitals or peripheral health units have neither the facilities nor the necessary expertise to perform and read serological tests. In the past, serological diagnosis, based on indirect fluorescent antibody tests and ELISA, was restricted to central-level facilities or specialized mobile teams. The card agglutination trypanosomiasis test has substantially simplified the use of serology but requires specifically equipped health units with a cold chain.

Parasitological diagnosis, such as the miniature anion exchange centrifugation test, is more expensive and complicated to use in field surveys despite the development of a simplified sterile kit version. Molecular diagnostics are not yet developed to a level appropriate for widespread field use.

Treatment. Despite the availability of drugs free of charge from WHO, treatment is hampered by the length of hospitalization required and by the toxicity of currently available drugs. In addition, inability to use the same drug in the early and late stages of the disease complicates the treatment protocol. The existing late-stage drug, melarsoprol, is unsafe, its secondary reactions are numerous, and the occurrence of a lethal encephalopathic syndrome in 5 to 10 percent of treated cases means that patients on melarsoprol must be hospitalized. A new oral drug for the early stage, soon to be registered, must be introduced in the field, which will take several years.

Drug resistance is well established in animal trypanosomes. For *T. congolense*, *T. vivax*, and *T. evansi*, resistance to all available drugs has been reported, along with trypanosome populations with multiple drug resistance (Geerts and Holmes 1998). Much less information is available on human pathogenic trypanosomes. The resurgence of human African trypanosomiasis in recent years has been accompanied by increasing reports of treatment failure using melarsoprol. As early as 1960, *T.b. rhodesiense* patients in Uganda were reported to have relapsed after two or more courses of melarsoprol, and in 1977, a 40 percent melarsoprol relapse rate was reported in the DRC.

Relapses after treatment with early-stage drugs remain rare. Whether relapses after melarsoprol treatment reflect parasite drug resistance or host factors is unknown. Furthermore, even though increasing rates of melarsoprol failure have been observed in several countries, the magnitude and geographic distribution of the problem have not been determined. Analyses of existing data are complicated by the lack of a standard treatment regimen and the range of clinical and laboratory criteria used to define a relapse.

Vector Control. Even though available techniques to control tsetse flies can be highly effective (Maudlin, Holmes, and Miles 2004), all are constrained by the difficulties of applying them on a large enough scale for long enough to achieve sustainable results. Insecticide spraying is efficient but is difficult to sustain because of logistical constraints and high costs. Targets and traps are effective, but their deployment is difficult to sustain for long periods, and implementation through community participation requires constant motivation and supervision to remain effective. To address these problems, the African Union has launched the Pan African Initiative (PATTEC), which focuses on identifying regions where elimination of the tsetse fly may be feasible using currently available techniques. This

initiative is designed as part of a poverty reduction strategy that aims at eliminating the problem of tsetseborne animal trypanosomiasis, but in several areas it will also reduce the risk of human infections.

SUMMARY

For dengue, leishmaniasis, and African trypanosomiasis, the longstanding problem is the lack of adequate specific treatment. For dengue, no specific treatment is available. For the leishmaniasis and African trypanosomiasis, specific treatment has long depended on antiquated drugs that would be considered far too toxic for introduction under modern registration systems. Even though progress is being made, especially in relation to the development of new oral drugs for leishmaniasis, in purely pragmatic terms what is currently available will probably represent almost the entire therapeutic arsenal for the coming decades. Even without toxicological problems, the development and registration of a new candidate drug will, given current requirements, take at least a decade.

Although basic research will continue (table 23.2), the current challenge is to make better use of what is already available. Dengue can be prevented with available vector control tools and strategies designed to reduce the risk of transmission. This method requires a sustainable surveillance system capable of providing early warning and predictions based on experience of factors predisposing to new epidemic outbreaks. To a large extent, it becomes a management exercise that accepts that some dengue transmission will occur but aims at preempting

epidemic outbreaks rather than instigating emergency measures after an outbreak is in full crudescence. Moreover, because preemptive measures and emergency responses are competing strategies, analyses of their relative cost-effectiveness would be appropriate.

Case finding and treatment for the leishmaniasis and African trypanosomiasis depend on the effectiveness of the diagnostic and treatment packages. Such packages are available, and research is required into the most cost-effective means for large-scale implementation. Again, the management exercise is to accept that some transmission will occur but to be aware that cases can be found and treated with minimal losses to healthy life. As with dengue, predictive surveillance will help focus attention on those areas where outbreaks seem most likely, and rapid, accurate diagnostics are crucial both to avoid the waste and danger of mistreatment and to minimize delays in administering the specific treatment required. But should such approaches rely on health centers, on mobile teams, or on some combination of the two? To what degree can the specialist diagnosis and treatment teams be integrated into more general approaches to health care? And, most crucially, how is the epidemiological surveillance to be organized: disease and vector notification, geographic information system mapping, analysis, and prediction?

For the leishmaniasis, vector control seems unlikely to become a major component of disease control except where sandfly distribution overlaps with that of other vectors or where use of personal protection measures can be more widely encouraged. For dengue, vector control is a major component,

Table 23.2 Control Strategies, Major Challenges, and Research Needs of Each Disease

Disease	Principal control strategy	Major problems and challenges	Major research needs
Dengue	Interruption of transmission through vector control	Lifestyles that provide abundant artificial larval habitats	Vector control thresholds to interrupt transmission
	Patient management and supportive treatment	Urban water infrastructure and management Sustainable vector control Early diagnosis and treatment Vaccine development	Behavioral changes conducive to dengue prevention Pathogenesis and disease prognosis Vaccine development
Leishmaniasis	Case detection and treatment	Rapid field diagnosis Deployment of oral drugs for treatment Vaccine development	Molecular-based field diagnostic kits Effective, safe, oral drug treatments, including combination therapy Diagnosis and treatment strategies
African trypanosomiasis	Case detection and treatment	Rapid field diagnosis, including determination of stage of infection	Molecular-based field diagnostic kits Effective, safe, oral drug treatments
	Interruption of transmission through vector control	Safer drug treatment regimens Sustainable large-scale vector control	Vector population genetics to determine areas amenable to vector population elimination

Source: Authors.

but unless *Aedes* eradication appears again on the agenda, predicting the levels of control required in specific situations will require much greater understanding of transmission dynamics. Significant resources have been wasted on emergency dengue vector control, which has subsequently been seen to have had little more than a palliative effect, whereas sustained suppression of vector populations may require changes in urban water management and in human behavior that exceed the usual remit of health specialists.

For African trypanosomiasis, however, the prospects for sustainable vector control are more promising. The vector's low reproductive rate, combined with its extreme sensitivity to ultra-low doses of biodegradable insecticides, put tsetse flies among the most promising candidates for large-scale elimination. Campaigns against tsetse flies during the past century were invariably successful until they were discontinued and the controlled areas became reinvaded. Thus, the operational issue is to design large-scale international programs that can successfully eliminate tsetse populations and prevent reinvasion of controlled areas, as contemplated by the African Union's Pan African Initiative.

In essence, all three diseases face parallel needs involving some marginal improvements to existing control techniques, but, most important, they require a management exercise that acknowledges the long-term need for surveillance, adequate reporting, case finding, and treatment. The primary challenges seem to reside less in the domain of new tools and more in the deployment of what is already available.

Helminth Infections: Soil-Transmitted Helminth Infections and Schistosomiasis

Peter J. Hotez, Donald A. P. Bundy, Kathleen Beegle, Simon Brooker, Lesley Drake, Nilanthi de Silva, Antonio Montresor, Dirk Engels, Matthew Jukes, Lester Chitsulo, Jeffrey Chow, Ramanan Laxminarayan, Catherine M. Michaud, Jeff Bethony, Rodrigo Correa-Oliveira, Xiao Shu-Hua, Alan Fenwick, and Lorenzo Savioli

Helminth infections caused by soil-transmitted helminths (STHs) and schistosomes are among the most prevalent afflictions of humans who live in areas of poverty in the developing world. The morbidity caused by STHs and schistosomes is most commonly associated with infections of heavy intensity. Approximately 300 million people with heavy helminth infections suffer from severe morbidity that results in more than 150,000 deaths annually (Crompton 1999; Montresor and others 2002). In addition to their health effects, helminth infections also impair physical and mental growth in childhood, thwart educational advancement, and hinder economic development. Because of the geographic overlap of these afflictions and their impact on children and adolescents, the World Health Organization (WHO); the World Bank; and other United Nations agencies and bilaterals; and civil society are working to integrate STH and schistosome control through a program of periodic school-based, targeted anthelmintic drug treatments.

CAUSES AND CHARACTERISTICS OF HELMINTH INFECTIONS

Emphasis is placed on the four most common STH infections and the three most common schistosome infections. Together, these infections account for most of the global helminth disease burden.

Soil-Transmitted Helminths

The four most common STHs are roundworm (*Ascaris lumbricoides*), whipworm (*Trichuris trichiura*), and the anthropophilic hookworms (*Necator americanus* and *Ancylostoma duodenale*). Recent estimates suggest that *A. lumbricoides* infects 1.221 billion people, *T. trichiura* 795 million, and hookworms 740 million (de Silva and others 2003) (table 24.1). The greatest numbers of STH infections occur in the Americas, China and East Asia, and Sub-Saharan Africa. *Strongyloides stercoralis* is also a common STH in some of these regions, although detailed information on the prevalence of strongyloidiasis is lacking because of the difficulties in diagnosing human infection. The life cycles of *Ascaris*, *Trichuris*, and hookworm follow a general pattern. The adult parasite stages inhabit the gastrointestinal tract (*Ascaris* and hookworm in the small intestine; *Trichuris* in the colon), reproduce sexually, and produce eggs, which are passed in human feces and deposited in the external environment.

STH infections rarely cause death. Instead, the burden of disease is related less to mortality than to the chronic and insidious effects on the hosts' health and nutritional status (Stephenson, Latham, and Ottesen 2000; Stoltzfus and others 1997). Hookworms have long been recognized as an important cause of intestinal blood loss leading to iron deficiency and protein malnutrition. The iron deficiency anemia that accompanies moderate and heavy hookworm burdens is sometimes referred to as *hookworm disease* (Hotez and others 2004). When host

Table 24.1 Global Prevalence and Distribution of Helminth Infections

Helminth infections	Total cases	Major geographic areas
STH infections	≥ 2 billion	
Ascariasis	1.221 billion	Sub-Saharan Africa, India, China and East Asia
Trichuriasis	795 million	Sub-Saharan Africa, India, China and East Asia
Hookworm	740 million	Sub-Saharan Africa, Americas, China and East Asia
Schistosomiasis	187 million	
<i>S. haematobium</i>	119 million	Sub-Saharan Africa
<i>S. mansoni</i>	67 million	Sub-Saharan Africa, Americas
<i>S. japonicum</i>	1 million	China and East Asia

Source: de Silva and others 2003.

iron stores are depleted, the extent of iron deficiency anemia is linearly related to the intensity of hookworm infection (Stoltzfus and others 1997). Because of their underlying poor iron status, children, women of reproductive age, and pregnant women are frequently the ones most susceptible to developing hookworm anemia (Brooker, Bethony, and Hotez 2004). Iron deficiency anemia during pregnancy has been linked to adverse maternal-fetal consequences, including prematurity, low birth-weight, and impaired lactation (WHO 2002).

Chronic STH infections resulting from *Ascaris*, *Trichuris*, and hookworm can dramatically affect physical and mental development in children (WHO 2002). Studies have also shown that the growth and physical fitness deficits caused by chronic STH infections are sometimes reversible following treatment with anthelmintic drugs (Stephenson, Latham, and Ottesen 2000). The effects on growth are most pronounced in children with the heaviest infections, but light infections may also contribute to growth deficits if the nutritional status of the community is poor (Stephenson, Latham, and Ottesen 2000).

Schistosomiasis

Five major species of parasitic trematodes of the family Schistosomatidae—*Schistosoma haematobium*, *S. intercalatum*, *S. japonicum*, *S. mansoni*, and *S. mekongi*—infect humans. These parasites have a complex, indirect life cycle involving an intermediate snail host. Disease is caused primarily by schistosome eggs, which are deposited by adult worms in the blood vessels surrounding the bladder or intestines. Urinary schistosomiasis, in which the bladder is affected, is caused by infection with *S. haematobium*, which occurs mainly in Africa. Intestinal schistosomiasis results from infection with *S. mansoni*, which occurs in the Middle East, South America, and Africa, and from

infection with *S. japonicum*, which occurs in parts of China and the Philippines (Ross and others 2002). Two other schistosome species are known to cause intestinal schistosomiasis in restricted geographical areas: *S. intercalatum*, found in Central Africa, and *S. mekongi*, found in Cambodia and the Lao People's Democratic Republic. Schistosomiasis is estimated to affect 187 million people worldwide (table 24.1).

A serious acute illness accompanied by fever and lymphadenopathy, known as Katayama Syndrome, can result from heavy schistosome infections. Chronic disease is mostly due to perforation of blood vessels and entrapment of eggs by host tissues. The host's reaction to entrapped eggs results in granuloma formation. *S. haematobium* causes bladder wall pathology, leading to ulcer formation, hematuria, and dysuria. Granulomatous changes and ulcers of the bladder wall and ureter can lead to bladder obstruction, dilatation, secondary urinary tract infections and subsequent bladder calcification, renal failure, lesions of the female and male genital tracts, and hydronephrosis. *S. haematobium* is also associated with increased risk of bladder cancer. The morbidity commonly associated with *S. mansoni* infection includes lesions of the liver, portal vein, and spleen, leading to periportal fibrosis, portal hypertension, hepatosplenomegaly, splenomegaly, and ascites. Schistosomiasis also causes chronic growth faltering and can contribute to anemia (Ross and others 2002).

EPIDEMIOLOGY OF STH INFECTIONS AND SCHISTOSOMIASIS

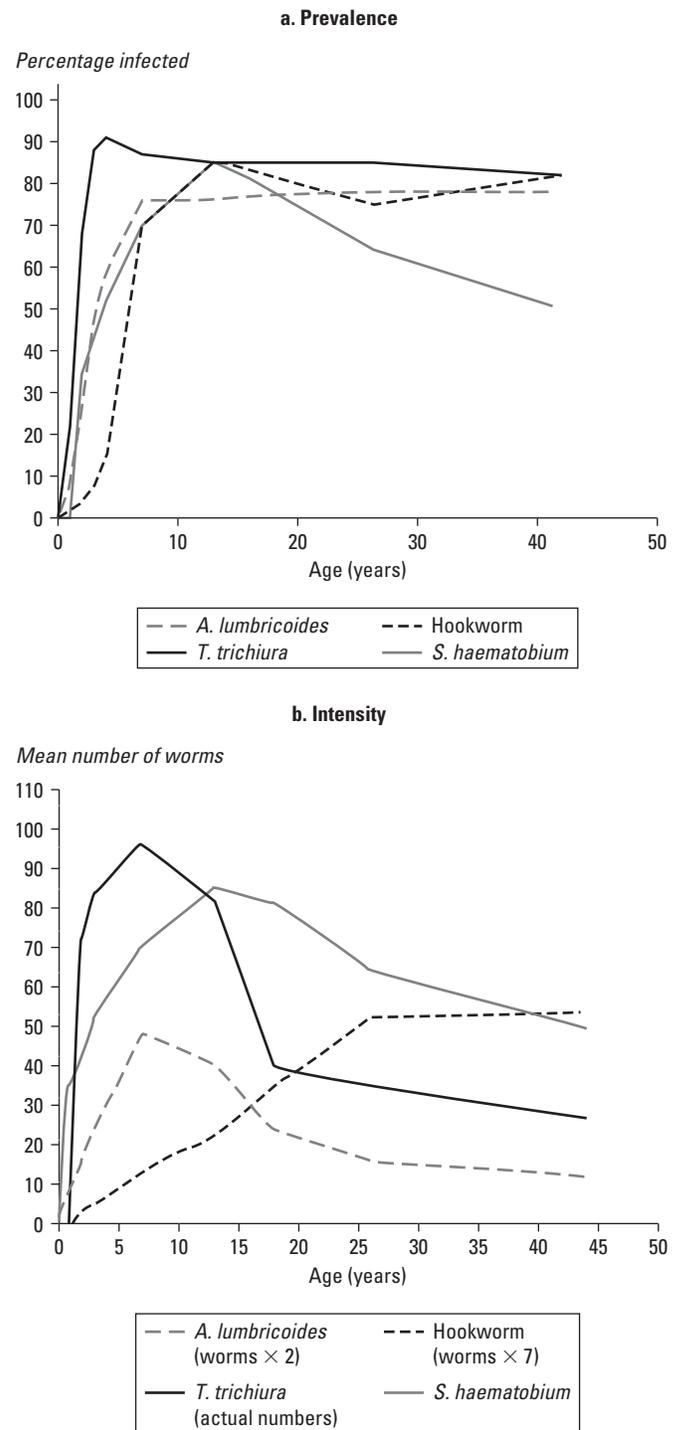

The most striking epidemiological features of human helminth infections are aggregated distributions in human communities, predisposition of individuals to heavy (or light) infection, rapid reinfection following chemotherapy, and age-intensity profiles that are typically convex (with the exception of hookworm).

For all the major human STH and schistosome infections studied to date, worm burdens exhibit a highly aggregated (overdispersed) distribution so that most individuals harbor just a few worms in their intestines, although a few hosts harbor disproportionately large worm burdens (Anderson and May 1991). As a rule, 20 percent of the host population harbors approximately 80 percent of the worm population. This overdispersion has many consequences, both with regard to the population biology of the helminths and the public health consequence for the host, because heavily infected individuals are simultaneously at highest risk of disease and the major source of environmental contamination. One feature that may help explain overdispersion is that individuals tend to be predisposed to heavy (or light) infections. Predisposition has been demonstrated for all four major STHs and the schistosomes. The underlying cause of such predisposition remains poorly understood. However, a combination of heterogeneity in

exposure to infection or differences in susceptibility to infection and the ability to mount effective immunity (genetic and nutritional factors) is likely to be important.

People of all ages rapidly reacquire infection following treatment, but in schistosomiasis, older people reacquire infection at slower rates than younger ones (Kabatereine and others 1999). The rate of reinfection is specific to certain species of helminths and depends on the life expectancy of that species (short-lived helminths reinfect more rapidly), on the intensity of transmission within a given community, and on the treatment efficacy and coverage. The basic reproductive rate (R_0) describes the transmission potential of a parasite (and thus its ability to reinfect the host). It defines the average number of female offspring produced during the life span of the parasite that survive to reproductive maturity in the absence of density dependence. R_0 is determined by parasite immigration and death rates as well as by host density (and, in schistosomiasis, also snail density). A parasite will fail to become established unless R_0 is greater than unity (Anderson and May 1991). Adult worms usually survive between one and four years, whereas eggs can sometimes remain viable for several more years in the environment. Therefore, reinfection rates will remain high until adults are removed with chemotherapy and until infective stages, through time, become uninfec-tive. In reality, density-dependent processes regulate parasite populations; at endemic equilibrium, the effective reproductive ratio equals unity (that is, each female replaces herself). Control programs rely on reducing the effective reproductive ratio long enough for the parasite population to be driven to local elimination. Theoretically, R_0 provides useful insights, and it is helpful to think of control programs attempting to break the transmission cycle by reducing R_0 to less than unity. Therefore, estimates can be made about how long and how many rounds of chemotherapy are required to treat intestinal helminths. For example, *A. lumbricoides* with an R_0 of three and a life expectancy of one year will need to be treated annually with a drug that is 95 percent efficacious and with coverage of more than 91 percent of the population. Where R_0 is five—that is, in areas where transmission is higher—treatment must be given more frequently than once a year (Anderson and May 1991).

The age-dependent patterns of infection prevalence are generally similar among the major helminth species, exhibiting a rise in childhood to a relatively stable asymptote in adulthood (figure 24.1). Maximum prevalence of *A. lumbricoides* and *T. trichiura* is usually attained before five years of age, and the maximum prevalence of hookworm and schistosome infections is usually attained in adolescence or in early adulthood. The nonlinear relationship between prevalence and intensity has the consequence that the observed age-prevalence profiles provide little indication of the underlying profiles of age intensity (age in relation to worm burden). Because intensity is

Source: Bundy 1995; reproduced and modified from Hotez, Ardra, and others 2005.

Figure 24.1 Age-Associated Prevalence and Intensity Profiles of STH and Schistosome Infections: Typical Age Profiles of Prevalence and Intensity of STH Infections and Schistosomiasis

linked to morbidity, the age-intensity profiles provide a clearer understanding of which populations are vulnerable to the different helminths (figure 24.1). For *A. lumbricoides* and *T. trichiura* infections, the age-intensity profiles are typically convex in form, with the highest intensities in children 5 to

15 years of age (Bundy 1995). For schistosomiasis, a convex pattern is also observed, with a similar peak but with a plateau in adolescents and young adults 15 to 29 years of age (Kabaterine and others 1999). In contrast, the age-intensity profile for hookworm exhibits considerable variation, although intensity typically increases with age until adulthood and then plateaus (Brooker, Bethony, and Hotez 2004). In East Asia it is also common to find the highest intensities among the elderly. However, more generally, children and young adults are at higher risk of both harboring higher levels of infection (thus greater levels of morbidity) and becoming reinfected more quickly. Both may occur at vital stages in a child's intellectual and physical development.

Risk Factors

Both host-specific and environmental factors have been identified that may affect the risk of acquiring or harboring heavy-intensity helminth infections.

Genetics. No genes that control for human helminth infection have yet been identified. However, recent genome scans have identified a locus possibly responsible for controlling *S. mansoni* infection intensity on chromosome 5q31-33 and loci controlling *A. lumbricoides* intensity on chromosomes 1 and 13. There is also evidence for genetic control of pathology attributable to *S. mansoni*, with linkage reported to a region containing the gene for the interferon gamma receptor 1 subunit (Quinnell 2003).

Behavior, Household Clustering, and Occupation. Specific occupations, household clustering, and behaviors influence the prevalence and intensity of helminth infections (Bethony and others 2001), particularly for hookworm, in which the highest intensities occur among adults (Brooker, Bethony, and Hotez 2004). Engagement in agricultural pursuits, for example, remains a common denominator for hookworm infection. Behavioral and occupational factors, through their effect on water contact, interact with environmental factors to produce variation in the epidemiology of schistosomiasis.

Poverty, Sanitation, and Urbanization. STH and schistosomiasis depend for transmission on environments contaminated with egg-carrying feces. Consequently, helminths are intimately associated with poverty, poor sanitation, and lack of clean water. The provision of safe water and improved sanitation are essential for the control of helminth infection. Although the STH and schistosome infections are neglected diseases that occur predominantly in rural areas, the social and environmental conditions in many unplanned slums and squatter settlements of developing countries are ideal for the persistence of *A. lumbricoides* (Crompton and Savioli 1993). Schistosomiasis transmission can also occur in urban areas.

Climate, Water, and Season. Adequate warmth and moisture are key features for each of the STHs. Wetter areas exhibit increased transmission, and in some endemic areas, both STH and schistosome infections exhibit marked seasonality (Brooker and Michael 2000). Recent use of geographical information systems and remote sensing has identified the distributional limits of STH and schistosomes on the basis of temperature and rainfall patterns (Brooker and Michael 2000). For schistosomiasis, specific snail intermediate hosts prefer certain types of aquatic environments. Construction of dams is known to extend the range of snail habitats, thereby promoting the reemergence of schistosomiasis.

BURDEN OF THE DISEASE

The revised estimates in 2003 (de Silva and others 2003) use the methodology developed by Chan and others (1994) and build on recent applications of geographical information systems to derive updated atlases of helminth infections. To reflect recent changes in the epidemiology of infection, de Silva and others used data from only 1990 onward. These data confirm that STH infections are the most prevalent infections of humans and that a large proportion of the population in developing countries is at risk. Of the 187 million cases of schistosomiasis estimated to occur worldwide, most are caused by *S. haematobium* in Sub-Saharan Africa (table 24.1).

WHO (2002) estimates that 27,000 people die annually from STH infections and schistosomiasis (case fatality rate of 0.0014 percent). Many investigators, however, believe that this figure is an underestimate. Crompton (1999) estimated that 155,000 deaths annually occur from these infections (case fatality rate of 0.08 percent), whereas Van der Werf and others (2003), using the limited data available from Africa, estimated the schistosomiasis mortality alone at 280,000 per year (case fatality rate of 0.014 percent) because of nonfunctioning kidneys (from *S. haematobium*) and hematemesis (from *S. mansoni*). Therefore, the difference between estimates for helminth-associated mortality is more than 10-fold.

Because it is uncommon for STHs and schistosomes to kill their human host, citing mortality figures provides only a small window on their health impact. Instead, measurements of disease burden using disability-adjusted life years (DALYs) and similar tools portray a more accurate picture for helminthic disease burden. WHO estimates the global burden of disease from STH infections and schistosomiasis on the basis of the enormous number of infected individuals, together with an associated low disability weight (Van der Werf and others 2003). However, because an estimated 2 billion people are infected with STHs and schistosomes, even minor adjustments to the disability weights produce enormous variations in DALYs or other measurements of disease burden. This helps to

explain why, for instance, in 1990 the disease burden for the STH infections and schistosomiasis was almost 18 million DALYs, whereas the 2001 estimate was only 4.7 million DALYs. In the intervening 11 years, the DALYs were as low as 2.6 million. Such disparities are substantial when one considers that the 1990 estimate ranks helminths close to major disease entities such as tuberculosis, measles, and malaria, whereas the lowest estimate during the 1990s ranks helminth infections on a par with gonorrhea, otitis media, and iodine deficiency. The Disease Control Priorities Project helminth working group has determined that the WHO global burden of disease estimates are low because they do not incorporate the full clinical spectrum of helminth-associated morbidity and chronic disability, including anemia, chronic pain, diarrhea, exercise intolerance, and undernutrition (King, Dickman, and Tisch 2005). However, for this chapter, the average disability weights estimated by WHO are used throughout. Some of the specific controversies are described below.

A. *Lumbricoides* and *T. Trichiura* infections

Because the most significant physical and intellectual growth disturbances occur as a consequence of moderate and heavy worm burdens, the age-associated epidemiology of *A. lumbricoides* and *T. trichiura* infections has focused attention on infected school-age children in developing countries (Bundy 1995). In a revised estimate of the probable number of ascariasis infections worldwide and a better categorization of the morbidity, de Silva, Chan, and Bundy (1997) indicated that 59 million of the 1.2 billion people infected (including 51 million children less than 15 years of age) were at risk of faltering growth, decreased physical fitness, or both as a result of infection. They estimated that about 1.5 million children would never make up the deficit in growth, even if treated. In addition to these chronic, insidious effects, they estimated that about 11.5 million individuals (almost all of them children) were at risk of more acute clinical illness. Their figures also indicated that at least 10,500 deaths annually were directly attributable to one of the serious complications of ascariasis; children account for more than 90 percent of those deaths. The actual threshold at which *A. lumbricoides* and *T. trichiura* worm burdens result in childhood morbidity is controversial because of the nonlinear relationship between intensity and pathogenesis and the difficulties of measuring and attributing morbidity in underserved populations suffering from other underlying conditions (Bundy 1995).

Hookworm Infection

Hookworm infection causes more DALYs lost than any other helminthiasis with the exception of lymphatic filariasis. Even these DALY measurements may still underestimate the true disease burden of iron deficiency anemia and protein

malnutrition resulting from hookworm disease. Iron deficiency anemia alone results in approximately 12 million DALYs lost annually, making it the world's most important nutrition problem. Data on the epidemiology of iron deficiency anemia in East Africa and elsewhere point to the important contribution of hookworms to this condition (Stoltzfus and others 1997). In Tanzania, where hosts' iron stores are often depleted, there is a correlation between the number of adult hookworms in the intestine and the amount of host blood loss (Stoltzfus and others 1997). However, it is unclear whether current disability weights effectively incorporate the full contribution of hookworm to severe iron deficiency anemia among iron-depleted populations or whether they take host protein losses and malnutrition into account. There is increasing interest in the importance of hookworm anemia in preschool children, especially in Africa (Brooker, Bethony, and Hotez 2004), where infants and preschool children are particularly vulnerable to the developmental and behavioral deficits caused by iron deficiency anemia (Stephenson, Latham, and Ottesen 2000). Closer assessment of the impact of hookworm on another important iron-deficient population—namely, women of reproductive age—could also significantly increase current DALY estimates. Approximately 44 million of these women harbor hookworms (Bundy, Chan, and Savioli 1995). In addition, severe anemia in pregnancy is associated with neonatal prematurity, reduced birthweight, and impaired lactation (Christian, Khattry, and West 2004).

Schistosomes

Scientists and public health workers disagree on the current assessments of both morbidity and mortality attributable to schistosomiasis. Several investigators have now initiated a process to recalculate the burden of disease attributable to schistosomiasis, focusing much more on the clinical course of the different types of schistosomiasis and chronic sequelae (King, Dickman, and Tisch 2005; Michaud, Gordon, and Reich 2003). Through a comprehensive literature review combined with mathematical modeling, Van der Werf and others (2003) estimate that urinary schistosomiasis in Africa results in approximately 18 million cases of bladder wall pathology and 20 million cases of hydronephrosis, and African intestinal schistosomiasis results in approximately 8.5 million cases of hepatomegaly. Mortality in Africa attributable to urinary and intestinal schistosomiasis was extrapolated from these figures using a limited number of studies reporting case fatality rates for nonfunctioning kidney and hematemesis. From these extrapolations, Fenwick and others (2003) conclude that in Africa the mortality attributable to urinary schistosomiasis could be as high as 150,000 per year, and the number dying as a result of intestinal schistosomiasis could be as high as 130,000 per year.

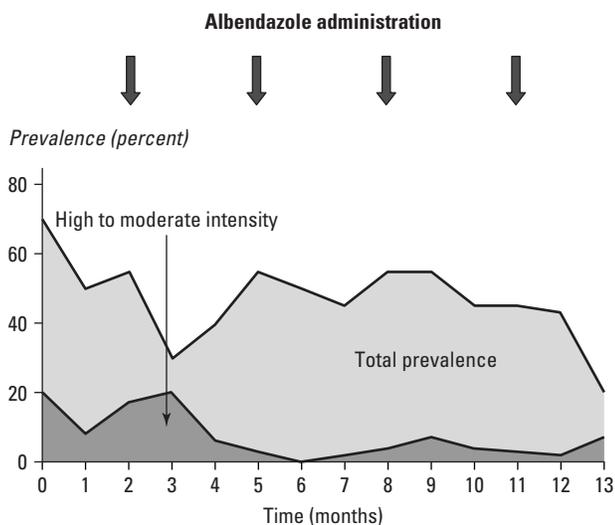

COST-EFFECTIVENESS ANALYSIS OF INTERVENTIONS

Classifying Interventions

The three major interventions are anthelmintic drug treatment, sanitation, and health education.

Anthelmintic Drug Treatment. Anthelmintic drug treatment (“deworming”) is aimed at reducing morbidity by decreasing the worm burden. Repeated chemotherapy at regular intervals (periodic deworming) in high-risk groups can ensure that the levels of infection are kept below those associated with morbidity (figure 24.2) and will frequently result in immediate improvement in child health and development. Anthelmintic drug treatment can prevent the development of irreversible consequences of schistosomiasis in adulthood. For ascariasis and trichuriasis, for which intensity peaks among school-age children, frequent and periodic deworming may reduce transmission over time. Obstacles that diminish the effectiveness of periodic deworming are the low efficacy of single-dose mebendazole and albendazole for the treatment of hookworm and trichuriasis, respectively (Adams and others 2004; Albonico and others 1994); high rates of posttreatment reinfection for STHs in areas of high endemicity (Albonico and others 1995); and diminished efficacy with frequent and repeated use (Albonico and others 2003), possibly because of anthelmintic resistance (see the section “Research and Development”).

Improved Sanitation. Improved sanitation is aimed at controlling transmission by reducing soil and water contamination.

Source: Albonico and others, forthcoming.

Figure 24.2 Predicted Effect on *Ascaris* and *Trichuris* Prevalence Following Frequent and Periodic Dewormings with Benzimidazole Anthelmintics

tion. Sanitation is the only definitive intervention to eliminate STH infections, but to be effective it should cover a high percentage of the population. Therefore, because of the high costs involved, implementing this strategy is difficult where resources are limited (Asaolu and Ofoezie 2003). Moreover, when used as the primary means of control, it can take years or even decades for sanitation to be effective (Brooker, Bethony, and Hotez 2004).

Health Education. Health education is aimed at reducing transmission and reinfection by encouraging healthy behaviors. For STH infections and schistosomiasis, the aim is to reduce contamination of soil and water by promoting the use of latrines and hygienic behavior. Without a change in defecation habits, periodic deworming cannot attain a stable reduction in transmission. Health education can be provided simply and economically and presents no contraindications or risks. Furthermore, its benefits go beyond the control of helminth infections. In this perspective, it is reasonable to include this component in all helminth control programs.

Other Control Measures. In specific epidemiological conditions, environmental or chemical control of snails can be useful tools for reducing the transmission of schistosomiasis. Research to develop new tools for control is in progress, including vaccine development programs for hookworm infection and schistosomiasis (see “Research and Development”).

Choosing Interventions

Periodic deworming stands out as the most cost-effective means to reduce the morbidity of STH and schistosome infections.

Periodic Anthelmintic Therapy. Periodic anthelmintic therapy, or periodic deworming, represents the main measure in areas where infections are intensely transmitted, resources for disease control are limited, and funding for sanitation is lacking. Drug treatment can be administered in the community using different strategies:

- *Universal treatment.* The entire community is treated, irrespective of age, sex, infection status, and other characteristics.
- *Targeted treatment.* Treatment targets population groups, which may be defined by age, sex, or other social characteristics, irrespective of the infectious status.
- *Selective treatment.* Treatment targets individual-level application of anthelmintic drugs, which is selected on the basis of either diagnosis or a suspicion of current infection.

Recommended drugs for use in public health interventions to control STH infection are the benzimidazole anthelmintics

(BZAs), albendazole (single dose: 400 mg, reduced to 200 mg for children between 12 and 24 months), or mebendazole (single dose: 500 mg), as well as levamisole or pyrantel pamoate (WHO 2002). Praziquantel (PZQ) (single dose: 40–60 mg/kg) is the major drug used for the treatment of schistosomiasis. However, therapy with oxamniquine has been the cornerstone for treatment of *S. mansoni* infection in South American national control programs over the past 20 years. The efficacy of oxamniquine and PZQ is comparable, although that of PZQ is slightly better. The BZAs and PZQ are inexpensive; they have undergone extensive safety testing and have been used by millions of individuals with only a few minor side effects. Drugs that do not need dosage according to weight, such as BZAs (in school-age children), are considered easier to use for population-based interventions; however, the use of proxy indicators—for example, substituting height for weight—has proved a successful implementation strategy for PZQ (Hall and others 1999).

Distribution Strategy and Frequency of Treatment. The selection of the distribution strategy and the frequency of treatment is based on epidemiological data. The recommended strategy for helminth control is a population-based approach, in which individuals in targeted communities are treated irrespective of their infection status (WHO 2002). This strategy is justified for several reasons, including the simplicity and safety of delivering treatment. Individual diagnosis is difficult and expensive and offers no safety benefit.

The intrinsic transmission potential of the parasite species determines the frequency of treatment (see “Epidemiology of STH Infections and Schistosomiasis,” earlier in this chapter). To control morbidity in areas of intense transmission (prevalence greater than 70 percent and more than 10 percent of moderate- and heavy-intensity infection), WHO (2002) recommends treatment two or three times a year for STH infections. In areas with a lower intensity of transmission (prevalence between 40 and 60 percent and less than 10 percent of moderate- and heavy-intensity infection), intervention once a year is recommended (WHO 2002).

School-Age Children as a High-Risk Population. School-age children typically have the highest intensity of worm infection of any age group, and chronic infection negatively affects all aspects of children’s health, nutrition, cognitive development, learning, and educational access and achievement (World Bank 2003). Regular deworming can cost-effectively reverse and prevent much of this morbidity. Furthermore, schools offer a readily available, extensive, and sustained infrastructure with a skilled workforce that is in close contact with the community. With support from the local health system, teachers can deliver the drugs safely. Teachers need only a few hours of training to understand the rationale for deworming and to learn how to give out the pills and keep a record of their distribution. School-

based deworming also has major externalities for untreated children and the whole community. By reducing transmission in the community of *Ascaris* and *Trichuris* infections, deworming substantially improves the health and school participation of both treated and untreated children, both in treatment schools and in neighboring schools (Bundy and others 1990; Miguel and Kremer 2003).

These observations provided a basis for the adoption of resolution 54.19 at the 2001 World Health Assembly, which urged member states to ensure access to essential drugs for STH and schistosome infections in endemic areas for the treatment of clinical cases and groups at high risk for morbidity (box 24.1). To achieve this goal, WHO has developed a broad partnership that promotes the incorporation of deworming into existing institutions and programs, for both the education sectors and the health sectors. The Partnership for Parasite Control was launched in 2001 with the aim of mobilizing resources and promoting synergy among public and private efforts for the control of soil-transmitted helminths and schistosomiasis at global and national levels. School-based deworming has its full effect when delivered within an integrated school health program that includes elements of the Focusing Resources on Effective School Health (FRESH) framework.

Other At-Risk Populations. Not only school-age children can benefit from treatment. Preschool children (one to five years of age) are vulnerable to the developmental and behavioral deficits caused by iron deficiency anemia, and recent analyses by Brooker, Bethony, and Hotez (2004) indicate that hookworm is an important contributor to anemia in that age group (see “Estimating Intervention Effectiveness”). Women of reproductive age (15 to 49 years of age) are particularly susceptible to iron deficiency anemia because of iron loss during menstruation and because of increased needs during pregnancy (Bundy, Chan, and Savioli 1995). In certain circumstances, male worker populations can also be at increased risk (Guyatt 2000).

Estimating Intervention Effectiveness

The evidence base for the health and educational effect of periodic deworming has accumulated significantly over the past decade.

STH Infections. All the anthelmintic drugs mentioned above substantially reduce the number of adult worms in the gastrointestinal tract. This effect is also reflected in reduced fecal egg counts. In some cases, however, the efficacy of single-dose mebendazole or albendazole on hookworm and *Trichuris* infections is low (Adams and others 2004; Albonico and others 1994). Moreover, pyrantel pamoate has little effect on *T. trichiura*.

Box 24.1

The 54th World Health Assembly

The 54th World Health Assembly, which met in May 2001, urged member states to ensure access to essential drugs for schistosomiasis and STH infections in endemic areas for the treatment of clinical cases and groups at high risk for morbidity. The helminth infections of concern are the major schistosomes and STHs outlined in the text. The World Health Assembly determined that simple and sustainable control measures can relieve a generally underestimated and unnecessary disease burden in high-transmission areas. The following minimal targets, aimed at reducing morbidity by 80 percent, can be achieved by all

Source: WHO 2002.

countries in which such disease is endemic as an integral part of the primary health care system: (a) access to adequate diagnosis and essential anthelmintic drugs in all health services in all endemic areas, even at peripheral levels, for the treatment of symptomatic cases and of children, women, and other groups at high risk of morbidity; (b) regular administration of chemotherapy to at least 75 percent of all school-age children at risk for morbidity by 2010; and (c) sustained, community-based efforts to improve sanitation, clean water supplies, and health education.

Overall, however, anthelmintic treatment significantly improves physical and cognitive outcomes in the following ways:

- *Preschool children.* Periodic distribution of anthelmintics has a positive effect on motor and language development and reduces malnutrition in very young children (Stoltzfus and others 2004).
- *School-age children.* Treating school-age children has a considerable effect on their nutritional status (Stoltzfus and others 2004), anemia, physical fitness, appetite, growth (Stephenson, Latham, and Ottesen 2000), and intellectual development (Drake and others 2000).
- *Women of reproductive age.* Studies of pregnant women conducted by Christian, Khatry, and West (2004) in Nepal indicate that albendazole treatment improves maternal hemoglobin as well as birth-weight and child survival.

Schistosomiasis. As with STH infections, anthelmintic chemotherapy for schistosomiasis has an important effect on child development, growth, and physical fitness (WHO 2002). Richter (2003) recently summarized details of the effect of PZQ on organ pathology. In *S. haematobium* infections, reversal of urinary tract pathology can be seen six months after a cure. In *S. mansoni* and *S. japonicum* infections, much of the intestinal pathology regresses after chemotherapy. However, more than one PZQ treatment is usually necessary to reverse hepatic pathology, especially in areas of intense transmission. Early intervention with PZQ is preferable to reverse organ pathology.

Intervention Costs

Several studies have evaluated the costs of school-based periodic deworming in several different settings, whereas comparable studies on other interventions are still lacking.

Periodic Deworming. The advantage of periodic deworming lies in its simplicity (one tablet per child) and safety. Teachers and other personnel without medical training can easily apply the simple measures, which can be incorporated without difficulty in existing health and nonhealth activities that reach the high-risk group. Several organizations, including nongovernmental organizations, include an STH and schistosome infection-control package within their routine activities and, with very limited budgets, relieve the burden of helminth infections in the population covered. The costs of albendazole and PZQ are available through the International Drug Price Indicator Guide (<http://www.msh.org>). Delivery systems for deworming have often depended on vertical programs, in which mobile teams visit schools or communities to carry out treatment (WHO 2002). Estimated costs for this approach are outlined in table 24.2. For STH infections in Tanzania, Nigeria, and Montserrat, the costs range from US\$0.21 to US\$0.51 per treatment. However, by training teachers and other school officials to administer anthelmintic drugs, the system could achieve low-cost delivery by “piggy-backing” on existing programs in the educational sector (WHO 2002). Specific examples of such programs conducted in Ghana and Tanzania are summarized in the section “Implementation of Control Strategies: Lessons of Experience,” later in this chapter. It was found that delivery of school-based targeted anthelmintic treatment could cost as little as US\$0.03 per child, which may be as low as one-tenth of the estimated costs for vertical delivery (WHO 2002). Thus, at current drug prices, the total cost (drug plus delivery) of a single treatment with albendazole or mebendazole may be as low as US\$0.05, and that of a combined treatment with PZQ may be as low as US\$0.25 per child (WHO 2002).

Table 24.2 Recent Examples of Delivery Costs for a Single Mass Treatment

Strategy	Drug	Country	Delivery cost per treatment	
			US\$	Percentage of total cost
Mobile team	Albendazole	Montserrat	0.51	67
	Albendazole	Bangladesh	—	42
	Levamisole	Nigeria	0.32	81
	PZQ	Tanzania	0.21	24
School-based	Albendazole	Ghana	0.04	17
	Albendazole	Tanzania	0.03	13
Out-of-school children		Arab Rep. of Egypt	0.16–0.21	40–47

Source: Guyatt 2003.
— = not available.

Integrating drug distribution through the school system rather than using mobile teams, along with a marked decline in the price of BZAs and PZQ, has resulted in a 10-fold reduction in delivery costs. However, those costs are artificially low because they do not include the external costs for the coordinating center responsible for supporting those approaches (Guyatt 2003). It has been estimated, for instance, that mass albendazole treatment of school-age children in Kenya could cost more than US\$3 million each year, equivalent to some 4 percent of current national public expenditure on health care (Guyatt 2003). This analysis has not been evaluated against actual operations, however, and current estimates from the parasite control authorities in Kenya suggest that the actual cost is likely to be far less. Large-scale chemotherapy programs for helminth control continue to rely heavily on donor support, suggesting that some affected countries may be unable to support the costs of deworming.

Monitoring of control programs is an important part of the managerial process, and it should be carried out at minimum cost so as not to divert resources from the intervention (Brooker and others 2004). It is recommended that, at the planning stage, approximately 5 to 10 percent of the program budget be reserved for monitoring activities (Montresor and others 2002).

Improved Sanitation. When sanitation improvements are made alongside deworming, the results obtained last longer. However, the investment needed to reach the level required to interfere with STH transmission could be high. To correctly evaluate the advantage of such investments, one must take into account the consequences for other health indicators and for economic development. An efficient sanitation infrastructure removes the underlying cause of most poverty-related communicable diseases and can boost the economic development of a country. The resources needed to improve hygienic standards can be huge and require the cooperation of several sectors of society (Asaolu and Ofoezie 2003). Currently, these are

qualitative judgments, and no cost-effectiveness analysis (CEA) estimates exist for sanitation in this context.

Health Education and Communication. Measures to increase the health awareness of the population are included as an essential component of any population-based activity aimed at controlling morbidity attributable to helminth infections. However, the effectiveness of those activities in reducing transmission of infection varies according to different reports. In some cases, health education can decrease costs, increase levels of knowledge, and decrease reinfection rates (Lansdown and others 2002). Health education efforts can build trust and engage communities, aspects that are crucial to the success of public health initiatives. No CEA estimates exist for health education in this context.

Linking Costs and Effects of Interventions

Interventions to reduce morbidity from helminth infections fall into two categories: targeting the transmission mechanisms and treating individuals directly. The former encompasses improvements in infrastructure, including water supply and sanitation, and health education. The latter entails the periodic drug treatment of the population. Substantial improvements through prevention may be a long-term outcome of economic growth in general, because wealthier households have improved sanitation facilities and practices, but those improvements are not an option in the short term without large investments in infrastructure. As shown in the previous section, deworming options dominate on both effectiveness and cost-effectiveness criteria. Costs continue to fall as drug costs decrease. With better data and detailed mapping of disease distribution within communities, targeting individuals at high risk becomes more feasible, thus improving the cost-effectiveness of control programs (Michaud, Gordon, and Reich 2003).

Box 24.2

The High Cost-Effectiveness of Mass Treatment for Helminth Infection

The combination of low-cost treatment and high prevalence rates suggests that the cost per DALY averted from treating helminth infections will be quite low. Following the consistent framework described in mass treatment of school-age children for both STH infections and schistosomiasis proves to be extremely cost-effective. In fact, benefit-cost ratios would be even higher if the analyses incorporated the additional benefits associated with externalities for the untreated. For a population of 1 million people in low- and middle-income countries, if treatment is limited to school-age children treated 1.1 times per year with

Source: Authors.

albendazole and then reinfected, the cost per DALY averted is estimated at US\$3.41 for STH infections. That is, if spending were capped at US\$1 million, total DALYs would be reduced by nearly 300,000. The estimate of cost per DALY is higher for schistosomiasis relative to STH infections because of higher drug costs and lower disability weights. Depending on whether generics or original formulations are used, the cost per DALY averted ranges from US\$3.36 to US\$6.92. However, in combination, treatment with both albendazole and PZQ proves to be extremely cost effective, in the range of US\$8 to US\$19 per DALY averted.

Evidence from existing programs that narrow the intervention to school-age children (a high-risk group) shows that the treatment costs of chemotherapy for helminth infections are quite low—well below US\$1 per school-age child. This finding is in part due to the accessibility of the target group and the cost savings of incorporating delivery into existing school and health programs. Moreover, as discussed in the following sections, the economic benefits of targeting this group may be substantial. Still other targeted groups may also have low cost per treatment when treatment is merged into existing programs. For example, interventions through prenatal care programs for pregnant women may be cost-effective. Likewise, evidence on costs of treatment through existing integrated management of infant and childhood illness (IMCI) programs for small children and health campaigns (such as vaccination and micronutrient programs) find low cost per case treated (Montresor and others 2002).

Several factors can potentially alter the ranking of interventions in regard to cost-effectiveness, although there are no existing studies to evaluate this. Previous analysis may underestimate the effectiveness and overestimate the cost-benefit ratios of mass treatment of school-age children if the externalities of treatment are not considered (Miguel and Kremer 2003). The cost-effectiveness of school-based deworming programs will change as the programs are extended to cover children who are not enrolled in school. Such program extensions are likely to have greater costs because they entail additional staff and outreach efforts per case treated. However, the effectiveness of mass treatment of school-age children (both enrolled and not enrolled) may be greater. Children who are not enrolled in school come from households with lower income levels. Lower income, which leads to poorer sanitation conditions, is associated with greater incidence and intensity of

infections. Expanding mass treatment to children not enrolled in school will result in treating populations that have higher incidence and intensity, thus raising effectiveness (box 24.2).

Distributional and Equity Consequences

Interventions to control helminth infections can have equity implications in several dimensions. Programs designed to target communities with high prevalence or high intensity of helminth infection focus on areas with lower income, as described in the sections on the causes, characteristics, and epidemiology of such infections. Although no studies undertake benefit-incidence analysis of public spending on such health services, this targeting implies that state subsidies on deworming services will be of most benefit to lower-income groups. With the increasing availability of poverty maps, empirical evaluation of the equity implications of deworming will be feasible.

AVERTED, AVERTABLE, AND NONAVERTABLE BURDEN

In the short run, deworming can avert helminth infections. In the long run, it is assumed that as income levels grow and infrastructure improves, the number of infections averted by reducing transmission will increase. However, given the slow rate of poverty reduction in the 1990s for the poorest regions, such as Sub-Saharan Africa, waiting for economic development to lead to a reduction in infections is only, at best, a slow-paced solution for the majority of the infected population. It is more likely that most averted infections will depend on periodic deworming. Thus, the question remains as to what portion of

existing infections is potentially avertable through recommended interventions and what portion is currently averted with existing programs. For schistosomiasis, successful programs in several countries, including Brazil, China, and the Arab Republic of Egypt, and the issues related to the sustainability of these successes have been described (see “Implementation of Control Strategies: Lessons of Experience” later in this chapter). However, the number of averted schistosomiasis infections in Sub-Saharan Africa is likely to be small, because few serious attempts at widespread control have been made in recent years, and not much of the burden of STH and schistosome infections is currently averted through private treatment. In part, the low number of averted infections may be due to the lack of information on the part of infected individuals, the insidious nature of the condition, and the lack of drugs in the public or private health delivery system.

ECONOMIC BENEFITS OF INTERVENTION

The characteristics of helminth infections make a compelling case for public sector intervention if based only on the evidence related to the intervention’s effect on health. From an economic perspective, the public sector has several reasons to become involved in improving health outcomes. First, other benefits may be gained, in addition to the benefit for the treated individual. Second, some forms of intervention are almost pure public goods; that is, no one can be excluded from using the goods or services the interventions deliver, and the private sector is thus unlikely to deliver them. Finally, preventive measures, such as information on the value of washing hands, may not be delivered through the private sector. The lack of knowledge about infections and subclinical symptoms may make individuals less likely to seek treatment. In analyzing the gains of interventions for worm control, one should account for the burden of helminth infections, which extends well beyond the health impacts and DALYs. The economic implications may be quite large.

The negative correlation between helminth infections and income level is clearly demonstrated both within and between countries (de Silva and others 2003). However, causality cannot be inferred from this established relationship; poverty promotes higher worm burdens, yet poor health induced by helminths can lead to lower income. There may also be opportunity costs to uninfected household members residing with infected persons. Few studies have been designed to evaluate, either directly or indirectly, the magnitude of the effect of deworming on economic productivity. The indirect evidence at the micro level suggests that helminth infection has a significant impact on adult productivity and, subsequently, on earnings. More direct evidence for children shows that helminth infection has long-term implications for educational attainment and economic status.

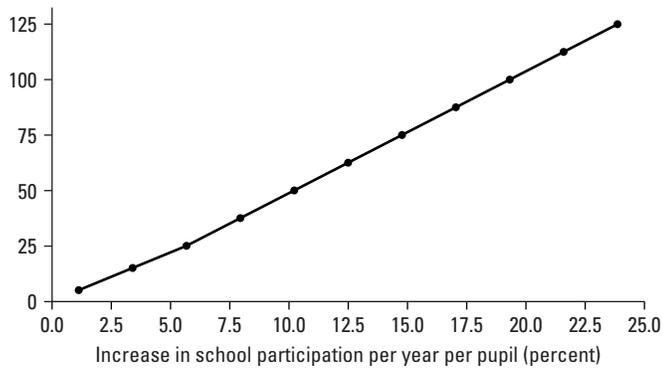

Studies are increasingly documenting a causal impact of adult health (broadly defined) on labor force participation, wages, and productivity in developing countries (Thomas and Strauss 1997). Moreover, helminth infection is known to affect some of the health conditions related to productivity—namely, iron deficiency anemia and wasting. Guyatt (2000) reviews numerous studies relating these conditions to physical fitness and productivity; Haas and Brownlie (2001) review studies on the effect of iron supplementation on work. The studies generally show productivity gains linked to better health along the various health dimensions studied. However, although some evidence points to the indirect impact of STHs on income earnings, these relationships have not been adequately studied, either directly or indirectly.

More compelling links between helminth infection and economic well-being may exist for children. The strong association between worm burden and poor health outcomes for children suggests that infections may affect school enrollment, attendance, grade repetition, and grade attainment. In turn, the potential impact on educational outcomes has implications for the assessment of the economic benefits of intervention. Numerous studies have demonstrated the benefits of schooling, showing that the return on education is quite high. Increased education is associated with, among other things, higher worker productivity and generally higher productivity in nonmarket production activities, including greater farmer efficiency and productivity (Psacharopoulos and Patrinos 2002).

Although observational studies show that lower levels of learning and schooling are linked to helminth infection (World Bank 2003), establishing a causal relationship requires adequately controlling for all unobserved or confounding factors. Miguel and Kremer (2003) note that several methodological issues hamper many existing randomized treatment-control evaluations. First, externalities associated with interventions can lead to underestimating impacts among the untreated population. Second, sample selection and attrition issues can affect the validity of findings, although the direction of this effect is ambiguous. Third, existing studies typically evaluate the impact of deworming on cognitive skills, likely the culmination of several years of health and education investments, as assessed by tests administered to treated and untreated children. Although studies find an effect on cognitive skills for those with the heaviest worm burden, they do not focus on other important education outcomes, which are likely to be more affected in the short run by health improvements, such as school enrollment and school attendance.

The study by Miguel and Kremer (2003) in Kenya attempts to address those shortcomings through improved study design and analytical methods. In addition to providing health gains, deworming reduced total primary school absenteeism by at least one-quarter in the first two years of the project. The gains were largest for the youngest children, who suffered from more

Net present value of discounted wages (US\$)

Note: Assumptions are as follows: a 7 percent return to an additional year of school; wage gains earned over 40 years in the workforce, discounted at 5 percent per year with no wage growth; and annual wage earnings of US\$400 per year, which is below the estimated agricultural and nonagricultural annual wages for low-income countries in the World Bank (2003).

Figure 24.3 Returns to School Participation

intense worm infections. Externalities would cause a substantial underestimation of this effect. In terms of cost-effectiveness as an *educational* intervention, deworming proved to be far more effective at improving school attendance than other educational interventions implemented in a study in Kenya. Deworming offers a high rate of return, increasing the net present value of discounted wages by more than US\$30 per treated child compared with per treatment costs of under US\$1. For realistic estimates of returns to schooling, these results show in general that the net present discounted value of lifetime earnings is high compared with the costs of treatment even for small gains in school participation (figure 24.3).

Bleakley (2003) examined the effect of a hookworm control program undertaken about 1910 in the southern part of the United States. Hookworm infection was estimated to cause a 23 percent drop in the probability of school attendance, and children with greater exposure to the hookworm eradication campaign were more likely to be literate. Moreover, the long-term follow-up of affected cohorts showed that hookworm infection in childhood led to significantly lower wages in adulthood.

Helminth infections in preschool-age children can have consequences for subsequent schooling, such as delaying primary school enrollment and school attainment, thereby affecting future labor market outcomes. Bobonis, Miguel, and Sharma (2003) conducted a study of preschool-age children, using iron supplementation and deworming drugs administered to children two to six years of age. Preliminary results indicate that, in addition to the weight gain associated with treatment, average preschool participation rates increased sharply by 6.3 percentage points among assisted children older than two, reducing preschool absenteeism by roughly one-fifth.

Beyond the current impacts on schooling and implications for cognition, helminth infection in children can have long-term implications for economic outcomes in adulthood through its effect on physical growth. Height has been shown to affect wage-earning capacity as well as participation in the labor force for men and women (Thomas and Strauss 1997). This relationship may be strongest in settings where infection rates are highest—that is, low-income areas, where physical endurance yields high returns in the labor market.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

Two case studies illustrate the profound health effects of periodic deworming.

Case Study Number 1: Periodic Deworming in Ghana and Tanzania

The Partnership for Child Development (PCD) undertook an evaluation of the use of schools in Ghana and Tanzania for the delivery of health interventions, including research into the processes, costs, and benefits (PCD 1999). The effort also involved operations research and evaluation of programs with regard to health and education outcomes and people's perceptions of the programs (Hall and others 1999). The results demonstrated the following:

- Simple interventions, such as deworming, have the potential to improve children's health and educational achievement, especially for those worst affected and most disadvantaged.
- The delivery of school-based health services is efficient and cost-effective and is supported by the key stakeholders involved. Implementers of the school health programs in the education and health sectors and the community are positive regarding the teacher's role in health provision, as long as the health interventions are simple, safe, familiar, and effective and are seen as responding to local needs.
- The provision of health services through schools need not require long and complex training, nor significantly add to the workload of teachers or administrators.
- Delivery through the existing education sector could occur effectively without any additional infrastructure, as long as the existing educational system is adequately functional.

The results of the evaluation of these programs also highlighted the need for deworming to be carried out in the context of a wider framework of school health, which includes core activities such as effective and nondiscriminatory school health policies, provision of safe water and sanitation, and effective

health education (<http://www.freshschools.org> and <http://www.schoolsandhealth.org>).

Case Study Number 2: Schistosomiasis Control in Egypt

In 1937, the prevalence of schistosomiasis in rural areas was about 50 percent, almost every boy had blood in his urine by the age of 12, and bladder cancer was the commonest cancer in Egypt. Molluscicides, from copper sulfate to niclosamide, have been used to try to kill the host snails, and drugs from antimony-based compounds, through niridazole, metrifonate, and PZQ, have been used to treat the millions of infected Egyptians. Finally, after a 14-year control campaign using PZQ, the prevalence of schistosomiasis has been reduced to below 10 percent. With infection intensities now low, the serious health consequences of schistosomiasis have disappeared. The program was started in 1988, when using loans from the African Development Bank and the World Bank, Egypt invested heavily in the purchase of PZQ, encouraging local production, to control morbidity caused by schistosomiasis. Since the drug was first made available in 1988, some 45 million doses have been dispensed. A television campaign has encouraged people to submit samples for diagnosis and to receive free treatment if their diagnoses are positive. Since 1997, a mass chemotherapy campaign was used to target populations in high-prevalence villages and children in selected governorates where prevalence was greater than 20 percent. In addition, molluscicides have been applied in canals around high-prevalence villages. The widespread use of PZQ has given dramatic results. Morbidity, including hematuria, has almost disappeared, and bladder cancer is on the decline.

RESEARCH AND DEVELOPMENT

Among the important tasks to be done to control helminth infections are collection of better data on helminth disease burden, research on the health and economic effects (and safety) of periodic deworming, monitoring of the emergence of anthelmintic drug resistance, and development of new tools to supplement or complement existing control strategies.

Health and Economic Impact

Overall, better estimates of disease burden are needed (Michaud, Gordon, and Reich 2003), especially with respect to obtaining a consistent and agreed-on estimate for the DALYs attributed to helminth infections. In a systematic review of randomized deworming trials, Dickson and others (2000) conclude that, although data support the effects of deworming on weight gain, there are inconsistencies among trials and insufficient evidence as to whether such interventions improve cogni-

tive performance. Plausible mechanisms by which helminths suppress growth in childhood and exert negative impacts on intelligence, cognition, and school performance are largely unstudied and unknown. In addition, some reports have questioned whether albendazole itself could adversely affect growth (Forrester and others 1998). Those issues require clarification as widespread deworming programs become more common. The impact of helminths on populations other than schoolchildren, including preschool-age children, women of childbearing age, and adult workers, appears to be substantial. However, those populations are understudied. Also unclear is the impact of childhood STH and schistosome infections on productivity in adulthood. The effect of chemotherapy on many of the manifestations of schistosomiasis has not been assessed systematically. It has been postulated that PZQ treatment of schistosomiasis promotes partial immunity by destroying worms in the vasculature and releasing parasite antigens (Colley and Secor 2004). In contrast, the frequent and periodic treatment of STH infections (Albonico and others 1995) do not appear to promote natural protective immunity.

The role of helminths and coinfections also warrants further exploration. Some studies suggest that HIV-1 infection may promote susceptibility to schistosomiasis (Secor, Karanja, and Colley 2004), and human T-cell lymphotropic virus-1 (HTLV-1) infection may promote susceptibility to strongyloidiasis. In addition, emerging evidence indicates that STH and schistosome infections may promote susceptibility to other infectious agents, possibly including HIV/AIDS and malaria (Fincham, Markus, and Adams 2003). This phenomenon, if verified in an epidemiologic study, would further increase helminth-associated DALY estimates.

Anthelmintic Drug Resistance and New Drug Development

A concern about the feasibility of sustainable control with BZAs is the possible emergence of drug resistance among human STHs. BZA resistance occurs because of the spread of point mutations in nematode-tubulin alleles. This phenomenon has already resulted in widespread BZA drug resistance among STHs of ruminant livestock. There is still no direct evidence for BZA resistance among human STHs, although such resistance could account for an observed failure of mebendazole for human hookworm in southern Mali, as well as a diminished efficacy against hookworm in Zanzibar following frequent and periodic use of mebendazole (Albonico and others 2003). PZQ resistance must also be considered, especially as it begins to be widely used in Sub-Saharan Africa (Hagan and others 2004). Should PZQ resistance develop, there will be new demands for antischistosomal drugs. Recently, the artemisins have shown activity against schistosomes and were successful in protecting against *S. japonicum* in China (Hagan and others 2004).

Anthelmintic Vaccines

The high rates of reinfection that can occur following treatment with anthelmintic drugs and concern about emerging drug resistance have prompted the search for alternative control tools. For most helminth infections, reduction in adult worm burden has been considered the “gold standard” for vaccine development. For schistosomiasis, however, a vaccine that targets parasite fecundity and egg viability, thereby reducing pathology and transmission, would also represent an important breakthrough. A 28-kDa glutathione S-transferase (GST) has shown promise as a protective antigen for *S. haematobium* infection (Capron and others 2005). The *S. haematobium* vaccine project based on GST has successfully passed phase 1 testing; the research group, which is based at the Pasteur Institute, is embarking on phase 2 clinical trials in Senegal and Niger. Additional schistosomiasis vaccines are also undergoing early-stage development. Efforts are also under way by the Human Hookworm Vaccine Initiative to develop and test a first-generation recombinant hookworm vaccine (Brooker and others 2005; Hotez, Bethony, and others 2005). The first vaccine manufactured under current good manufacturing practices and tested for quality control and toxicity is the Na-ASP-2 hookworm vaccine, which was developed from research demonstrating human correlates of immunity and partial protection data in vaccinated laboratory animals. Phase 1 human trials for evaluating the safety and immunogenicity of the Na-ASP-2 hookworm vaccine are in progress. Additional research is needed to determine how an anthelmintic vaccine can be incorporated into existing control programs, as well how it would be used for at-risk populations not currently targeted for periodic deworming in schools.

CONCLUSIONS: PROMISES AND PITFALLS

Fulfilling the mandate of World Health Assembly resolution 54.19 will require the regular treatment of hundreds of millions of children over decades. The obstacles in this undertaking are formidable, and success will depend on the ability of countries to identify or create reliable and sustained infrastructures for this purpose. A focus on using preexisting school systems may be key to achieving this goal. The treatment of schoolchildren for *A. lumbricoides*, *T. trichiura*, and schistosome infections achieves large externalities that reduce infection in other vulnerable age groups. However, the different epidemiology of hookworm raises concerns about the risks to preschool children and women of reproductive age who remain untreated. Providing regular treatment to these populations appears to be a less cost-effective option, largely because of the absence of a preexisting infrastructure. This situation presents a strong argument for developing a hookworm vaccine that could be used to protect these vulnerable groups. It has yet to be seen whether the emergence of BZA drug resistance is a genuine

concern that could derail global deworming efforts in much the same way that resistance to DDT and chloroquine has affected the ambitions for global malaria control. It is possible that the specific dynamics of helminth populations will provide sufficient genetic flow to maintain susceptibility in much the same way that insecticides remain the effective staple of global agribusiness. Until new technologies become available, anthelmintic chemotherapy for school-age children remains the most practical and substantive means to control STH and schistosome infections in the developing world.

Chapter 25

Acute Respiratory Infections in Children

Eric A. F. Simoes, Thomas Cherian, Jeffrey Chow, Sonbol Shahid-Salles, Ramanan Laxminarayan, and T. Jacob John

Acute respiratory infections (ARIs) are classified as upper respiratory tract infections (URIs) or lower respiratory tract infections (LRIs). The upper respiratory tract consists of the airways from the nostrils to the vocal cords in the larynx, including the paranasal sinuses and the middle ear. The lower respiratory tract covers the continuation of the airways from the trachea and bronchi to the bronchioles and the alveoli. ARIs are not confined to the respiratory tract and have systemic effects because of possible extension of infection or microbial toxins, inflammation, and reduced lung function. Diphtheria, pertussis (whooping cough), and measles are vaccine-preventable diseases that may have a respiratory tract component but also affect other systems; they are discussed in chapter 20.

Except during the neonatal period, ARIs are the most common causes of both illness and mortality in children under five, who average three to six episodes of ARIs annually regardless of where they live or what their economic situation is (Kamath and others 1969; Monto and Ullman 1974). However, the proportion of mild to severe disease varies between high- and low-income countries, and because of differences in specific etiologies and risk factors, the severity of LRIs in children under five is worse in developing countries, resulting in a higher case-fatality rate. Although medical care can to some extent mitigate both severity and fatality, many severe LRIs do not respond to therapy, largely because of the lack of highly effective antiviral drugs. Some 10.8 million children die each year (Black, Morris, and Bryce 2003). Estimates indicate that in 2000, 1.9 million of them died because of ARIs, 70 percent of them in Africa and Southeast Asia (Williams and others 2002). The World Health Organization (WHO) estimates that 2 million children under five die of pneumonia each year (Bryce and others 2005).

CAUSES OF ARIs AND THE BURDEN OF DISEASE

ARIs in children take a heavy toll on life, especially where medical care is not available or is not sought.

Upper Respiratory Tract Infections

URIs are the most common infectious diseases. They include rhinitis (common cold), sinusitis, ear infections, acute pharyngitis or tonsillopharyngitis, epiglottitis, and laryngitis—of which ear infections and pharyngitis cause the more severe complications (deafness and acute rheumatic fever, respectively). The vast majority of URIs have a viral etiology. Rhinoviruses account for 25 to 30 percent of URIs; respiratory syncytial viruses (RSVs), parainfluenza and influenza viruses, human metapneumovirus, and adenoviruses for 25 to 35 percent; corona viruses for 10 percent; and unidentified viruses for the remainder (Denny 1995). Because most URIs are self-limiting, their complications are more important than the infections. Acute viral infections predispose children to bacterial infections of the sinuses and middle ear (Berman 1995a), and aspiration of infected secretions and cells can result in LRIs.

Acute Pharyngitis. Acute pharyngitis is caused by viruses in more than 70 percent of cases in young children. Mild pharyngeal redness and swelling and tonsil enlargement are typical. Streptococcal infection is rare in children under five and more common in older children. In countries with crowded living conditions and populations that may have a genetic predisposition, poststreptococcal sequelae such as acute rheumatic fever and carditis are common in school-age children but may also

occur in those under five. Acute pharyngitis in conjunction with the development of a membrane on the throat is nearly always caused by *Corynebacterium diphtheriae* in developing countries. However, with the almost universal vaccination of infants with the DTP (diphtheria-tetanus-pertussis) vaccine, diphtheria is rare.

Acute Ear Infection. Acute ear infection occurs with up to 30 percent of URIs. In developing countries with inadequate medical care, it may lead to perforated eardrums and chronic ear discharge in later childhood and ultimately to hearing impairment or deafness (Berman 1995b). Chronic ear infection following repeated episodes of acute ear infection is common in developing countries, affecting 2 to 6 percent of school-age children. The associated hearing loss may be disabling and may affect learning. Repeated ear infections may lead to mastoiditis, which in turn may spread infection to the meninges. Mastoiditis and other complications of URIs account for nearly 5 percent of all ARI deaths worldwide (Williams and others 2002).

Lower Respiratory Tract Infections

The common LRIs in children are pneumonia and bronchiolitis. The respiratory rate is a valuable clinical sign for diagnosing acute LRI in children who are coughing and breathing rapidly. The presence of lower chest wall indrawing identifies more severe disease (E. Mulholland and others 1992; Shann, Hart, and Thomas 1984).

Currently, the most common causes of viral LRIs are RSVs. They tend to be highly seasonal, unlike parainfluenza viruses, the next most common cause of viral LRIs. The epidemiology of influenza viruses in children in developing countries deserves urgent investigation because safe and effective vaccines are available. Before the effective use of measles vaccine, the measles virus was the most important viral cause of respiratory tract-related morbidity and mortality in children in developing countries.

Pneumonia. Both bacteria and viruses can cause pneumonia. Bacterial pneumonia is often caused by *Streptococcus pneumoniae* (pneumococcus) or *Haemophilus influenzae*, mostly type b (Hib), and occasionally by *Staphylococcus aureus* or other streptococci. Just 8 to 12 of the many types of pneumococcus cause most cases of bacterial pneumonia, although the specific types may vary between adults and children and between geographic locations. Other pathogens, such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*, cause atypical pneumonias. Their role as a cause of severe disease in children under five in developing countries is unclear.

The burden of LRIs caused by Hib or *S. pneumoniae* is difficult to determine because current techniques to establish bacterial etiology lack sensitivity and specificity. The results of

pharyngeal cultures do not always reveal the pathogen that is the cause of the LRI. Bacterial cultures of lung aspirate specimens are often considered the gold standard, but they are not practical for field application. Vuori-Holopainen and Peltola's (2001) review of several studies indicates that *S. pneumoniae* and Hib account for 13 to 34 percent and 1.4 to 42.0 percent of bacterial pneumonia, respectively, whereas studies by Adegbola and others (1994), Shann, Gratten, and others (1984), and Wall and others (1986) suggest that Hib accounts for 5 to 11 percent of pneumonia cases.

Reduced levels of clinical or radiological pneumonia in clinical trials of a nine-valent pneumococcal conjugate vaccine provide an estimate of the vaccine-preventable disease burden (*valency* indicates the number of serotypes against which the vaccine provides protection; *conjugate* refers to conjugation of polysaccharides to a protein backbone). In a study in The Gambia, 37 percent of radiological pneumonia was prevented, reflecting the amount of disease caused by *S. pneumoniae*, and mortality was reduced by 16 percent (Cutts and others 2005).

Upper respiratory tract colonization with potentially pathogenic organisms and aspiration of the contaminated secretions have been implicated in the pathogenesis of bacterial pneumonia in young children. Infection of the upper respiratory tract with influenza virus or RSVs has been shown to increase the binding of both *H. influenzae* (Jiang and others 1999) and *S. pneumoniae* (Hament and others 2004; McCullers and Bartmess 2003) to lining cells in the nasopharynx. This finding may explain why increased rates of pneumococcal pneumonia parallel influenza and RSV epidemics. A study in South Africa showed that vaccination with a nine-valent pneumococcal conjugate vaccine reduced the incidence of virus-associated pneumonia causing hospitalization by 31 percent, suggesting that pneumococcus plays an important role in the pathogenesis of virus-associated pneumonia (Madhi, Petersen, Madhi, Wasas, and others 2000).

Entry of bacteria from the gut with spread through the bloodstream to the lungs has also been proposed for the pathogenesis of Gram-negative organisms (Fiddian-Green and Baker 1991), but such bacteria are uncommon etiological agents of pneumonia in immune-competent children. However, in neonates and young infants, Gram-negative pneumonia is not uncommon (Quiambao forthcoming).

Viruses are responsible for 40 to 50 percent of infection in infants and children hospitalized for pneumonia in developing countries (Hortal and others 1990; John and others 1991; Tupasi and others 1990). Measles virus, RSVs, parainfluenza viruses, influenza type A virus, and adenoviruses are the most important causes of viral pneumonia. Differentiating between viral and bacterial pneumonias radiographically is difficult, partly because the lesions look similar and partly because bacterial superinfection occurs with influenza, measles, and RSV infections (Ghafoor and others 1990).

In developing countries, the case-fatality rate in children with viral pneumonia ranges from 1.0 to 7.3 percent (John and others 1991; Stensballe, Devasundaram, and Simoes 2003), with bacterial pneumonia from 10 to 14 percent and with mixed viral and bacterial infections from 16 to 18 percent (Ghafoor and others 1990; Shann 1986).

Bronchiolitis. Bronchiolitis occurs predominantly in the first year of life and with decreasing frequency in the second and third years. The clinical features are rapid breathing and lower chest wall indrawing, fever in one-third of cases, and wheezing (Cherian and others 1990). Inflammatory obstruction of the small airways, which leads to hyperinflation of the lungs, and collapse of segments of the lung occur. Because the signs and symptoms are also characteristic of pneumonia, health workers may find differentiating between bronchiolitis and pneumonia difficult. Two features that may help are a definition of the seasonality of RSVs in the locality and the skill to detect wheezing. RSVs are the main cause of bronchiolitis worldwide and can cause up to 70 or 80 percent of LRIs during high season (Simoes 1999; Stensballe, Devasundaram, and Simoes 2003). The recently discovered human metapneumovirus also causes bronchiolitis (Van den Hoogen and others 2001) that is indistinguishable from RSV disease. Other viruses that cause bronchiolitis include parainfluenza virus type 3 and influenza viruses.

Influenza. Even though influenza viruses usually cause URIs in adults, they are increasingly being recognized as an important cause of LRIs in children and perhaps the second most important cause after RSVs of hospitalization of children with an ARI (Neuzil and others 2002). Although influenza is considered infrequent in developing countries, its epidemiology remains to be investigated thoroughly. The potential burden of influenza as a cause of death in children is unknown. Influenza virus type A may cause seasonal outbreaks, and type B may cause sporadic infection. Recently, avian influenza virus has caused infection, disease, and death in small numbers of individuals, including children, in a few Asian countries. Its potential for emergence in human outbreaks or a pandemic is unknown, but it could have devastating consequences in developing countries (Peiris and others 2004) and could pose a threat to health worldwide. New strains of type A viruses will almost certainly arise through mutation, as occurred in the case of the Asian and Hong Kong pandemics in the 1950s and 1960s.

HIV Infection and Pediatric LRIs

Worldwide, 3.2 million children are living with HIV/AIDS, 85 percent of them in Sub-Saharan Africa (UNAIDS 2002). In southern Africa, HIV-related LRIs account for 30 to 40 percent of pediatric admissions and have a case-fatality rate of 15 to

34 percent, much higher than the 5 to 10 percent for children not infected with HIV (Bobat and others 1999; Madhi, Petersen, Madhi, Khoosal, and others 2000; Nathoo and others 1993; Zwi, Pettifor, and Soderlund 1999). *Pneumocystis jirovecii* and cytomegalovirus are important opportunistic infections in more than 50 percent of HIV-infected infants (Jeena, Coovadia, and Chrystal 1996; Lucas and others 1996). Gram-negative bacteria are also important in more than 70 percent of HIV-infected malnourished children (Ikeogu, Wolf, and Mathe 1997). Patient studies have confirmed the frequent association of these bacteria but added *S. pneumoniae* and *S. aureus* as important pathogens (Gilks 1993; Goel and others 1999). The first South African report on the overall burden of invasive pneumococcal disease reported a 41.7-fold increase in HIV-infected children compared with uninfected children (Farley and others 1994).

INTERVENTIONS

Interventions to control ARIs can be divided into four basic categories: immunization against specific pathogens, early diagnosis and treatment of disease, improvements in nutrition, and safer environments (John 1994). The first two fall within the purview of the health system, whereas the last two fall under public health and require multisectoral involvement.

Vaccinations

Widespread use of vaccines against measles, diphtheria, pertussis, Hib, pneumococcus, and influenza has the potential to substantially reduce the incidence of ARIs in children in developing countries. The effects of measles, diphtheria, and pertussis vaccines are discussed in chapter 20. The limited data on influenza in developing countries do not permit detailed analysis of the potential benefits of that vaccine. This chapter, therefore, focuses on the potential effects of Hib and pneumococcal vaccines on LRIs.

Hib Vaccine. Currently three Hib conjugate vaccines are available for use in infants and young children. The efficacy of Hib vaccine in preventing invasive disease (mainly meningitis, but also pneumonia), has been well documented in several studies in industrialized countries (Black and others 1992; Booy and others 1994; Eskola and others 1990; Fritzell and Plotkin 1992; Heath 1998; Lagos and others 1996; Santosham and others 1991) and in one study in The Gambia (K. Mulholland and others 1997). All studies showed protective efficacy greater than 90 percent against laboratory-confirmed invasive disease, irrespective of the choice of vaccine. Consequently, all industrialized countries include Hib vaccine in their national immunization programs, resulting in the virtual elimination of

invasive Hib disease because of immunity in those vaccinated and a herd effect in those not vaccinated. Available data from a few developing countries show a similar herd effect (Adegbola and others 1999; Wenger and others 1999).

The initial promise and consequent general perception was that Hib vaccine was to protect against meningitis, but in developing countries the vaccine is likely to have a greater effect on preventing LRIs. The easily measured effect is on invasive disease, including bacteraemic pneumonia. The vaccine probably has an effect on nonbacteremic pneumonia, but this effect is difficult to quantify because of the lack of an adequate method for establishing bacterial etiology. In Bangladesh, Brazil, Chile, and The Gambia, Hib vaccine has been associated with a reduction of 20 to 30 percent in those hospitalized with radiographically confirmed pneumonia (de Andrade and others 2004; Levine and others 1999; K. Mulholland and others 1997; WHO 2004a). However, results of a large study in Lombok, Indonesia, were inconclusive with regard to the effect of Hib vaccine on pneumonia (Gessner and others 2005).

Pneumococcal Vaccines. Two kinds of vaccines are currently available against pneumococci: a 23-valent polysaccharide vaccine (23-PSV), which is more appropriate for adults than children, and a 7-valent protein-conjugated polysaccharide vaccine (7-PCV). A 9-valent vaccine (9-PCV) has undergone clinical trials in The Gambia and South Africa, and an 11-valent vaccine (11-PCV) is being tried in the Philippines.

Studies of the efficacy of the polysaccharide vaccine in preventing ARIs or ear infection in children in industrialized countries have shown conflicting results. Whereas some studies of this vaccine show no significant efficacy (Douglas and Miles 1984; Sloyer, Ploussard, and Howie 1981), studies from Finland show a generally protective effect against the serotypes contained in a 14-PSV (Douglas and Miles 1984; Karma and others 1980; Makela and others 1980). The efficacy was more marked in children over two years of age than in younger children. The only studies evaluating the effect of the polysaccharide vaccine in children in developing countries are a series of three trials conducted in Papua New Guinea (Douglas and Miles 1984; Lehmann and others 1991; Riley and others 1981; Riley, Lehmann, and Alpers 1991). The analysis of the pooled data from these trials showed a 59 percent reduction in LRI mortality in children under five at the time of the vaccination and a 50 percent reduction in children under two. On the basis of these and other studies, the investigators concluded that the vaccine had an effect on severe pneumonia. The greater-than-expected efficacy in these trials was attributed to the greater contribution of the more immunogenic adult serotypes in pneumonia in Papua New Guinea (Douglas and Miles 1984; Riley, Lehmann, and Alpers 1991). On account of the poor immunogenicity of the antigens in the 23-PSV against prevalent pediatric serotypes, attention is now directed at more

immunogenic conjugate vaccines (Mulholland 1998; Obaro 1998; Temple 1991).

The 7-PCV and 9-PCV have been evaluated for efficacy against invasive pneumococcal disease in four trials, which demonstrated a vaccine efficiency ranging from 71.0 to 97.4 percent (58 to 65 percent for HIV-positive children, among whom rates of pneumococcal disease are 40 times higher than in HIV-negative children) (Black and others 2000; Cutts and others 2005; Klugman and others 2003; O'Brien and others 2003).

In the United States, the 7-PCV was included in routine vaccinations of infants and children under two in 2000. By 2001 the incidence of all invasive pneumococcal disease in this age group had declined by 69 percent and disease caused by the serotypes included in the vaccine and related serotypes had declined by 78 percent (Whitney and others 2003). Similar reductions were confirmed in a study in northern California (Black and others 2001). A slight increase in rates of invasive disease caused by serotypes of pneumococcus not included in the vaccine was observed, but it was not large enough to offset the substantial reduction in disease brought about by the vaccine. The studies also found a significant reduction in invasive pneumococcal disease in unvaccinated older age groups, especially adults age 20 to 39 and age 65 and older, suggesting that giving the vaccine to young children exerted a considerable herd effect in the community. Such an advantage is likely to occur even where the prevalence of adult HIV disease is high and pneumococcal disease may be recurrent and life threatening.

The effect of the vaccine on pneumococcal pneumonia as such is difficult to define given the problems of establishing the bacterial etiology of pneumonia. Three studies have evaluated the effect of the vaccine on radiographic pneumonia (irrespective of the etiological agent) and have shown a 20.5 to 37.0 percent reduction in radiographically confirmed pneumonia (9.0 percent for HIV-positive individuals) (Black and others 2000; Cutts and others 2005; Klugman and others 2003).

Several field trials have evaluated the efficacy of PCV against ear infection. Even though the vaccine resulted in a significant reduction in culture-confirmed pneumococcal otitis, no net reduction of ear infection was apparent among vaccinated children, probably because of an increase in the rates of otitis caused by types of pneumococci not covered by the vaccine, *H. influenzae* and *Moraxella catarrhalis* (Eskola and others 2001; Kilpi and others 2003). However, a trial in northern California showed that the vaccine had a protective effect against frequent ear infection and reduced the need for tympanostomy tube placement (Fireman and others 2003). Thus, a vaccine for ear infection may be beneficial in developing countries with high rates of chronic otitis and conductive hearing loss and should be evaluated by means of clinical trials.

The most striking public health benefit of a vaccine in developing countries would be a demonstrable reduction in mortality. Although the primary outcome in The Gambia trial

was initially child mortality, it was changed to radiological pneumonia. Nevertheless, the trial showed a 16 percent (95 percent confidence level, 3 to 38) reduction in mortality. This trial was conducted in a rural area in eastern Gambia where access to round-the-clock curative care, including case management, is difficult to provide. This trial demonstrates that immunization delivered through outreach programs will have substantial health and economic benefits in such populations. One additional study evaluating the effect of an 11-PCV on radiological pneumonia is ongoing in the Philippines; results are expected in the second half of 2005.

Case Management

The simplification and systematization of case management for early diagnosis and treatment of ARIs have enabled significant reductions in mortality in developing countries, where access to pediatricians is limited. WHO clinical guidelines for ARI case management (WHO 1991) use two key clinical signs: *respiratory rate*, to distinguish children with pneumonia from those without, and *lower chest wall indrawing*, to identify severe pneumonia requiring referral and hospital admission. Children with audible stridor when calm and at rest or such danger signs of severe disease as inability to feed also require referral. Children without these signs are classified as having an ARI but not pneumonia. Children showing only rapid breathing are treated for pneumonia with outpatient antibiotic therapy. Children who have a cough for more than 30 days are referred for further assessment of tuberculosis and other chronic infections.

Pneumonia Diagnosis Based on Rapid Breathing. The initial guidelines for detecting pneumonia based on rapid breathing were developed in Papua New Guinea during the 1970s. In a study of 200 consecutive pediatric outpatients and 50 consecutive admissions (Shann, Hart, and Thomas 1984), 72 percent of children with audible crackles in the lungs had a respiratory rate of 50 or more breaths per minute, whereas only 19 percent of children without crackles breathed at such a rapid rate. Therefore, the initial WHO guidelines used a threshold of 50 breaths per minute, at or above which a child with a cough was regarded as having pneumonia.

The major concern was the relatively low sensitivity of this approach, which could miss 25 to 40 percent of cases of pneumonia. A study in Vellore, India, found that sensitivity could be improved by lowering the threshold to 40 for children age 1 to 4, while keeping the 50 breaths per minute cutoff for infants age 2 months through 11 months (Cherian and others 1988). Subsequent studies showed that when these thresholds were used, sensitivity improved from 62 to 79 percent in the Philippines and from 65 to 77 percent in Swaziland, but at the same time, the specificity fell from 92 to 77 percent in the Philippines and 92 to 80 percent in Swaziland (Mulholland and

others 1992). On the basis of these and other data (Campbell, Byass, and others 1989; Kolstad and others 1997; Perkins and others 1997; Redd 1994; Simoes and others 1997; Weber and others 1997), WHO recommends a respiratory rate cutoff of 50 breaths per minute for infants age 2 through 11 months and 40 breaths per minute for children age 12 months to 5 years.

Rapid breathing, as defined by WHO, detects about 85 percent of children with pneumonia, and more than 80 percent of children with potentially fatal pneumonia are probably successfully identified and treated using the WHO diagnostic criteria. Antibiotic treatment of children with rapid breathing has been shown to reduce mortality (Sazawal and Black 2003). The problem of the low specificity of the rapid breathing criterion is that some 70 to 80 percent of children who may not need antibiotics will receive them. Nevertheless, for primary care workers for whom diagnostic simplicity is essential, rapid breathing is clearly the most useful clinical sign.

Pneumonia Diagnosis Based on Chest Wall Indrawing. Children are admitted to hospital with severe pneumonia when health workers believe that oxygen or parenteral antibiotics (antibiotics administered by other than oral means) are needed or when they lack confidence in mothers' ability to cope. The rationale of parenteral antibiotics is to achieve higher levels of antibiotics and to overcome concerns about the absorption of oral drugs in ill children.

The Papua New Guinea study (Shann, Hart, and Thomas 1984) used chest wall indrawing as the main indicator of severity, but studies from different parts of the world show large differences in the rates of indrawing because of variable definitions. Restriction of the term to lower chest wall indrawing, defined as inward movement of the bony structures of the chest wall with inspiration, has provided a better indicator of the severity of pneumonia and one that can be taught to health workers. It is more specific than intercostal indrawing, which frequently occurs in bronchiolitis.

In a study in The Gambia (Campbell, Byass, and others 1989), a cohort of 500 children from birth to four years old was visited at home weekly for one year. During this time, 222 episodes of LRI (rapid breathing, any chest wall indrawing, nasal flaring, wheezing, stridor, or danger signs) were referred to the clinic. Chest indrawing was present in 62 percent of these cases, many with intercostal indrawing. If all children with any chest indrawing were hospitalized, the numbers would overwhelm pediatric inpatient facilities.

Studies in the Philippines and Swaziland (E. Mulholland and others 1992) found that lower chest wall indrawing was more specific than intercostal indrawing for a diagnosis of severe pneumonia requiring hospital admission. In the Vellore study (Cherian and others 1988), lower chest wall indrawing correctly predicted 79 percent of children with an LRI who were hospitalized by a pediatrician.

Antimicrobial Options for Oral Treatment of Pneumonia.

The choice of an antimicrobial drug for treatment is based on the well-established finding that most childhood bacterial pneumonias are caused by *S. pneumoniae* or *H. influenzae*. A single injection of benzathine penicillin, although long lasting, does not provide adequate penicillin levels to eliminate *H. influenzae*. WHO has technical documents to help assess the relevant factors in selecting first- and second-line antimicrobials and comparisons of different antimicrobials in relation to their antibacterial activity, treatment efficacy, and toxicity (WHO 1990).

The emergence of antimicrobial resistance in *S. pneumoniae* and *H. influenzae* is a serious concern. In some settings, in vitro tests show that more than 50 percent of respiratory isolates of both bacteria are resistant to co-trimoxazole, and penicillin resistance to *S. pneumoniae* is gradually becoming a problem worldwide.

In pneumonia, unlike in meningitis, in vitro resistance of the pathogen does not always translate into treatment failure. Reports from Spain and South Africa suggest that pneumonia caused by penicillin-resistant *S. pneumoniae* can be successfully treated with sufficiently high doses of penicillin. Amoxicillin is concentrated in tissues and in macrophages, and drug levels are directly correlated with oral dosages. Therefore, higher doses than in the past—given twice a day—are now being used to successfully treat ear infections caused by penicillin-resistant *S. pneumoniae*. Amoxicillin is clearly better than penicillin for such infections. The situation with co-trimoxazole is less clear (Strauss and others 1998), and in the face of high rates of co-trimoxazole resistance, amoxicillin may be superior for children with severe pneumonia.

Intramuscular Antibiotics for Treatment of Severe Pneumonia.

Even though chloramphenicol is active against both *S. pneumoniae* and *H. influenzae*, its oral absorption is erratic in extremely sick children. Thus, the WHO guidelines recommend giving intramuscular chloramphenicol at half the daily dose before urgent referral of severe pneumonia cases. An additional rationale is that extremely sick children may have sepsis or meningitis that are difficult to rule out and must be treated immediately. Although intravenous chloramphenicol is superior to intramuscular chloramphenicol, the procedure can delay urgently needed treatment and adds to its cost.

Investigators have questioned the adequacy and safety of intramuscular chloramphenicol. Although early studies suggested that adult blood levels after intramuscular administration were significantly less than those achieved after intravenous administration, the intramuscular route gained wide acceptance following clinical reports that confirmed its efficacy. Local complications of intramuscular chloramphenicol succinate are rare, unlike the earlier intramuscular preparations. Although concerns about aplastic anemia following

chloramphenicol are common, this complication is extremely rare in young children. There is no evidence that intramuscular chloramphenicol succinate is more likely to produce side effects than other forms and routes of chloramphenicol.

Hypoxemia Diagnosis Based on WHO Criteria.

The ARI case-management and integrated management of infant and childhood illness (IMCI) strategies depend on accurate referral of sick children to a hospital and correct inpatient management of LRI with oxygen or antibiotics. Hypoxemia (deficiency of oxygen in the blood) in children with LRI is a good predictor of mortality, the case-fatality rate being 1.2 to 4.6 times higher in hypoxemic LRI than nonhypoxemic LRI (Duke, Mgone, and Frank 2001; Onyango and others 1993), and oxygen reduces mortality. Thus, it is important to detect hypoxemia as early as possible in children with LRI to avert death. Although diagnoses of acute LRIs are achieved very easily by recognizing tachypnoea, and although severe LRI is associated with chest wall indrawing, the clinical recognition of hypoxemia is more problematic. Different sets of clinical rules have been studied to predict the presence of hypoxemia in children with LRI (Cherian and others 1988; Onyango and others 1993; Usen and others 1999). Although some clinical tools have a high sensitivity for detecting hypoxemia, a good number of hypoxemic children would still be missed using these criteria. Pulse oximetry is the best tool to quickly detect hypoxemia in sick children. However, pulse oximeters are expensive and have recurring costs for replacing probes, for which reasons they are not available in most district or even referral hospitals in developing countries.

Treatment Guidelines.

Current recommendations are for co-trimoxazole twice a day for five days for pneumonia and intramuscular penicillin or chloramphenicol for children with severe pneumonia. The problems of increasing resistance to co-trimoxazole and unnecessary referrals of children with any chest wall indrawing have led to studies exploring alternatives to the antibiotics currently used in ARI case management. One study indicated that amoxicillin and co-trimoxazole are equally effective for nonsevere pneumonia (Catchup Study Group 2002), though amoxicillin costs twice as much as co-trimoxazole. With respect to the duration of antibiotic treatment, studies in Bangladesh, India, and Indonesia indicate that three days of oral co-trimoxazole or amoxicillin are as effective as five days of either drug in children with nonsevere pneumonia (Agarwal and others 2004; Kartasasmita 2003). In a multicenter study of intramuscular penicillin versus oral amoxicillin in children with severe pneumonia, Addo-Yobo and others (2004) find similar cure rates. Because patients were treated with oxygen when needed for hypoxemia and were switched to other antibiotics if the treatment failed, this regimen is not appropriate for treating severe pneumonia in an outpatient setting.

WHO recommends administering oxygen, if there is ample supply, to children with signs and symptoms of severe pneumonia and, where supply is limited, to children with any of the following signs: inability to feed and drink, cyanosis, respiratory rate greater than or equal to 70 breaths per minute, or severe chest wall retractions (WHO 1993). Oxygen should be administered at a rate of 0.5 liter per minute for children younger than 2 months and 1 liter per minute for older children. Because oxygen is expensive and supply is scarce, especially in remote rural areas in developing countries, WHO recommends simple clinical signs to detect and treat hypoxemia. Despite those recommendations, a study of 21 first-level facilities and district hospitals in seven developing countries found that more than 50 percent of hospitalized children with LRI were inappropriately treated with antibiotics or oxygen (Nolan and others 2001)—and in several, oxygen was in short supply. Clearly, providing oxygen to hypoxemic babies is lifesaving, though no randomized trials have been done to prove it.

Prevention and Treatment of Pneumonia in HIV-Positive Children. Current recommendations of a WHO panel for managing pneumonia in HIV-positive children and for prophylaxis of *Pneumocystis jiroveci* are as follows (WHO 2003):

- *Nonsevere pneumonia up to age 5 years.* Oral co-trimoxazole should remain the first-line antibiotic, but oral amoxicillin should be used if it is affordable or if the child has been on co-trimoxazole prophylaxis.
- *Severe or very severe pneumonia.* Normal WHO case-management guidelines should be used for children up to 2 months old. For children from 2 to 11 months, injectable antibiotics and therapy for *Pneumocystis jiroveci* pneumonia are recommended, as is starting *Pneumocystis jiroveci* pneumonia prophylaxis on recovery. For children age 12 to 59 months, the treatment consists of injectable antibiotics and therapy for *Pneumocystis jiroveci* pneumonia. *Pneumocystis jiroveci* pneumonia prophylaxis should be given for 15 months to children born to HIV-infected mothers; however, this recommendation has seldom been implemented.

COST-EFFECTIVENESS OF INTERVENTIONS

Pneumonia is responsible for about a fifth of the estimated 10.6 million deaths per year of children under five. Where primary health care is weak, reducing mortality through public health measures is a high priority. As noted earlier, the available interventions are primary prevention by vaccination and secondary prevention by early case detection and management.

The cost-effectiveness of Hib vaccines is discussed in chapter 20. We did not attempt an analysis of the cost-effectiveness

of pneumococcal vaccines, because global and regional estimates of the pneumococcal pneumonia burden are currently being developed and will not be available until later in 2005. In addition, current vaccine prices are relatively stable in developed countries, but the prices for low- and middle-income countries are expected to be substantially lower when vaccines are purchased through a global tender.

We evaluate case-management intervention strategies for LRIs in children under five. Health workers who implement case management diagnose LRIs on the basis of fast breathing, lower chest wall indrawing, or selected danger signs in children with respiratory symptoms. Because this method does not distinguish between pneumonia and bronchiolitis, nor between bacterial and viral pneumonia, we group these conditions into the general category of “clinical pneumonia” (Rudan and others 2004). This approach assumes that a high proportion of clinical pneumonia is of bacterial origin and that health workers can considerably reduce case fatality through breathing rate diagnosis and timely administration of antibiotics (Sazawal and Black 2003). We calculated treatment costs by World Bank region using standardized input costs provided by the volume editors and costs published in the *International Drug Price Indicator Guide* (Management Sciences for Health 2005) and other literature (table 25.1). The analysis addresses four categories of case management, which are distinguished by the severity of the infection and the point of treatment:

- nonsevere pneumonia treated by a community health worker
- nonsevere pneumonia treated at a health facility
- severe pneumonia treated at a hospital
- very severe pneumonia treated at a hospital.

Information about these categories of case management and their outcomes is drawn from a report on the methodology and assumptions used to estimate the costs of scaling up selected health interventions aimed at children (WHO and Child Adolescent Health forthcoming). We assumed a total of three follow-up visits for each patient treated by a community health worker rather than the twice-daily follow-ups for 10 days recommended by the report. We also assumed that all severe pneumonia patients receive an x-ray examination, rather than just 20 percent as suggested by the report. Moreover, we assumed a five-hour workday for a community health worker, the minimum workday required for community health workers under the Child Health and Survival initiative of the U.S. Agency for International Development (Bhattacharyya and others 2001).

Table 25.2 presents region-specific estimates of average treatment costs per episode for the four case-management strategies. Because we considered the prices of tradable commodities such as drugs and oxygen to be constant across

Table 25.1 Inputs for Case Management of Pneumonia in Low- and Middle-Income Countries

Condition and intervention	Cost per unit (2001 US\$)	Quantity	Percentage of patients
<i>Nonsevere pneumonia at the community level</i>			
Oral amoxicillin (15 mg/kg)	0.03/dose	3 doses/day for 3 days	100
Acetaminophen (100-mg tablet)	0.001/dose	6 doses	100
Community health worker hour ^a	1.83/hour	1 initial 1-hour visit and 3 follow-up visits	100
<i>Nonsevere pneumonia at the facility level</i>			
Oral amoxicillin (15 mg/kg)	0.03/dose	3 doses/day for 3 days	100
Acetaminophen (100-mg tablet)	0.001/dose	6 doses	100
Oral salbutamol (2-mg tablet)	0.003/dose	3 doses/day for 4 days	10
Outpatient health facility visit ^a	1.72/visit	1 visit	100
<i>Severe pneumonia at the hospital level</i>			
Oral amoxicillin (15 mg/kg)	0.03/dose	3 doses/day for 5 days	100
Nebulized salbutamol (2.5 mg)	0.13/dose	6 doses/day for 4 days	50
Injectable ampicillin (50 mg/kg)	0.21/dose	4 doses/day for 3 days	100
X-ray ^a	9.21/test	1 test	100
Oxygen (1 liter/minute) ^b	20/day	3.5 days	50
Inpatient hospital care ^a	10.8/day	3 days	100
<i>Very severe pneumonia at the hospital level</i>			
Oral amoxicillin (15 mg/kg)	0.03/dose	3 doses/day for 5 days	100
Nebulized salbutamol (2.5 mg)	0.13/dose	6 doses/day for 4 days	50
Injectable ampicillin (50 mg/kg)	0.21/dose	4 doses/day for 5 days	100
Injectable gentamicin (2.5 mg/kg)	0.14/dose	1 dose/day for 10 days	100
Oral prednisolone (1 mg/kg)	0.02/dose	1 dose/day for 3 days	5
X-ray ^a	9.21/test	1 test	100
Oxygen (1 liter/minute) ^b	20/day	5 days	100
Inpatient hospital care ^a	10.8/day	5 days	100

Note: We assumed that the average patient weighs 12.5 kilograms.

a. Provided by the volume editors. Input costs vary by region.

b. Median costs obtained from Dobson 1991; Pederson and Nyrop 1991; Schneider 2001; WHO 1993.

Table 25.2 Average per Episode Treatment Costs of Case-Management Interventions for Acute Lower Respiratory Infection (2001 US\$)

Region	Nonsevere, community level	Nonsevere, facility level	Severe, hospital level	Very severe, hospital level
Low- and middle-income countries	8	2	82	172
East Asia and the Pacific	6	2	75	160
Latin America and the Caribbean	13	4	134	256
Middle East and North Africa	22	3	113	223
South Asia	5	2	66	148
Sub-Saharan Africa	7	2	64	145

Source: Authors' calculations.

regions, regional variations were due to differences in hospital and health worker costs. Latin America and the Caribbean and the Middle East and North Africa had the highest treatment costs.

We calculated region-specific cost-effectiveness ratios (CERs) for a model population of 1 million in each region, following the standardized guidelines for economic analyses (see chapter 15 for details). Input variables included the treatment

costs detailed in tables 25.1 and 25.2, region-specific LRI morbidity rates, adapted from Rudan and others (2004), region-specific mortality rates and age structures provided by the volume editors, and region-specific urban to rural population ratios (World Bank 2002). The Europe and Central Asia region was excluded from this analysis because of a lack of incidence information. In the absence of region-specific information, we assumed uniform intervention effectiveness rates.

Disability-adjusted life years are averted through reduced duration of illness and decreased mortality with treatment. We assumed an average illness duration of 8.5 days for those not treated and of 6.0 days for those treated. We used a case-fatality reduction of 36.0 percent on account of treatment (Sazawal and Black 2003) and a diagnosis specificity of 78.5 percent for patients diagnosed based on breath rate alone. The disability weight contemporaneous with infection was 0.28. We did not consider disabilities caused by chronic sequelae of LRIs because it is unclear whether childhood LRI causes long-term impaired lung function or whether children who develop impaired lung function are more prone to infection (von Mutius 2001).

Because a single year of these interventions yields only contemporaneous benefits—because effectively treated individuals do not necessarily live to life expectancy given that they are likely to be infected again the following year—we calculated the cost-effectiveness of a five-year intervention. This time period enabled us to consider the case in which an entire cohort of newborns to four-year-olds avoids early childhood clinical pneumonia mortality because of the intervention and receives the benefit of living to life expectancy. Finally, this analysis considered only long-run marginal costs, which vary with the number of individuals treated, and did not include the fixed costs of initiating a program where none currently exists.

Table 25.3 presents the region-specific CERs of the four case-management categories as well as the CER for providing all four categories to a population of 1 million people. Among all low- and middle-income countries, treatment of nonsevere clinical pneumonia was more cost-effective at the facility level

than at the community level, and of all four case-management categories, treatment of very severe clinical pneumonia at the hospital level was the least cost-effective. Treatment of non-severe clinical pneumonia at the facility level was more cost-effective than treatment by a community health worker because of the lower cost of a single visit to a health facility than of multiple visits by a health worker. The CER of providing all levels of treatment to all low- and middle-income countries was estimated at US\$398 per disability-adjusted life year.

Because we assumed that effectiveness rates were constant, regional variations in the CER for each case-management category were due only to variations in the intervention costs, and the relative cost-effectiveness rankings for the strategies was the same for all the regions. Variation in the CERs for providing all categories of care was also due to region-specific urban to rural population ratios. We assumed that all patients in urban areas seek treatment at the facility level or higher, whereas 80 percent of nonseverely ill patients in rural areas receive treatment at the community level and the remainder seek treatment at the facility level.

IMPLEMENTATION OF ARI CONTROL STRATEGIES: LESSONS OF EXPERIENCE

The lessons of ARI prevention and control strategies that have been implemented by national programs include the vaccination and case-management strategies discussed below.

Vaccine Strategies

Hib vaccine was introduced into the routine infant immunization schedule in North America and Western Europe in the early 1990s. With the establishment of the Global Alliance for Vaccines and Immunization (GAVI) and the Vaccine Fund, progress is being made in introducing it in developing countries, although major hurdles remain. By 2002, only 84 of the 193 WHO member nations had introduced Hib vaccine. Five

Table 25.3 CERs of Case-Management Interventions for Pneumonia (2001US\$/disability-adjusted life year)

Region	Nonsevere, community level	Nonsevere, facility level	Severe, hospital level	Very severe, hospital level	Provision of all four interventions
Low- and middle-income countries	208	50	2,916	6,144	398
East Asia and the Pacific	439	91	6,511	13,945	900
Latin America and the Caribbean	547	424	14,719	28,106	1,941
Middle East and North Africa	733	180	6,810	13,438	1,060
South Asia	140	28	1,931	4,318	264
Sub-Saharan Africa	139	24	1,486	3,376	218

Source: Authors' calculations.

countries have since been approved for support from GAVI for Hib vaccine introduction in 2004–5.

The United States added 7-PCV to the infant immunization program in 2000. Several other industrialized countries have plans to introduce the vaccine into their national immunization programs in 2005, whereas others recommend the use of the vaccine only in selected high-risk groups. In some of these last countries, the definition of *high risk* is quite broad and includes a sizable proportion of all infants. The currently licensed 7-PCV lacks certain serotypes important in developing countries, but the 9-PCV and 11-PCV would cover almost 80 percent of serotypes that cause serious disease worldwide.

Despite the success of Hib vaccine in industrial countries and the generally appreciated importance of LRIs as a cause of childhood mortality, as a result of a number of interlinked factors, uptake in developing countries has been slow. Sustained use of the vaccine is threatened in a few of the countries that have introduced the vaccine. First, the magnitude of disease and death caused by Hib is not recognized in these countries, partly because of their underuse of bacteriological diagnosis (a result of the lack of facilities and resources). Second, because the coverage achieved with traditional Expanded Program on Immunization vaccines remains low in many countries, adding more vaccines has not been identified as a priority. Third, developing countries did not initiate efforts to establish the utility of the vaccine until after the vaccine had been licensed and used routinely for several years in industrialized countries. Consequently, Hib vaccination has been perceived as an intervention for rich countries. As a result of all these factors, actual demand for the vaccine has remained low, even when support has been available through GAVI and the Vaccine Fund.

In 2004, the GAVI board commissioned a Hib task force to explore how best to support national efforts to make evidence-based decisions about introducing the Hib vaccine. On the basis of the task force's recommendations, the GAVI board approved establishment of the Hib Initiative to support those countries wishing either to sustain established Hib vaccination or to explore whether introducing Hib vaccine should be a priority for their health systems. A consortium consisting of the Johns Hopkins Bloomberg School of Public Health, the London School of Hygiene and Tropical Medicine, the Centers for Disease Control and Prevention, and the WHO has been selected to lead this effort.

Case-Management Strategies

Sazawal and Black's (2003) meta-analysis of community-based trials of the ARI case-management strategy includes 10 studies that assessed its effects on mortality, 7 with a concurrent control group. The meta-analysis found an all-cause mortality reduction of 27 percent among neonates, 20 percent among infants, and 24 percent among children age one to four. LRI-

specific mortality was reduced by 42, 36, and 36 percent, respectively. These data clearly show that relatively simplified, but standardized, ARI case management can have a significant effect on mortality, not only from pneumonia, but also from other causes in children from birth to age four. Currently, the ARI case-management strategy has been incorporated into the IMCI strategy, which is now implemented in more than 80 countries (see chapter 63).

Despite the huge loss of life to pneumonia each year, the promise inherent in simplified case management has not been successfully realized globally. One main reason is the underuse of health facilities in countries or communities in which many children die from ARIs. In Bangladesh, for example, 92 percent of sick children are not taken to appropriate health facilities (WHO 2002). In Bolivia, 62 percent of children who died had not been taken to a health care provider when ill (Aguilar and others 1998). In Guinea, 61 percent of sick children who died had not been taken to a health care provider (Schumacher and others 2002). Schellenberg and others' (2003) study in Tanzania shows that children of poorer families are less likely to receive antibiotics for pneumonia than children of better-off families and that only 41 percent of sick children are taken to a health facility. Thus, studies consistently confirm that sick children, especially from poor families, do not attend health facilities.

A number of countries have established large-scale, sustainable programs for treatment at the community level:

- The Gambia has a national program for community-level management of pneumonia (WHO 2004b).
- In the Siaya district of Kenya, a nongovernmental organization efficiently provides treatment by community health workers for pneumonia and other childhood diseases (WHO 2004b).
- In Honduras, ARI management has been incorporated in the National Integrated Community Child Care Program, whereby community volunteers conduct growth monitoring, provide health education, and treat pneumonia and diarrhea in more than 1,800 communities (WHO 2004b).
- In Bangladesh, the Bangladesh Rural Advancement Committee and the government introduced an ARI control program covering 10 subdistricts, using volunteer community health workers. Each worker is responsible for treating childhood pneumonia in some 100 to 120 households after a three-day training program.
- In Nepal during 1986–89, a community-based program for management of ARIs and diarrheal disease was tested in two districts and showed substantial reductions in LRI mortality (Pandey and others 1989, 1991). As a result, the program was integrated into Nepal's health services and is being implemented in 17 of the country's 75 districts by female community health volunteers trained to detect and treat pneumonia.

- In Pakistan, the Lady Health Worker Program employs approximately 70,000 women, who work in communities providing education and management of childhood pneumonia to more than 30 million people (WHO 2004b).

RESEARCH AND DEVELOPMENT AGENDA

The research and development agenda outlined below summarizes the priorities that have been established by advisory groups to the Initiative for Vaccine Research (vaccine intervention strategies) and the WHO Division of the Child and Adolescent Health (case-management strategies).

Vaccine Intervention Strategies

The GAVI task force on Hib immunization made a number of recommendations that vary depending on the country. Countries that have introduced Hib vaccine should focus on documenting its effect and should use the data to inform national authorities, development partners, and other agencies involved in public health to ensure sustained support to such vaccination programs. Countries eligible for GAVI support that have not yet introduced Hib vaccines are often hindered by a lack of local data and a lack of awareness of regional data. They can address these issues through subregional meetings at which country experts can pool data and review information from other countries. In addition, most of the countries need to carry out economic analyses that are based on a standardized instrument. Finally, all countries that face a high Hib disease burden need to develop laboratory facilities so that they can establish the incidence of Hib meningitis at selected sites. Countries in which the disease burden remains unclear may have limited capacity to document the occurrence of Hib disease using protocols that are based on surveillance for meningitis invasive disease. They will need to explore the possibilities of using alternative methods for measuring disease burden, including the use of vaccine-probe studies.

On the basis of experience with introducing Hib and hepatitis B vaccines, GAVI took a proactive approach and in 2003 established an initiative based at the Johns Hopkins School of Public Health in Baltimore to implement an accelerated development and introduction program for pneumococcal vaccines (the PneumoADIP; see <http://www.preventpneumonia.org>). The program's intent is to establish and communicate the value of pneumococcal vaccines and to support their delivery. Establishing the value of the vaccine involves developing local evidence about the burden of disease and the vaccines' potential effect on public health. This effort can be accomplished through enhanced disease surveillance and relevant clinical trials in a selected number of lead countries. Once established, the evidence base will be communicated to decision makers and key opinion leaders to ensure that data-driven decisions are made. Once the cost-effectiveness of routine vaccination is

established, delivery systems will have to be established, and countries will need financial support so that the vaccines can be introduced into their immunization programs. These activities are being initiated before the launch of vaccine formulations designed for use in developing countries, so as to inform capacity planning, product availability, and pricing.

Case-Management Strategies

In 2003, WHO's Division of Child and Adolescent Health convened a meeting to review data and evidence from recent ARI case-management studies and to suggest the following revisions to case-management guidelines and future research priorities:

- Nonsevere pneumonia:
 - Improve the specificity of clinical diagnostic criteria.
 - Reassess WHO's current recommended criteria for detecting and managing treatment failure, given the high rates of therapy failure.
 - Reanalyze data from short-course therapy studies to better identify determinants of treatment failure.
 - Carry out placebo-controlled trials among children presenting with wheezing and pneumonia in selected settings that have a high prevalence of wheezing to determine whether such children need antibiotics.
- Severe pneumonia: In a randomized clinical trial in a controlled environment, Addo-Yobo and others (2004) showed that oral amoxicillin is as effective as parenteral penicillin or ampicillin; however, the following actions need to be undertaken before it can be recommended on a general basis:
 - Analyze data on exclusions from the trial.
 - Identify predictors that may help distinguish children who require hospitalization and who subsequently deteriorate.
 - Reassess WHO's current recommended treatment failure criteria for severe pneumonia, given the overall high rates of therapy failure.
 - Conduct descriptive studies in a public health setting in several centers worldwide, to evaluate the clinical outcomes of oral amoxicillin in children age 2 to 59 months who present with lower chest wall indrawing.
 - Document the effectiveness of WHO's treatment guidelines for managing children with pneumonia and HIV infection.
- LRI deaths:
 - To help develop more effective interventions to reduce LRI mortality, study the epidemiology of LRI deaths in various regions in detail, using routine and advanced laboratory techniques.
- Oxygen therapy:
 - Carry out studies to show the effectiveness of oxygen for managing severe respiratory infections.

- Collect baseline information about the availability and delivery of oxygen and its use in hospital settings in low-income countries.
- Explore the utility of pulse oximetry for optimizing oxygen therapy in various clinical settings.
- Undertake studies to improve the specificity of clinical signs in the overlapping signs and symptoms of malaria and pneumonia.
- Study rapid diagnostic tests for malaria to assess their effectiveness in differentiating between malaria and pneumonia.
- Examine the effect of widespread use of cotrimoxazole on sulfadoxine-pyrimethamine resistance to *Plasmodium falciparum*.
- Etiology: Data on the etiology of pneumonia in children are somewhat out of date, and new etiological studies are needed that use modern technology to identify pathogens.

CONCLUSIONS: PROMISES AND PITFALLS

The evidence clearly shows that the WHO case-management approach and the wider use of available vaccines will reduce ARI mortality among young children by half to two-thirds. The systematic application of simplified case management alone, the cost of which is low enough to be affordable by almost any developing country, will reduce ARI mortality by at least one-third. The urgent need is to translate this information into actual implementation.

The case-management strategy has to be applied and prospectively evaluated so that emerging problems of antimicrobial resistance, reduced efficacy of current treatment with the recommended antimicrobials, or emergence of unexpected pathogens can be detected early and remedial steps can be taken rapidly. If community-level action by health workers is supplemented by the introduction of the IMCI strategy at all levels of primary care, then both applying and evaluating this strategy will be easier. Such synergy may also help in gathering information that will help further fine-tune clinical signs, so that even village health workers can better distinguish bronchiolitis and wheezing from bacterial pneumonia. The criticism that the case-management steps may result in overuse of antimicrobials should be countered by documenting their current overuse and incorrect use by doctors and other health workers. Although there is a resurgent interest in basing interventions at the community level, our analysis suggests that doing so may not be cost-effective. Indeed, ARI case management at the first-level facility may still be the most cost-effective when coupled with better care-seeking behavior interventions.

The international medical community is only beginning to appreciate the potential benefits of Hib and pneumococcal vaccines. They are currently expensive compared with Expanded Program on Immunization vaccines, but the price of Hib

vaccine may fall with the entry of more manufacturers into the market in the next few years. Nevertheless, convincing evidence of the vaccines' cost-effectiveness is required to facilitate national decisions on introducing the vaccine and using it sustainably. In low-income countries, positive cost-benefit and cost-effectiveness ratios alone appear to be insufficient to enable the introduction of these vaccines into national immunization programs.

Maternal and Perinatal Conditions

Wendy J. Graham, John Cairns, Sohinee Bhattacharya, Colin H. W. Bullough, Zahidul Quayyum, and Khama Rogo

The Millennium Declaration includes two goals directly relevant to maternal and perinatal conditions: reducing child mortality and improving maternal health. The fact that two out of the eight Millennium Development Goals (MDGs) are exclusively targeted at mothers and children is testament to the significant proportion of the global burden of disease they suffer and to the huge inequities within and between countries in the magnitude of their burden. Achieving these goals is inextricably linked at the biological, intervention, and service delivery levels (Bale and others 2003).

Maternal and child health services have long been seen as inseparable partners, although over the past 20 years the relative emphasis within each, particularly at a policy level, has varied (De Brouwere and Van Lerberghe 2001). The launch of the Safe Motherhood Initiative in the late 1980s, for example, brought heightened attention to maternal mortality, whereas the International Conference on Population and Development (ICPD) broadened the focus to reproductive health and, more recently, to reproductive rights (Germain 2000). Those shifts can be linked with international programmatic responses and terminology—with the preventive emphasis of, for instance, prenatal care being lowered as a priority relative to the treatment focus of emergency obstetric care. For the child, integrated management of childhood illnesses has brought renewed emphasis to maintaining a balance between preventive and curative care. The particular needs of the newborn, however, have only started to receive significant attention in the past three or four years (Foegen 2001).

Although health experts agree that the single clinical interventions needed to avert much of the burden of maternal and perinatal death and disability are known, they also accept that

these interventions require a functioning health system to have an effect at the population scale. Levels of maternal and perinatal mortality are thus regarded as sensitive indicators of the entire health system (Goodburn and Campbell 2001), and they can therefore be used to monitor progress in health gains more generally. What is also clear is that maternal mortality and the neonatal component of child mortality continue to represent two of the most serious challenges to the attainment of the MDGs, particularly in South Asia and Sub-Saharan Africa.

An estimated 210 million women become pregnant each year, and close to 60 million of these pregnancies end with the death of the mother ($\approx 500,000$) or the baby or as abortions. This chapter focuses on the adverse events of pregnancy and childbirth and on the intervention strategies to eliminate and ameliorate this burden.

EPIDEMIOLOGY OF MATERNAL AND PERINATAL CONDITIONS

Much has been written about the lack of reliable data on maternal and perinatal conditions in developing countries (AbouZahr 2003; Graham 2002; Save the Children 2001). Weak routine information systems, inadequate vital registration, and reliance on periodic household surveys as the main source of population-based data are all familiar obstacles to improving public health in poor countries (Godlee and others 2004). Recognizing the implications of these obstacles for prioritizing health needs and interventions is important and is now endorsed by a global movement toward evidence-based decision making for policy and practice (Evans and Stansfield 2003).

However, there has been much less appreciation of the consequences for evaluations of effectiveness—and thus cost-effectiveness—of the weaknesses in current outcomes measurement and in routine data collection. Those weaknesses also affect the monitoring of progress toward the MDGs. Initiatives for improved health surveillance are thus urgently needed (CMH 2002). For the vast majority of the world's population, the magnitude of adverse maternal and perinatal outcomes is not known reliably. It is impossible to determine whether many of the patterns apparently observed, especially at a cause-specific level, are real or are artifacts of the measurement process.

Definitions

The terms *maternal* and *perinatal* encompass a continuum of health states—from the most positive (complete physical, mental, and social well-being) to the most negative—and a huge number of clinical conditions. This chapter focuses on eight major conditions, hereafter referred to as the *focus conditions*, which are estimated to account for about 75 percent of maternal deaths and more than 60 percent of perinatal deaths. For the mother, these conditions are hemorrhage, sepsis, hypertensive disorders of pregnancy, obstructed labor, and unsafe abortion. For the baby, they are low birthweight, birth asphyxia, and infection (table 26.1).

We define *maternal conditions* as encompassing events occurring from conception to 42 days postpartum (WHO 1992a). The chapters on women's health, family planning, adolescent health, and surgery address the longer-term sequelae of pregnancy and childbirth; the preconception period; pregnancy at an early age; and specific interventions, such as repair of obstetric fistulas. Within the period from conception to 42 days postpartum, two broad categories of conditions can be distinguished: those arising specifically from pregnancy and parturition (*direct obstetric conditions*), and those aggravated by or aggravating to pregnancy (*indirect obstetric conditions*). Because the latter conditions, such as malaria, HIV/AIDS, or anemia, are not exclusive to pregnant or parturient women, they are not dealt with here but in the relevant disease-specific chapters.

Regarding perinatal conditions, we focus on those for which interventions can be directed to the baby through the mother during pregnancy or delivery. Our discussion is complemented by the discussion in chapter 27, which concentrates on the neonate, including special care of the small baby and emergency care of the sick newborn.

Formal definitions of perinatal conditions tend to vary by data source. Taken literally, they refer to conditions that arise in the perinatal period (Murray and Lopez 1998), which are not the same as events that occur in the perinatal period—that is, from 28 weeks of gestation to the end of the seventh day of life. For example, death resulting from conditions that arise in the

perinatal period can happen at any age, although it tends to take place during the neonatal period (up to 28 days of life). By contrast, perinatal deaths include both stillborn babies and those who are born alive but die before the end of the seventh day. Early neonatal deaths only include live births.

Nature and Characteristics

Pregnancy and childbirth are not inherently pathological. Maintaining an effective balance, however, between preserving normality and ensuring a state of readiness to deal with abnormality represents a fundamental challenge to health systems and a tension in safe motherhood programming. Although this balance between prevention and treatment is not peculiar to maternal and perinatal conditions (or complications), the following additional characteristics are relevant to assessing the burden as well as the effectiveness of interventions:

- The principle of “first, do no harm” has particular significance in this area, because many preventive practices related to pregnancy and childbirth can readily become harmful in unskilled hands—for example, inappropriately early induction of labor or poor forceps technique. The iatrogenic burden of maternal and perinatal conditions is rarely factored into assessments of intervention effectiveness.
- The lives of two individuals, mother and baby, are potentially at stake (Stoll and Measham 2001); however, interventions will not necessarily benefit both equally, and indeed, some will be in direct conflict.
- A large number of maternal and perinatal conditions present clinically not as single entities but as complexes, such as hemorrhage and sepsis or preterm delivery and birth asphyxia. For the mother, the situation may be further complicated by the role of underlying conditions, such as HIV/AIDS underlying puerperal sepsis.
- The most extreme negative outcome, death of both the mother and the baby, is highly concentrated around the time of delivery, from the onset of labor or abortion to 48 hours postpartum or postabortion. Estimates indicate that about two-thirds of maternal deaths occur within this time window (AbouZahr 1998), and the proportion for perinatal deaths appears to be even higher (Bale and others 2003). For the mother, however, a growing number of studies highlight the contribution of direct and indirect causes of deaths, including violence, when a one-year postpartum reference period is used (Etard, Kodio, and Traore 1999; Hoj and others 2003).
- The initial clinical presentation of some conditions can be severe, with rapid escalation to a life-threatening state, and these conditions often require surgical intervention.
- A distinct clinical feature of some maternal conditions is their unpredictability (AbouZahr 1998). This fact has had a

Table 26.1 Maternal and Perinatal Focus Conditions and Risk Factors for These Conditions

Condition	Definition or complications and sequelae	Case fatality rate ^a (percent)	Average duration until death if condition fatal	Timing of presentation	Risk factors for condition		Risk factors for death from condition	
					Distal or proximate	Direct, physiological	Distal or proximate	Direct, physiological
<i>Maternal</i>								
Hemorrhage	<p><i>Definition</i> Antepartum hemorrhage: bleeding from the genital tract during the last 3 months of pregnancy</p> <p>Primary postpartum hemorrhage: excessive bleeding (more than 500 milliliters) from the genital tract following delivery</p>	Not available	12 hours	28 weeks of gestation up to delivery	Primigravidity Grand multiparity (greater than 4) Fibroids Anemia	Placental abnormalities (including placenta previa; abruptio; placenta accreta, percreta, increta; other adhesions) Polyhydramnios Multiple gestation Previous third-stage complication	Remote location Anemia Coagulopathies	Lack of blood transfusion Badly managed third stage of labor Delay or absence of oxytocic treatment
Sepsis	<p><i>Definition</i> Infection of the genital tract or extragenital infections following childbirth</p>	1.3	6 days	Delivery to 6 weeks postpartum	Immunosuppression Anemia Sexually transmitted infections Inadequate prenatal care	Prolonged labor Obstructed labor Premature rupture of membranes Frequent pelvic examinations Intrauterine death Foreign body insertion (for example, herbs) Episiotomy Instrumental delivery	Delivery by untrained personnel Immunosuppression Anemia Lack of knowledge about warning signs Lack of postnatal care Cultural practices	Misdiagnosis Inappropriate use of antibiotics Lack of access to intravenous antibiotics

c. Excludes stillbirths.

d. Includes preterm deliveries and small for gestational age.

profound effect on the prioritization of interventions in safe motherhood, and it is an area in urgent need of further research. The situation is confused by the alternative endpoints, such as death or disability, and by the extent to which there are clear and predictable risk factors. Table 26.1 summarizes some of these key characteristics as they relate to the eight focus conditions.

Causes and Conceptual Frameworks

One of the most frequently quoted figures in safe motherhood is that 88 to 98 percent of maternal deaths are avoidable with moderate levels of health care (WHO 1986). This advocacy statement simplifies the multiple pathways leading to death and, thus, the multiple opportunities for primary and secondary prevention. In part, this simplicity is a further reflection of the grouping together of clinical conditions that in reality are distinctly different in terms of prevalence, case fatality, and scope for intervention, such as eclampsia and puerperal sepsis or congenital anomalies and birth asphyxia. The multiple endpoints and conditions, for both the mother and the fetus or newborn, have implications for what is regarded as an antecedent (a cause, a determinant, or a risk factor)¹ and what is regarded as a consequence (an outcome or a sequela).

A large number of conceptual frameworks depict pathways to adverse maternal and perinatal outcomes (Bale and others 2003; McCarthy and Maine 1992). Several identify three levels of contributory factors, which are also found in causal models for general health outcomes (WHO 2002): (a) distal, (b) proximal or intermediate, and (c) physiological or direct. Table 26.1 highlights the risk factors for the focus maternal and perinatal conditions. The distal determinants emphasize that maternal and perinatal well-being is not just a medical issue. Improvements throughout the health sector must be complemented by attention to wider social, economic, and cultural factors as well as to reproductive rights (CMH 2002). Many conceptual frameworks also differentiate between the timing of interventions: before pregnancy, during pregnancy, during labor and delivery, or during the postpartum period. Similarly, a further distinction can be made in terms of the timing of the outcome, although from a programmatic perspective, such a temporal focus may lead to fragmented care for women and their babies.

Levels, Trends, and Differentials

The latest regional estimates of maternal mortality are for 2000–1 (table 26.2), with most of the figures for the developing world produced by modeling (WHO 2004b). More than 99 percent of annual maternal deaths occur in the developing world. At a national level, the magnitude of the differential in terms of lifetime risk is almost 500-fold between the highest figure for a

developing country (1 in 6) and the lowest estimate for a developed country (1 in 29,800) (WHO 2004b). This differential is often cited as the largest discrepancy between the developing and developed world of all public health statistics, reflecting major differences both in obstetric risk, as measured by the maternal mortality ratio, and in levels of fertility, as reflected in the total fertility rate.

In terms of medical causes of maternal mortality, even greater caution is needed regarding the reliability of any patterns observed, because of their dependence on whether the data are health service based or population based and on coding conventions. Figure 26.1a shows the percentage distribution among direct causes at a crude global level. Direct causes account for about 80 percent of all maternal deaths, with indirect causes responsible for the remainder. Of the direct causes, hemorrhage is generally regarded as the most common and may be underestimated, because health facilities are unaware of many such deaths, given the short interval between onset and death (see table 26.1). In terms of indirect causes, the pattern varies enormously between different parts of the world, primarily according to the prevalence of HIV/AIDS, malaria, and tuberculosis.

The published data on severe maternal morbidity are weaker still. A recent World Health Organization (WHO) systematic review indicates how prevalence figures vary hugely according to the criteria used to identify cases (Say, Pattinson, and Gulmezoglu 2004). Using disease-specific criteria, WHO found that prevalence ranged from 0.80 to 8.23 percent. Using organ system criteria, WHO found that the range was 0.38 to 1.09 percent. Finally, using management-based criteria, WHO found that the range was 0.01 to 2.99 percent. Estimates suggest that for every maternal death, at least 16 or 17 other women suffer a life-threatening complication during pregnancy or childbirth (Gay and others 2003) and at least 30 women are left with long-term disabilities, such as an obstetric fistula (UNFPA 2003). These estimates must be regarded as crude approximations, most originating from small-scale studies and most in urgent need of updating and verification. Given the varying case fatality rates shown in table 26.1, the fact that the distributional pattern for morbidity (figure 26.1b) does not completely mirror the one for mortality is not surprising.

As concerns mortality in babies, an estimated 5.7 million perinatal deaths occur each year, 47 percent as stillbirths and 53 percent in the first week of life (J. Zupan, personal communication, August 25, 2004). Many of those deaths are linked directly with complications experienced by the mothers, and several studies have shown that the survival prospects for a baby whose mother dies are generally poor—less than 1 percent in one study in Bangladesh (Koenig, Fauveau, and Wojtyniak 1991). In 2004, neonatal deaths represented 36 percent of all deaths of children under five in developing

Table 26.2 Estimates of Maternal Mortality by Region, 2000–1

Region	Maternal mortality ratio (maternal deaths per 100,000 live births), 2000	Number of maternal deaths as modeled by WHO, 2000	Estimated number of maternal deaths, 2001	Lifetime risk of maternal death (1 in number shown)	Range of uncertainty of maternal mortality ratio estimates		Total fertility rate
					Lower estimate	Upper estimate	
Central and Eastern Europe, Commonwealth of Independent States, Baltic states, Europe, and Central Asia	64	3,400	3,000	770	29	100	1.6

countries, with about 1 million of these 3.94 million neonatal deaths occurring in the first week of life (Jamison and others 2004). Table 26.3 presents modeled estimates for early neonatal deaths in 2001. The data on the magnitude and patterns of stillbirths remain particularly poor.

Given weak sources of information, the dearth of reliable trends data is hardly surprising. At a global level, a major difficulty arises from the need to use models to estimate maternal mortality. As the basic methodology for the models has changed over time, the data are not appropriate for trend assessment. AbouZahr and Wardlaw (2001) provide patchy support for downward trends in some parts of the world, mostly on the basis of civil registration data and mostly restricted to countries with maternal mortality ratios of less than 100 per 100,000 live births—thus notably excluding South Asia and Sub-Saharan Africa. Even where declines appear to have occurred, they did so prior to 1990. Countries with sustained falls since then, such as Argentina and China, cannot be regarded as representative of all developing countries. Cause-specific trend data are extremely rare, often gathered through small-scale hospital-based studies

or special inquiries (see, for example, Pattinson 2002). Recent WHO (2004c) statistics on unsafe abortion show an apparent decrease in incidence in all world regions, although the risk of death remains high at 50 per 100,000 live births, and in parts of Sub-Saharan Africa the risk is as high as 140 per 100,000 live births (Rogo, Bohmer, and Ombaka 1999). These adverse events, however, are often also the most seriously underreported, as elaborated further in chapter 57.

The availability of reliable trends data for perinatal mortality is even more problematic. A demand for population-based estimates for newborn mortality is comparatively recent; thus, there has been insufficient time to accumulate multiple data points. Demographic and health surveys (DHSs) are a key source for tracking trends in infant and child mortality. Several DHSs now have data that can be disaggregated to show neonatal deaths, but only a few have information on stillbirths, and the quality of that information is still being assessed. Information from WHO suggests that early neonatal death rates fell slightly, from 28 per 1,000 live births around 1980 to about 25 per 1,000 in 2000, for low- and middle-income countries,

Source: Mortality: WHO 2004d; Morbidity: Murray and Lopez 1998.
 Note: Nonobstetric (indirect) causes of death and morbidity, such as tuberculosis and malaria, have been excluded.

Figure 26.1 Medical Causes of Direct Maternal Mortality and Morbidity (percentage distribution)

and the equivalent trend for stillbirths is suggested to be a drop from 36 per 1,000 deliveries to 22 per 1,000 deliveries (J. Zupan, personal communication, August 25, 2004).

Two types of differentials are particularly relevant: geographic (or regional) and socioeconomic. Table 26.2 indicates the wide variation in the magnitude of maternal mortality across regions, and a similar difference can be seen between countries. In terms of absolute numbers of deaths, just 13 countries account for 70 percent of the global total (WHO 2004b).² Caution is again needed, because the poorest countries also have the weakest information systems and, therefore, have estimates derived solely from modeling. One regression model (WHO 2004b), for example, uses independent variables, such as the percentage of deliveries with health professionals present and the proportion of deaths of women of reproductive age that are maternal deaths. Those variables are themselves subject to error and likely to be least reliable where information systems are weakest. Geographic differences in maternal mortality within countries are poorly documented, although remote populations are often assumed to suffer the highest levels because of poor access to emergency obstetric care. Although this assumption seems logical, few reliable data are available to confirm or refute it, and the possibility of high levels of mortality in urban areas linked to unsafe abortion (Thonneau and others 2002) makes the topic of geographic differentials a priority for research.

Until recently, socioeconomic differentials in mortality have tended to be inferred from utilization patterns for prenatal care and health professionals at delivery. The DHSs continue to provide the main data sources in this regard, for both international and national analyses, and they demonstrate huge differences between wealth quintiles. A relevant recent development, however, is the familial technique, which can be used to examine socioeconomic differences in maternal mortality using existing survey data (Graham and others 2004). Because

maternal health and health care are clearly associated with stillbirths and early neonatal deaths, the same differentiating factors are likely to apply to perinatal outcomes. Indeed, data from many DHSs show large gaps between rich and poor in relation to neonatal mortality, with the greatest average disparity being found in Latin American and the Caribbean (<http://www.worldbank.org/poverty/health/>).

Attributable Burden

The estimation of maternal and perinatal conditions as part of international assessments of the burden of disease has long been controversial, and much has been written about the problems and potential distortions of priorities (AbouZahr 1998; Sadana 2001). Some of those criticisms relate to methods of valuation based on disability-adjusted life years (DALYs), especially in relation to discounting and the omission of stillbirths, and others to the inaccuracies and selectivity of the base data on the incidence of complications, on case fatalities, and on disabilities. Table 26.4 presents DALYs for South Asia and Sub-Saharan Africa for the focus conditions for 2001. Those two regions together account for 74 percent of the global burden of maternal conditions and 64 percent of the global burden of perinatal conditions.

The significance of the burden of maternal and perinatal conditions is clear from two recent global assessments (CMH 2002; WHO 2002). The approaches the two initiatives adopted have led to different conclusions about public health priorities.

The former focused on avoidable mortality resulting primarily from direct obstetric conditions, whereas the latter considered population risk assessments and highlighted the contribution of indirect obstetric problems—especially micronutrient deficiencies—and the role for preventive strategies. Clearly, the choice between different measures of burden has a crucial influence both on the strategic approach to achieving health gains and on the prioritization of interventions.

INTERVENTIONS

Given the scope and nature of the burden of maternal and perinatal conditions, no quick fix is available and, thus, no single intervention warrants exclusive attention. Rather, clusters or packages of interventions need to be considered, and this understanding has long been reflected in maternity services throughout the world (Milne and others 2004). Even though these clusters can be characterized or differentiated solely on the basis of content—namely, the component interventions—in practice, the health system or implementation context is also a defining factor.

Levels and Types of Interventions

Box 26.1 presents one example of a comprehensive strategy for safe motherhood. It illustrates the range of programmatic

Box 26.1

Components of a Comprehensive Safe Motherhood Strategy

The following are part of a comprehensive safe motherhood strategy:

- community education on safe motherhood and newborn care
- evidence-based prenatal care and counseling
 - nutritional advice
 - iron and folate supplements (multivitamins and micronutrients)
 - iodization of edible oils and salt and vitamin A in areas of endemic deficiency
 - blood pressure screening
- screening and treatment for syphilis
- antiretrovirals, where voluntary counseling and testing undertaken, and breastfeeding advice
- tetanus toxoid immunization
- treatment of urinary tract infections
- skilled assistance at delivery
- care of obstetric complications and emergencies
- postpartum care
- safe abortion and postabortion services
- family-planning information and services
- adolescent reproductive health education and services

Source: Dayaratna and others 2000.

issues raised by maternal and perinatal conditions:

- the scope for both primary and secondary prevention
- the difference between the individual receiving specific interventions (here, the mother) and the beneficiary (the baby)
- the multiple effects of single (component) interventions on different outcomes
- the multiple benefits to the same outcome of different interventions
- the short- and long-term time frames for interventions and outcomes
- the balance between supply-side and demand-side interventions
- the role for interventions outside the health sector.

Three main pathways are available for averting adverse outcomes: preventing pregnancy, preventing complications, and preventing death or disability from complications. The first pathway is the only truly primary preventive strategy. It requires intervention to avert the occurrence or mistiming of pregnancy by means of effective family-planning methods, as discussed in chapter 57. This preventive approach is relevant for those women who are able to and wish to avoid or delay pregnancy, but it has a limited role for those not in this position, estimated at between 15 and 57 percent of women age 15 to 29 (WHO 2002). As concerns the primary prevention of complications, comparatively limited reliable evidence is available on the true size of the avoidable fraction for many conditions at a population level. The emphasis in this preventive pathway is on maintaining normality and on managing mild complications—and thus on good quality of care. Finally,

maternal death and disability may be avoided by effective, timely, and appropriate clinical interventions, often referred to as *emergency obstetric care*.

Given this complexity and the multiple approaches used to address maternal and perinatal conditions, no perfect framework for categorizing interventions exists. We, therefore, cluster the alternative intervention pathways on the basis of the following three parameters:

- level of care—home, primary, and secondary
- time period—pregnancy, labor and delivery, and postpartum
- strategic approach—population-based versus personal interventions.

Quality of Evidence

Pregnancy and childbirth have been the subjects of medical investigation for centuries and, indeed, are among the oldest clinical specialties. As a consequence, a substantial body of opinion exists on the signs, symptoms, etiology, prognosis, natural history, and management and treatment options for many maternal and perinatal complications, particularly in developed countries. Much of it can be regarded as conventional wisdom acquired through practice. In contrast, a comparatively small proportion of interventions can be regarded as based on evidence, by contemporary scientific standards, and arrived at through the conduct of robust research. Thus, in specification of the content of intervention clusters, a built-in tension exists between using the best available knowledge and using only evidence that passes minimum quality criteria. Equally important

is recognizing the fundamental distinction between knowing what is effective at an individual case-management level, for which an evidence base exists for maternal and perinatal conditions, and demonstrating effectiveness at the aggregate levels of composite strategies and entire countries or regions, for which robust evidence is extremely limited (Graham 2002).

Population-Based Interventions

The primary aim of population-based interventions is to reduce the risks leading to adverse outcomes at the population level rather than at the individual level (WHO 2002). Population-based interventions are essentially preventive and seek to promote healthy behaviors, thereby reducing incidence in the entire population. In the case of maternal and perinatal conditions, such an approach could be adopted for two major risk factors: lack of contraception and maternal undernutrition. The grade of evidence for these population-based interventions is primarily level C for the former, but a mixture of A and B for the latter.³

Fertility Behavior Change. Fertility behavior is ultimately the primary exposure factor for both maternal and perinatal conditions. Investigators have shown that the frequency (number and spacing), the timing with regard to age, and the desirability of pregnancy are associated with increased risks, although some dispute remains about the effect of birth intervals. Researchers have also investigated the influence of those factors on perinatal conditions, finding clear associations with old or young maternal age, short interpregnancy intervals, and high or first birth order, with many of those variables also being interrelated (Bale and others 2003).

Lack of effective use of contraception may result in unwanted or mistimed pregnancies. Unintended pregnancies are known to be associated with adverse maternal outcomes, including unsafe abortion. Contraceptive behavior is clearly determined by a host of socioeconomic, cultural, religious, and medical factors (Hussain, Fikree, and Berendes 2000; Marston and Cleland 2003; Mwangeni, Ankomah, and Powell 2001), which also have a bearing on intervention options. Most of the options on the demand side focus on information, education, and communication; those on the supply side focus on client-friendly services. At a macro level, those intervention options have been credited with the substantial increase in contraceptive use in developing countries over the past 40 years, which, in turn, is seen as a contributor to the overall fall in the total fertility rate from 6 to 3 (Cleland and Ali 2004). Nevertheless, a significant unmet need for contraception persists in many developing countries, with high levels of unsafe abortion as a proxy indicator of that need.

As regards evidence of the effectiveness of family planning in explicitly reducing maternal mortality or disability, no

primary sources are available, but there are a variety of modeled estimates, such as Prata and others (2004), Walsh and others (1993), and Winikoff and Sullivan (1987). Model estimates vary enormously in terms of the size of the effect, depending primarily on assumptions about the proportion of maternal deaths caused by unsafe abortion. Investigators estimate the potential gain from the avoidance of unintended or mistimed pregnancies to be a 20 percent decrease in maternal deaths in developing countries (Donnay 2000; Kurjak and Bekavac 2001; UNICEF 1999).

Nutritional Interventions. Maternal undernutrition encompasses two main dimensions: underweight and micronutrient deficiencies (principally iron and vitamin A). Unlike many of the direct maternal complications, which are acute at onset and of relatively short duration, these nutritional problems are chronic and long term and, indeed, are intergenerational (Tomkins 2001). The physiological mechanisms by which undernutrition exerts an influence on outcomes in the mother and baby are not entirely understood, but a large body of epidemiological evidence supports associations with, for example, fetal growth or length of pregnancy (Villar and others 2002). Those findings have originated mostly from populations with either severe levels of undernutrition or significant cofactors, such as malaria and other infections.

Considerable uncertainty surrounds the issue of timing potential interventions, with conflicting opinions about making targeted interventions during pregnancy; addressing undernutrition among girl children or adolescents, and applying strategies for women of reproductive age, including periconceptual women (Gay and others 2003; Rush 2000). Further debate relates to the use of supplements versus food fortification. A systematic review by Villar and others (2002) of randomized controlled trials to prevent or treat adverse maternal outcomes and preterm delivery concludes that limited evidence supports large-scale interventions with multivitamins, minerals, or protein-energy supplementation, but that iron and folic acid are effective against anemia. Rouse (2003) emphasizes the potential cost-effectiveness of vitamin A or beta-carotene supplementation in reducing maternal mortality if the findings of West and others (1999) from Nepal are replicable elsewhere.

Personal Interventions

When we consider interventions directed at individuals rather than whole populations, the need for a continuum of care for mother and baby in terms of time (before and after delivery), place (linking home and health services through an effective referral chain), and person (the provider of care) is important. A variety of conceptual frameworks emphasize this continuum and the dangers of fragmentation. Care to prevent or treat the vast majority of maternal and perinatal conditions can be

provided at home, at the primary level (clinic or health center), and at the secondary level (district hospital),⁴ with the district or equivalent regarded as the essential planning unit for service delivery (WHO 1994). This system is comparable to the “close-to-client” health system that the Commission on Macroeconomics and Health (CMH 2002) has proposed, whereby trained staff members other than doctors provide much of the care, with an emphasis on primary prevention and management of acute conditions.

Home-Based Care. Two topical interventions that fall into the category of home-based care are (a) information, education, and communication and birth preparedness and (b) male involvement (for home-based newborn care, see chapter 27). Evidence in this cluster of interventions falls predominantly into the level C category.

Birth Preparedness Many descriptive studies indicate that women, relatives, and other members of the community frequently do not recognize danger signs in pregnancy, childbirth, or the puerperium, and that lack of recognition can have serious consequences for mother and baby (Gay and others 2003). Health education interventions at prenatal clinics appear to be less successful at raising awareness and increasing the use of emergency obstetric care than the use of pictorial cards (Khanum and others 2000) or community education (Bailey, Szaszdi, and Schieber 1995).

Birth preparedness includes planning for the place and the attendant at delivery, as well as arranging for rapid transfer to a health center or hospital, when needed, and sometimes identifying a compatible blood donor in the case of hemorrhage (Portela and Santarelli 2003). Initiatives to promote birth preparedness can clearly be home or community based, but studies have emphasized the importance of linkages with prenatal care so as to include appropriate recommendations for intrapartum care (Shehu, Ikeh, and Kuna 1997). In circumstances in which prenatal services are of poor quality or are underused, traditional birth attendants or relatives are often the only source of information; thus, initiatives need to reach those individuals too.

Male Involvement Many studies have observed positive benefits from the involvement of male partners in care-seeking behavior related to pregnancy and delivery (Gay and others 2003). That involvement is now advocated as an essential element of WHO’s Making Pregnancy Safer Initiative (WHO 2003). Models and mechanisms for achieving this involvement have not been robustly evaluated, and considerable controversy concerns those that are based on behavioral and social cognitive theories that presume lack of knowledge as the root problem (Portela and Santarelli 2003; Raju and Leonard 2000).

Primary-Level Care. Primary-level care is widely regarded as the crucial entry point to maternity services—and also to care before and after pregnancy. The focus here is essentially preventive, but with the capacity to detect problems, to manage mild complications appropriately, and to stabilize and then refer cases that require higher-level care. Although the name used for primary care facilities varies from country to country, we employ the commonly used term *health center*. In terms of functionality in relation to maternal and perinatal care, the health center should provide prenatal, delivery (including management of complicated abortion), and postpartum care (including family planning and postabortion counseling), as well as care of the newborn.

The management of complicated cases is usually discussed at two levels: basic emergency obstetric care (BEmOC) and comprehensive emergency obstetric care (CEmOC), the distinction being made on the basis of the number of signal or essential clinical functions performed.⁵ This distinction forms the basis of a set of process indicators that the United Nations (UN) has endorsed for program monitoring (UNFPA 2003). The capacity of health centers to provide BEmOC depends on the availability of supplies, drugs, infrastructure, and skilled providers. Some of the signal functions may not always be performed by midwives or nurses, sometimes because of the regulation of roles by the government or professional bodies. For this reason, a further distinction can be made between full BEmOC, which comprises six functions, some of which may require a doctor, and obstetric first aid, which includes two signal functions universally performed by midwives and nurses: the administration of antibiotics or oxytocics, intravenously or intramuscularly.

Routine Prenatal Care The literature available on routine prenatal care is extensive, and there is a long history of assessing the component interventions (Hall, MacIntyre, and Porter 1985; Rooney 1992). In safe motherhood programs, prenatal care provides one of the rare examples of robust assessment of an intervention package (Villar and others 2001). As Bale and others (2003) note, even though many of the component clinical interventions are effective in terms of perinatal outcomes (Bergsjö and Villar 1997), reliable evidence of an effect on maternal mortality in developing countries is not available (McDonagh 1996). However, where early detection is followed by appropriate treatment, prenatal care does seem to reduce adverse outcomes from specific maternal conditions, including hypertensive disorders of pregnancy, urinary tract infections, and breech presentations (Carroli, Rooney, and Villar 2001; Villar and Bergsjö 1997). Conversely, the limited effectiveness of prenatal risk screening at a population level is now widely acknowledged (Graham 1998). The poor predictive value of many screening tools for maternal complications reinforces the importance of access to emergency obstetric care for all women

who develop a need for it and underlies calls for skilled attendance at all deliveries. Many health experts, however, do accept screening and treatment for syphilis and immunization with tetanus toxoid as important prenatal interventions (Bale and others 2003). Similarly, the prevention and treatment of anemia and of malaria, with prophylaxis or bednets, are widely regarded as essential elements of routine prenatal care. Nutritional supplementation, however, remains more controversial.

Prenatal care has been assessed not only in terms of content, but also in relation to alternative models of the number and timing of visits (Munjanja, Lindmark, and Nystrom 1996). Strong evidence exists on the cost-effectiveness of a targeted, four-visit schedule (Villar and others 2001) that includes an educational element on the recognition of danger signs and the use of skilled attendance at delivery.

The principal sources of international data on levels, trends, and differentials in prenatal care coverage are the DHSs. The latest statistics show comparatively high coverage levels when measured in terms of one or more visits—levels average 71 percent for Sub-Saharan Africa—but comparatively little improvement between 1990 and 2000. Within countries, wide socioeconomic differentials in uptake are apparent.

Delivery Care As indicated earlier, the risks of adverse outcomes in mother and baby are usually highest during the intrapartum period. Even though health experts have long appreciated this fact, prioritization of this element of safe motherhood is comparatively recent. Much has been written both on this shift in emphasis and on the underlying rationale, as well as on what skilled attendance at delivery should comprise (De Brouwere and Van Lerberghe 2001). Investigators have suggested a variety of conceptual models for defining content, with varying degrees of emphasis on the attendant and on the enabling environment (Bell and others 2003). All these models recognize that skilled attendance encompasses both normal and complicated deliveries, with the focus on the former and on the management of mild complications at the primary level, as is consistent with BEmOC, and with referral to CEmOC at the secondary level when necessary.

Key unresolved issues at the primary level relate to the skills and scope of work of the attendant, especially in relation to being a multipurpose health worker, and to the potential role of nonprofessionals, such as auxiliaries and trained traditional birth attendants (Buttiens, Marchal, and De Brouwere 2004). Work by Koblinsky and Campbell (2003) has helped to inform this debate by proposing four basic models of delivery care that vary according to configurations of place of delivery and attendant. Evidence on the effectiveness of the alternative models at a population level is lacking, and support for skilled attendance at delivery is, thus, based primarily on historical and contemporary ecological analysis (De Brouwere and Van Lerberghe 2001). Conversely, high-grade

evidence supports a number of clinical interventions, such as active management of the third stage of labor, as well as essential newborn care.

Once again, the principal sources of data on levels and trends in coverage of skilled attendants at delivery are the DHSs. The data, however, are based on women's self-reports of who attended their deliveries, include only live births, and have major definitional uncertainties. Some countries, for example, use terms such as *supervised deliveries* and include as attendants both auxiliaries and trained traditional birth attendants (see Bell, Curtis, and Alayon 2003 for a critique of these data). A global analysis of trends in deliveries by skilled attendants showed wide variations in progress across different regions, with the latest figures for Sub-Saharan Africa, Asia, and Latin America and the Caribbean for 1990–2003 being 48, 59, and 82 percent, respectively (AbouZahr and Wardlaw 2001; WHO 2004a). The proportion of deliveries with health professionals present (doctors, midwives, nurses) is one of the proxy indicators for the MDG on maternal health (Graham and Hussein 2004). It demonstrates not only major differentials between countries, but also wide variation in uptake across socioeconomic groups within countries (De Brouwere and Van Lerberghe 2001). Although skilled attendants do not necessarily operate only in fixed health facilities such as health centers, the DHS data show low levels of professional attendance in the community. Promoting skilled attendance is thus essentially advocating for institutionalizing deliveries.

Postpartum Care Primary care services continue to neglect the postpartum period despite significant morbidity among mothers and babies during this time. Routine performance of postnatal checks is not widespread, and most contacts with services after delivery tend to focus on educational messages on, for example, danger signs, breastfeeding, nutrition, and lifestyle.

Postabortion Care One significant area of service delivery that does not fit well with descriptive frameworks based on prenatal, intrapartum, and postpartum care is the management of complicated abortions. Unsafe abortion accounts for a significant proportion of the burden of maternal conditions, but it is still treated as the poor relation in the debate on intervention strategies (De Brouwere and Van Lerberghe 2001). In particular, with the prioritization in recent years of skilled attendance at delivery, both the service base for and the provider of postabortion care have become less well defined (Dayaratna and others 2000). This crucial element of obstetric care falls into BEmOC in the case of mild complications and CEmOC for more serious cases, but whether it is regarded as part of prenatal, delivery, or postnatal services appears to vary from setting to setting. Moreover, postabortion care illustrates the dangers of the fragmentation of broader reproductive health

care, because primary prevention and counseling after treatment for complications tend to fall within the remit of family-planning services, whereas emergency care at the primary level is usually provided as part of maternity services and at the secondary level may fall within obstetrics or gynecology services.

Secondary-Level Care. Secondary-level care is hospital-based care, generally at the district level, including CEmOC. As a center for referral, this level of care needs to be linked to the primary level through an effective chain of communications (Murray and others 2001). The focus at the district hospital is on secondary prevention, with the ability to manage the principal maternal and perinatal conditions discussed earlier; thus, district hospitals must be able to provide surgical interventions and the requisite backup, such as blood banks (Kusiako, Ronsmans, and Van der Paul 2000). In many countries, however, the district hospital is also the local provider of preventive services, including prenatal and normal delivery care; as such, it is responsible for attending to a wide mix of uncomplicated and complicated cases.

Although no high-grade evidence of the effectiveness of CEmOC is available, many health experts agree that maternal mortality cannot be significantly reduced in the absence of such care (Bale and others 2003). The issue thus becomes one of the cost-effectiveness of other strategies, given the presence of CEmOC. The UN agencies have endorsed the threshold of one CEmOC facility per 500,000 people. Data indicating the attainment of this ratio—and, indeed, the percentage of met need for CEmOC—are not widely available. Similarly, reliable information on geographic or socioeconomic differentials in access to CEmOC is extremely limited.

Policy Considerations and Approaches

The health of mothers and babies is a human right and needs to be underpinned by policies and laws that increase access to information and good-quality, affordable health services (Germain 2000). A positive policy environment is crucial for promoting maternal health and reducing the burden of maternal and perinatal conditions. Such policy considerations need to go beyond the health sector to include related issues, such as transportation, nutrition, girls' access to education, and gender biases in the control of economic resources. Through a human rights-based approach, programs can be fashioned to ensure that every woman has the right to make informed decisions about her own health and has access to quality services before, during, and after childbirth (Freedman 2001).

The ICPD marked a dramatic shift not only by putting the concepts of rights and choice center stage, but also by introducing the reproductive health paradigm. The first decade of the ICPD plan of action was marked by major improvements in policies related to maternal health in most of the 179

signatory countries. However, as observed at the ICPD + 10 Conference, many promised changes remain at the level of policy pronouncement and have not yet been implemented. The stagnation is most notable in relation to maternal mortality and the HIV pandemic, especially in Sub-Saharan Africa. The failure to fully implement the ICPD consensus can be attributed to lack of political will, inadequate funding for programs to further reproductive health, and weak health systems. It is too early to judge the effect of the MDG proclamation (Johansson and Stewart 2002), although it could well suffer the same fate unless special attention is given to maternal and child health in the context of sectorwide approaches and Poverty Reduction Strategy Papers (UNFPA 2003). Some suspect that both these modalities may not give reproductive health the focus and attention it requires, because competing needs may crowd it out. Others argue, however, that sectorwide approaches can be a boon for maternal health because they offer a more effective platform for addressing ailing health systems (Goodburn and Campbell 2001).

Whether at the national or international level, advocacy for maternal and perinatal health should focus on the following seven key message areas:

- magnitude of the problem
- factors influencing maternal and perinatal outcomes
- functions of maternal health programs and which interventions work
- consequences of not addressing maternal and perinatal health
- costs of improving maternal and perinatal health
- responsibilities at each level of the health system and beyond
- policy and legal impediments to implementing comprehensive safe motherhood and newborn health programs.

Major advocacy networks, such as the Partnership for Safe Motherhood and Newborn Health, the White Ribbon Alliance, and the Healthy Newborn Partnership, seek to promote maternal and newborn health at the global level. Their purpose is to create awareness by changing the language of discourse, building international political commitment, developing global guidelines, and improving access to technical information for providers and program managers.

COST-EFFECTIVENESS OF SELECTED INTERVENTION PACKAGES

Cost-effectiveness analysis (CEA) faces several major challenges with respect to evaluating the prevention and treatment of maternal and perinatal conditions. First is the sheer range of conditions and potential interventions. The breadth of the clinical area implies the need to make tough choices with

respect to which packages of interventions to compare. A second and related challenge is the lack both of reliable data on the burden of conditions and of high-grade evidence on the effectiveness and costs of packages. As a result, we can assess only the relative cost-effectiveness of different packages of interventions by means of modeling. Thus, the third set of challenges is associated with modeling, which makes the analysis vulnerable to all the usual criticisms of the modeling of cost-effectiveness—in particular, uncertainty about the direction of any bias introduced and the difficulty of establishing the validity of the model (Sheldon 1996). Finally, there are the related issues of the appropriateness to maternal and perinatal conditions of standard outcome measures used in the model—in particular, DALYs, which exclude stillbirths and indirect maternal conditions (AbouZahr 1999; De Brouwere and Van Lerberghe 2001).

Selected Intervention Packages

For some of the reasons mentioned in the previous subsection, researchers have made few attempts to model packages of interventions for maternal and perinatal conditions, and many of those attempts do not specify content in sufficient detail to replicate the package. Our approach is to define content by beginning with a literature search of best practices in preventing and managing the focus maternal and perinatal conditions, acknowledging that, by excluding conditions that impose a lesser burden, we ignore interventions that might be highly effective and cost-effective. We then grouped those interventions that are considered effective and that are either being or likely to be implemented on a substantial scale into packages of care, bearing in mind previous CEA work, such as the WHO mother-baby package (WHO 1994). Expert panels then reviewed the component interventions and the packages and assisted with identifying resource requirements. Given the complementary CEA elsewhere in this volume on interventions relevant to maternal and perinatal conditions such as family planning, we focus on care during pregnancy, postpregnancy care, and care immediately postdelivery—in other words, on clusters or packages of interventions typically referred to as *pre-natal care*, *delivery* or *intrapartum care*, and *emergency obstetric care*. Table 26.5 outlines the content of those packages.

When one considers the intervention packages, contextual factors are clearly crucial. Given the particularly high burden in South Asia and Sub-Saharan Africa, we chose those two regions as the specific health system scenarios for this chapter. Those regions are also characterized by high levels of poverty and encompass some of the most heavily indebted countries in the world.

Comparison of Alternative Intervention Package Scenarios. Following the approach of generalized CEA (Hutubessy and

others 2003), we evaluated intervention packages with respect to a counterfactual (base scenario), varying the content and coverage. We also performed sensitivity analyses to examine the effects of changing the values of key variables for costs, effectiveness, or both. Each intervention package scenario specifies different dimensions of prenatal and intrapartum care provided at primary and secondary care facilities. As regards the assumed pathways through which women with normal or complicated pregnancies may or may not access care, the crucial entry point in our model is prenatal care. That choice influences the detection and treatment of mild and severe complications during the antepartum period at both the primary and the secondary levels, as well as the proportion of women delivering with a health professional present and with improved access to emergency care for intrapartum or abortion-related complications. In our CEA model, these effects are achieved primarily through two types of interventions:

- improvements in the quality of care, incorporating the technical content or the proportion of women in receipt of the care needed (that is, met need)
- increases in the coverage of care—namely, the proportion of women accessing care.

Routine prenatal care can be characterized in terms of whether it is a basic or an enhanced package—in other words, its technical content (table 26.5)—and by the percentage of women accessing the package—in other words, its coverage. Delivery at a primary-level health center is viewed as having a single quality dimension in terms of content—namely, whether BEmOC is available for women who develop mild complications, including complicated abortion (table 26.5). BEmOC is assumed to require the presence of a doctor at the health center; otherwise, only obstetric first aid is presumed to be available, covering just the two signal functions described earlier.

A percentage of women with severe complications who access primary care will go on to secondary care. This percentage is assumed to be 20 or 50 percent of complicated cases attending primary care. Our model makes no provision for women who access secondary care directly in the event of a serious complication, although it does allow for those who were attending the hospital as their local provider of primary care. Of those women who access the secondary care facility from the primary level, a proportion will receive the CEmOC that they need (assumed to vary between 50 and 90 percent of complicated cases that reach secondary care). This figure reflects such issues as staff skills and motivation and the availability of drugs and equipment. For the other quality-of-care element—namely, the technical content of CEmOC—we consider two levels: with (enhanced package) and without (base package) selected interventions for high-risk babies (table 26.5).

Table 26.5 Care Packages at the Primary and Secondary Levels

Level of care and condition	Content	Base package	Enhanced package
Routine prenatal care at the primary level ^a	Clinical examination, including for severe anemia, height and weight, blood pressure	✓	✓
	Obstetric examination for gestational age estimation and uterine height, fetal heart, detection of malpresentation and position, and referral	✓	✓
	Gynecological examination	✓	✓
	Urine test (multiple dipstick)	✓	✓
	Laboratory tests: hemoglobin, blood type and rhesus status, syphilis and other symptomatic testing for sexually transmitted diseases	✓	✓
	Advice on emergencies, delivery, lactation, and contraception	✓	✓
	Education about clean delivery, warning signs, and premature rupture of membranes	✓	✓
	Iron and folic acid supplementation	✓	✓
	Multivitamin supplementation	—	✓
	Tetanus toxoid immunization	✓	✓
	HIV voluntary testing and counseling	—	✓
	Antimalarial chemoprophylaxis in endemic areas	—	✓
	Screening and treatment for syphilis	✓	✓
	Balanced protein-energy supplementation for all women	—	✓
Delivery care at the primary level ^b	Clean delivery technique, clean cord cutting, clean delivery of baby and placenta	✓	✓
	Active management of the third stage of labor, including oxytocics	✓	✓
	Episiotomy in appropriate cases	✓	✓
	Recognition and first-line management of delivery complications (for example, obstructed labor, early detection of cephalopelvic disproportion, malposition and malpresentation, previous cesarean delivery, postpartum hemorrhage, and preeclampsia or eclampsia) and referral	✓	✓
	Intravenous fluid	✓	✓
	Intravenous uterotonics, if bleeding occurs	✓	✓
	Partograph	✓	✓
	Essential newborn care	✓	✓
	Intravenous antibiotics	✓	✓
	Magnesium sulfate	—	✓
	Forceps or vacuum extraction	—	✓
	Manual removal of placenta	—	✓
	Removal of retained products of conception	—	✓
	Corticosteroids for preterm labor	—	✓
	Antiretrovirals for prevention of mother-to-child transmission of HIV	—	✓
Antibiotics for premature rupture of membranes	—	✓	
<i>CEmOC package at the secondary level^c</i>			
Postpartum hemorrhage	Recognition of high-risk cases and arrangements for delivery in a facility	✓	✓
	Grouping of blood	✓	✓
	Iron and folate supplementation	✓	✓
	Blood transfusion	✓	✓
	Uterotonic drugs, oxytocics	✓	✓
	Bimanual compression of uterus	✓	✓
	Manual removal of placenta	✓	✓
	Uterine packing or balloon tamponade	✓	✓
	Fluid replacement	✓	✓
	Hysterectomy	✓	✓
	Removal of products of conception	✓	✓
	Secondary postpartum hemorrhage management (antibiotics, uterotonics, removal of products of conception, and fluid and blood replacement)	✓	✓

(Continues on the following page.)

Table 26.5 Continued

Level of care and condition	Content	Base package	Enhanced package
Antepartum hemorrhage	Early detection of major placenta previa and abruption	✓	✓
	Grouping and saving blood	✓	✓
	Iron and folate supplementation	✓	✓
	Cesarean section for major-degree placenta previa, abruption with a live baby	✓	✓
	Blood and fluid replacement	✓	✓
	Oxytocics	✓	✓
Sepsis	Antibiotics for premature rupture of membranes, cesarean section	✓	✓
	Fluid and blood transfusion	✓	✓
	Intravenous antibiotics	✓	✓
	Evacuation of products of conception	✓	✓
	Drainage of abscess	✓	✓
	Treatment of shock with fluids or blood, nitroglycerine	✓	✓
Pregnancy-induced hypertension	Early detection and management of preeclampsia	✓	✓
	Calcium supplementation in high-risk cases	✓	✓
	Aspirin to prevent preeclampsia	✓	✓
	Antioxidants to prevent preeclampsia	✓	✓
	Intravenous magnesium sulfate	✓	✓
	Antihypertensive drugs to reduce blood pressure	✓	✓
	Immediate delivery if more than 36 weeks	✓	✓
	Magnesium sulfate and antihypertensives for postpartum eclampsia	✓	✓
Obstructed labor	Partograph	✓	✓
	Cesarean section	✓	✓
	Symphiotomy	✓	✓
	Destructive operation	✓	✓
	Antibiotics	✓	✓
	Fluid and blood transfusion	✓	✓
	Hysterectomy	✓	✓
Abortion	Evacuation of retained products of conception	✓	✓
	Intravenous antibiotics	✓	✓
	Fluid or blood transfusion	✓	✓
	Postabortion contraceptive advice	✓	✓
Ectopic pregnancy	Proof puncture (culdocentesis)	—	—
	Laparotomy and salpingectomy	—	—
	Blood transfusion (autotransfusion)	✓	✓
High-risk infant	Forceps or vacuum extraction ^d	✓	✓
	Corticosteroids for preterm labor	—	✓
	Antiretrovirals for prevention of mother-to-child transmission of HIV	—	✓
	Antibiotics for premature rupture of membranes	—	✓

Source: Authors.

— = not available.

a. The base package includes the four-visit schedule recommended by WHO (Villar and others 2001).

b. The base package includes the provision of obstetric first aid (intravenous or intramuscular antibiotics and oxytocics). The enhanced package includes the availability of a doctor, and thus the full range of BEmOC (UNFPA 2003). In some settings, experienced midwives or clinical officers may perform all six BEmOC functions.

c. At the hospital level, prenatal or delivery care will also be provided for normal, uncomplicated cases and, thus, also includes all care listed in the first two panels of the table.

d. Forceps or vacuum delivery can also be used for several other conditions, such as prolonged labor (not obstructed), fetal distress, preterm birth, aftercoming head of breech, and preeclampsia to speed up delivery.

The base case for our CEA model assumes the following:

- basic technical content for the prenatal care package
- prenatal care coverage for 50 percent of pregnancies
- only obstetric first aid (two signal functions) available in health centers
- 20 percent of women with severe complications accessing secondary care
- 50 percent of those severe cases receiving the CEmOC that they need.

The different assumptions regarding quality of care and coverage can be combined in many different ways, yielding a large number of potential packages and a larger number of potential comparisons between those and the base package. However, not all possible scenarios are meaningful. For example, because the base prenatal care package does not screen for HIV, matching that package with enhanced delivery care that provides antiretrovirals to reduce vertical transmission would be inappropriate. We identified six packages for comparison with the base case, representing a range of safe motherhood strategies and focusing on prenatal and delivery care. Table 26.6 summarizes these alternatives and indicates their essential characteristics from a safe motherhood perspective.

Resource Use and Costs

We adopted an ingredients approach (Creese and Parker 1994) to identify resource use. For this type of bottom-up costing, we prepared lists for primary- and secondary-level care facilities of types of personnel, drugs, supplies (medical and nonmedical), medical and surgical equipment relevant for the interventions, and capital items (vehicles, buildings, building space). For most of the scenarios, our identification of resources was based on the WHO mother-baby package costing tool (WHO 1999), with necessary modifications because of the content of care packages indicated in table 26.5. We estimated the costs for clinical personnel on the basis of salaries for different grades according to the guidelines provided by the volume editors for the two selected regions. The time required by different staff members for each care intervention and the changes in time and personnel because of varying content and coverage of packages were informed by expert panel reviews, and we then calculated the costs. We valued the other nontraded inputs using information primarily provided by WHO-CHOICE (2004).

Cost-Effectiveness Ratios

The CEA involves a number of fixed and variable assumptions (see annex 26.A). The most important assumptions concern the reducible burden of these conditions, the effectiveness of the interventions, and the availability of appropriate human

resources. We have assumed that increases in care can be achieved without major capital investments and that human resources are not in short supply; therefore, more could be used (with given wage rates) as required for increased activity and enhanced coverage.

Table 26.7 summarizes the findings of the CEA in terms of incremental cost-effectiveness ratios (ICERs) for the six primary comparisons between the base scenario and alternative intervention packages for a population of 1 million. Table 26.8 gives details of total costs, deaths averted, life years saved, and DALYs averted. Table 26.9 shows the findings of the sensitivity analysis in terms of how the ICERs change when different assumptions (see annex 26.A) are made with respect to effectiveness, met need, and inpatient costs.

In interpreting the results, note that they are point estimates. Even though they are based on the best information currently available, all the inputs into the model are subject to some degree of uncertainty. Without access to robust data on individual costs and effects or without specifying distributions for each variable, it is impossible to identify confidence limits for the estimated ICERs. Thus, we do not know, for example, whether the difference in the incremental cost per DALY averted for Sub-Saharan Africa between increased coverage at the primary level (US\$92) and improved quality of CEmOC (US\$151) reflects a genuine difference in cost-effectiveness or whether there are overlapping confidence intervals (table 26.7).

With those important caveats in mind, at first sight the results for South Asia and Sub-Saharan Africa appear quite different. For each intervention package, regardless of the specific assumptions made, the cost per DALY averted is always lower in Sub-Saharan Africa. The higher costs of care in Sub-Saharan Africa (see annex 26.A) are thus more than compensated for by the higher effectiveness, which is a result of the region's greater burden. However, some important similarities are apparent between South Asia and Sub-Saharan Africa. Leaving aside options 3b and 5b (the options without nutritional supplements), the results for both regions show a consistent pattern. Improvements in the overall quality of care, especially at the primary level through the provision of BEmOC (option 3a), together with increased overall coverage (option 5a), are the most cost-effective intervention packages—and both include nutritional supplements. They are followed by increased coverage at the primary level (option 2). Improved quality of CEmOC (option 4) is the least cost-effective option. Removing nutritional supplements from the packages makes relatively little difference in Sub-Saharan Africa, slightly increasing cost-effectiveness, but in South Asia, options 3b and 5b become less cost-effective with the nutritional supplements removed. The explanation lies in the ICERs of nutritional supplements as such, which are US\$48 or US\$45 in South Asia and US\$118 or US\$110 in Sub-Saharan Africa, depending on whether the

Table 26.6 Comparisons Undertaken for CEA

Abbreviated description of package	Option number	Primary level			Secondary level			Safe motherhood strategy	Resource implications
		Coverage	Quality of care: technical content	Coverage ^a	Percentage of care: care needed	Quality of care: technical content	Interpretation		
Routine maternity care	Base	50 percent of pregnant women attend prenatal care; 50 percent of pregnant women have professional intrapartum care ^b	See first two panels of table 26.5	20 percent of complicated cases at the primary level referred to the secondary level	50 percent of those reaching the secondary level receive the CEmOC needed	See table 26.5 ^c	Basic package of prenatal and delivery care	Content of package essentially the same as WHO mother-baby package, plus magnesium sulfate and active management of labor	Costs typical of WHO mother-baby package
Increased primary-level coverage	2	70 percent prenatal care; 70 percent delivery care	No change from base	No change from base	No change from base	No change from base	Benefit from increasing coverage	Information, education, and communication for increasing uptake of prenatal and delivery care	Costs of information, education, and communication; increased personnel; drugs
Improved overall quality of care with nutritional supplements	3a	No change from base	Enhanced prenatal and delivery care (BEmOC)	No change from base	70 percent	Enhanced CEmOC (adds interventions for high-risk babies)	Benefit from enhancing quality (content needed) at the primary and secondary levels	Provision of BEmOC at the primary level	Costs of doctors and equipment at the primary level, training for BEmOC and CEmOC, costs of BPS
Improved overall quality of care without nutritional supplements	3b	No change from base	Enhanced prenatal and delivery care (BEmOC) without BPS	No change from base	70 percent	Enhanced CEmOC (adds interventions for high-risk babies)	As for 3a without BPS	As for 3a	As for 3a without costs of BPS

Improved quality of CEmOC	4	No change from base	No change from base	No change from base	80 percent	No change from base	Benefit from increased percentage of women with severe complications receiving the CEmOC needed	Improved quality of CEmOC	Cost of additional personnel time and drugs
Improved overall quality of care and coverage with nutritional supplements	5a	70 percent prenatal care; 70 percent delivery care	Enhanced prenatal and delivery care (BEEmOC)	50 percent	90 percent	Enhanced CEmOC (adds interventions for high-risk babies)	Benefit from improved quality (technical content and percentage receiving care needed) and coverage at the primary and secondary levels	Comprehensive package: improved coverage and content with BPS	Costs of providing and running ambulances, costs of additional personnel and drugs, training for BEEmOC and CEmOC, costs of BPS
Improved overall quality of care and coverage without nutritional supplements	5b	70 percent prenatal care; 70 percent delivery care	Enhanced prenatal and delivery care (BEEmOC) without BPS	50 percent	90 percent	Enhanced CEmOC (adds interventions for high-risk babies)	Benefit from improved quality and coverage at the primary and secondary levels without BPS	Improved coverage and content without BPS	As for 5a without the costs of BPS

BPS = balanced protein-energy supplementation.

a. Defined in terms of the percentage of complicated cases at the primary level referred to and reaching the secondary level.

b. Includes obstetric first aid for complicated cases, including abortion and postpartum complications.

c. The secondary level will also provide some prenatal and delivery care for normal cases, as defined in the first two panels of table 26.5 for the base package at the primary level.

Source: Authors' calculations.

comparison is with or without increased coverage (options 5a and 3a, respectively). This difference reflects the high burden from low birthweight in South Asia and, thus, the gain from nutritional supplements.

Comparing the content of the three most cost-effective intervention packages (3a, 5a, and 2) suggests that much can be achieved through improvements at the primary care level. Improved quality in relation to managing complications—in other words, the provision of BEmOC—and increases in coverage (a combination of options 3a and 2) at the primary level are likely to have even lower ICERs than those shown in table 26.7. This finding is consistent with the Commission on Macroeconomics and Health's emphasis on close-to-client services (CMH 2002), and it is highlighted further in chapter 53. As noted earlier, given the importance of prompt intervention in the event of obstetric complications, the effectiveness of intervention packages that may reduce delays by bringing services closer to communities is hardly surprising.

The benefits from option 2 were achieved essentially by increasing prenatal care coverage from 50 to 70 percent, because our model assumes that those women taking advantage of professional delivery are those who have also had prenatal contact. Prenatal care is, thus, a crucial entry point to the health system. Small changes in prenatal care coverage (20 per-

cent) lead to larger numbers of women also benefiting from the rest of the care package in terms of obstetric first aid and CEmOC.

This issue is important for safe motherhood and newborn health, because the role of prenatal care has been subject to intense debate about its benefits relative to resource use (De Brouwere and Van Lerberghe 2001; Maine and Rosenfield 1999). Much of this discussion has focused on the lack of evidence on the direct contribution of prenatal care to reducing maternal mortality (McDonagh 1996; Rooney 1992), which, in turn, is explained partly by the poor performance of at-risk screening tools. However, differentiating the contribution to the prevention of maternal deaths of the prenatal care component alone is difficult. Ultimately, life-saving interventions depend on the functioning of the entire health system, including an effective referral network.

Our model also made assumptions about women's willingness and capacity to respond to referral to higher levels of care in case of complications. This willingness and capacity depend on many factors and are undoubtedly also driven by communities' perceptions of quality of care. As noted earlier, coverage rates of prenatal care are already high in many Sub-Saharan African countries, but significant socioeconomic differentials are apparent within countries. Our model does not address this

equity dimension but, given the recent work showing higher risks of maternal death among the poorest groups (Graham and others 2004), targeting disadvantaged women for improvements in uptake might be worth considering (Gwatkin and Deveshwar-Bahl 2002; De Brouwere and Van Lerberghe 2001).

Whereas option 2, increased primary-level coverage, relates predominantly to the demand side of the health system (Williams 1987), the most cost-effective packages (3a and 5a) focus on the supply side, particularly at the health center level. The latter packages are particularly relevant to the baby, including screening of the HIV status of the mother and treatment with antiretrovirals at the time of delivery to reduce the risk of mother-to-child transmission, as well as provision of anti-malarials. As a consequence, these options have a particularly marked effect on the burden from perinatal conditions, accounting for two-thirds to three-fourths of the total DALYs averted (table 26.8). Note that these cost-effective options include a doctor at the health center level to provide all six BEmOC functions. In some situations, highly skilled midwives will be able to act in this capacity, which would reduce costs and further increase cost-effectiveness.

The most comprehensive packages in our model provide for improved quality of care and coverage at both the primary and the secondary levels (options 5a and 5b). Costing US\$1.79 and US\$1.63 per capita, respectively, in Sub-Saharan Africa (as calculated from the total costs of these packages shown in table 26.8, and divided by the base of 1 million people), these are also the most expensive packages. Not surprisingly, therefore, these two options avert much higher numbers of DALYs, with the package that includes nutritional supplementation averting nearly three times as many DALYs as the base package (table 26.8). In CEA, generally the most comprehensive packages—that is, those that result in the greatest gain in quality and coverage and, thus, cost the most—are often not cost-effective, and yet our analysis found otherwise. This finding may partly be explained by the linear assumptions about effectiveness in the model and the assumption that the marginal cost of care is constant. Such a finding also stresses both the importance of a well-functioning health system (rather than an excessive focus on one element) and the absence of any quick fix. Moreover, we did not model these more comprehensive options as perfect but unrealistic scenarios. We also still allowed for 30 percent of pregnant women not attending prenatal care, 50 percent of severe complications at a primary level not reaching CEmOC, and 10 percent of those reaching secondary care not receiving the emergency treatment they need.

Finally, a note of caution is warranted on the interpretation of the CEA results. First, our model has necessarily used a number of assumptions for which data are extremely limited, and it remains fairly crude, having been subject to only a limited sensitivity analysis. Second, many comparisons are possible from our model, but we have selected only six. Thus, we may not

have identified even more cost-effective intervention packages, such as a combination of options 3a and 2.

ECONOMIC BENEFITS OF INTERVENTION

A narrow definition of the economic benefits of safe motherhood interventions would focus primarily on the impact of maternal mortality and morbidity on household investment and consumption. Investment in this context refers not so much to financial investment as to investment in improving housing conditions, agricultural productivity, education, and so on. The key elements to capture include the loss of productivity and the disruption of planned investment and consumption. In addition to the loss of a woman's own productivity, consequent effects are likely on the productivity of other household members—effects that may be particularly long lived in the case of young children whose health and education suffer because of their mother's death. The household will also be worse off because it will have diverted resources from preferred consumption and investment activities in response to the health crisis. Thus, recognizing the dynamic consequences of maternal death and disability and selecting an appropriate time horizon for the analysis are important.

The potential benefits to individual households arising from investments in safe motherhood are relatively clear, although challenges in quantifying and valuing them remain. The benefits may, however, be more widely spread in that improvements in safe motherhood may reduce poverty, which in turn may stimulate economic development. Increased economic development may then feed back into further improvements in maternal health, generating a virtuous cycle. The mechanisms whereby changes in maternal health affect other parts of the economy may be identified by a close examination of the influence of maternal health on productivity and educational attainment.

A number of links may exist between safe motherhood and the performance of the health care system; therefore, strategies to improve safe motherhood may be a means of achieving wider health service improvements (Goodburn and Campbell 2001). Jowett (2000, 213) notes that “to improve a facility's capacity to respond to obstetric emergencies, it is necessary to have the skills and supplies to deal with trauma, give blood transfusions and anesthesia, and have a functional operating theatre.” Thus, initiatives in safe motherhood could be an entry point for wider health sector reform and improvement.

LESSONS FOR IMPLEMENTATION

The findings from the CEA indicate potential health gains and the reduced burden that may be achieved by implementing selected packages of interventions. Such implementation

assumes, first, that decision makers accept the evidence and are willing and able to act and, second, that an enabling health system environment exists within which the requisite scale and quality of care can be effectively delivered. These factors are not peculiar to safe motherhood, but they undoubtedly help explain the significant gap between evidence and action that many argue is one of the main obstacles to progress (Godlee and others 2004; Villar and others 2001). The gains from bridging this gap would be significant: the MDGs for child survival and maternal health might become more than mere rhetoric for poor regions if intervention packages of the scope and nature described here were implemented. The most cost-effective of the packages averted nearly 50 percent more direct maternal deaths than the base package. This gain would be encouraging, but the prospects for achieving it by 2015 are weak (Johansson and Stewart 2002).

At the macro level, a supportive policy environment clearly is crucial, as noted earlier. At the micro level, an enabling health system implies a reduction in the disequilibrium between the demand and supply sides (Williams 1987), with particular attention to three interrelated issues: access, quality, and finance. The CEA reported in this chapter emphasizes the potential benefits to mother and baby of improved access to care, particularly the importance of entry to the health system through primary-level services. The increases in coverage could be achieved by a variety of mechanisms but clearly require both demand- and supply-side interventions.

On the supply side, this chapter has shown that improved quality of care at both the primary and the secondary levels encompassing technical, infrastructural, and human resource dimensions (Pittrof, Campbell, and Filippi 2002) is a particularly cost-effective option. The widespread call for all women to deliver with skilled attendance immediately raises major questions about quality of care and capacity, because much of the developing world faces an acute shortage, as well as an unequal geographic distribution, of health professionals.

Our CEA assumes that redistributing human resources within countries will accommodate the increased uptake of care by women, although the most effective mechanisms for achieving this goal, such as incentives, use of nonphysicians, and increased private sector involvement, have not yet been established (De Brouwere and Van Lerberghe 2001). What is clear, however, is the importance of the interplay between supply and demand, with the supply of quality care stimulating demand for care and vice versa. Quality care includes an effective referral system (Murray and others 2001) to ensure the required match between the various levels of care different women and their babies need at different times (De Brouwere and Van Lerberghe 2001). Such systems require not only financial resources to support transportation, communications, and feedback mechanisms, but also structured fee and exemption strategies to reduce both inappropriate self-referral

to hospitals and financial barriers to access on the part of the poor.

The financing of prenatal and delivery care services at an adequate and sustainable level is a subject of much debate and uncertainty, given the difficulty of distinguishing these elements from broader health expenditure categories (De Brouwere and Van Lerberghe 2001). Given the low level of overall per capita expenditure on health in developing countries—estimated at US\$13 in 2002 for the poorest 49 countries (Bale and others 2003)—attaining our base intervention package (costing approximately US\$0.41 per capita in South Asia and US\$0.60 in Sub-Saharan Africa) does not sound unrealistic at current resource levels (see table 26.8, and divide by base population of 1 million people).

The effects of health sector reforms, particularly decentralization of management and budget holding, appear to be mixed in terms of increasing resource flows into maternity services, with both apparent positive benefits, as in Bolivia (De Brouwere and Van Lerberghe 2001), and negative effects through the exacerbation of inequities (Russell and Gilson 1997). Effective management decisions on finance, access, and quality require information, an essential ingredient for stimulating action. To allocate scarce resources where they are likely to achieve the greatest gain, countries need information to assess the burden of ill health, evaluate the performance of current intervention strategies, identify the scope for improvement and implement changes, and close the loop by evaluating effects and cost-effectiveness (Lawn, McCarthy, and Ross 2001).

Even though the challenges that the poorest countries face today clearly differ in many respects from those that developed or transition countries experienced in the past, six historical lessons provide particularly relevant insights. First, examples abound of supportive policy contexts and individual champions of progress in addressing maternal and newborn health, such as those reported by De Brouwere and Van Lerberghe (2001). Second, historical data on the uptake of prenatal care demonstrate that community-based providers and advocates played a crucial role. Third, the role of various professionals and professional bodies has not always been positive, particularly as regards the “war” between advocates for home and institutional deliveries (Koblinsky and Campbell 2003). Moreover, good historical evidence indicates that excessive rates of forceps deliveries and other interventions were significant contributors to maternal mortality in countries such as the United Kingdom and the United States (Buekens 2001). Fourth, primary-level care depends on an effective referral system being in place to maintain the confidence of both women and providers (Loudon 1997). Fifth, to reduce the burden of maternal and perinatal conditions, the system of health care financing must facilitate access for the poorest groups and guarantee service quality (De Brouwere and Van Lerberghe 2001). Finally, the role of population-based information on births and maternal deaths was

crucial in ensuring that actions were locally relevant (Sorenson and others 1998), in demonstrating progress, and thus in stimulating further action. This crucial role is particularly apparent in the literature on several European countries in the past century (Graham 2002; De Brouwere and Van Lerberghe 2001).

RESEARCH AND DEVELOPMENT NEEDS

The priorities for research and development arising from this chapter need to be put in the context of wider requirements for safe motherhood and newborn health that have been well articulated elsewhere (see, for example, Bale and others 2003). The general heading under which the specific needs emerging from this chapter can be grouped is evidence-based decision making, which has five crucial requirements:

- recognizing the weakness of current approaches to allocating scarce health care resources in poor countries
- making efforts to improve the scope and quality of data on the burden from maternal and perinatal conditions
- carrying out robust evaluation of the costs and effectiveness of intervention strategies
- using reliable evidence to inform the decision-making process
- implementing prioritized strategies and robust, continuous assessment of their performance.

Within those major areas, specific topics relevant to the CEA undertaken here include the following:

- *Ascertaining the burden of maternal and perinatal conditions.* Greater clarity and consensus are needed on the scope of this important burden category and the implications of significant current exclusions, such as indirect maternal conditions and stillbirths. Practical assessment tools are needed to enable meta-analysis and other modeling approaches to systematically factor in data constraints. Huge gaps in knowledge exist with regard to the levels and consequences of maternal morbidity (Say, Pattinson, and Gulmezoglu 2004), the contribution of iatrogenic factors, the unpredictability of maternal complications, and the levels of mortality. Most of those gaps require significant developments in relation to available measurement tools and in poor countries' capacity to use them as part of routine health surveillance. These improvements not only are needed to inform future CEA but also have wider implications for global health monitoring.
- *Implementing change.* In addition to evidence on the content of intervention strategies, assessments of how to implement changes are urgently needed. A limitation of our analysis is that, even though the model may be a reasonable representation of the resource and health consequences of different intervention packages, the way to achieve the required

change, such as a particular increase in the uptake of prenatal care, may not be known. Thus, the ICERs may be too low, in that they do not fully capture the costs of the intervention.

- *Estimating cost-effectiveness.* More sophisticated economic models need to be developed to facilitate the evaluation of a wider range of safe motherhood strategies, particularly as better primary evidence becomes available from other studies and initiatives using a variety of outcome measures (Cairns, McNamee, and Hernandez 2003). Similarly, probabilistic sensitivity analysis would be a valuable development that would permit fuller exploration of the uncertainties regarding the model's parameters.

CONCLUSIONS

In 2001, maternal and perinatal conditions represented the single largest contributor to the global burden of disease, at nearly 6 percent of total DALYs (Mathers and others 2004). Reducing that burden is widely stated as a priority at both national and international levels, but the track record of translating the rhetoric into action on a sufficiently large and equitable scale to make a difference at the population level remains disappointing. The literature abounds with examples of this disappointment (see, for example, Maine and Rosenfield 1999; Weil and Fernandez 1999). Many reasons account for the limited progress, especially in the poorest regions of the world, and researchers offer many interpretations of the bottlenecks. Lack of evidence on the size of the burden and on the effectiveness of alternative intervention strategies figures prominently in these interpretations.

The modeling in this chapter is, therefore, based on imperfect knowledge and needs to be supplemented with data from primary evaluations. The findings do, however, provide some tentative insights into programmatic options that may represent the optimal use of resources in South Asia and Sub-Saharan Africa. In this context, three issues deserve emphasis. First, for intervention packages to achieve the degree of cost-effectiveness shown here, improvements are needed across health systems, and both the supply and the demand sides need to be addressed. Second, crucial entry points to this system can be achieved at the primary level, particularly through prenatal care. The effect of increasing the volume of women in contact with these services is likely to manifest itself in an increased proportion of deliveries with skilled attendance and of deliveries in which women obtain access to emergency obstetric care. Finally, the quality of these services is crucial, and even with only 50 percent uptake of care, benefits can still be achieved in terms of overall DALYs averted and of reduced maternal and perinatal mortality.

Initiatives to improve the quality of care, particularly at a primary level, thus appear to be cost-effective options for the

poorest regions of the world. Overall those findings appear to lend support to a safe motherhood and newborn health strategy that is close to the client and boosts community confidence in health systems.

ANNEX 26.A: CEA MODEL ASSUMPTIONS

We assumed that there are four primary-level health facilities (health centers) and one secondary-level care facility (district hospital) for every 500,000 people. We estimated the numbers of pregnancies and births from the crude birth rate for each region. We assumed that pregnant mothers attending for routine prenatal care are equally distributed between the five facilities and that each facility provides similar routine prenatal and delivery care. Routine prenatal care is assumed to comprise four visits—except for mothers with complications, who make six visits. Mothers with complications are referred to the district hospital after their first visit if they cannot be treated at the health center. We assumed that complications such as anemia and sexually transmitted diseases are treated without referral to secondary care, as are preeclampsia and incomplete abortion, if a doctor is present at the facility. The average number of bed days is assumed to be three days for normal deliveries and six days for cesarean section and other complications. Table 26.A1 shows the U.S. dollar costs per inpatient bed day used in the main analysis and in the sensitivity analysis.

We assumed the existence of excess capacity, so that an increase in prenatal care coverage from 50 to 70 percent would not require an increase in the number or capacity of existing health care facilities, and the increased costs would mostly be increases in variable costs. For increased coverage of prenatal care, we assumed a need for increased expenditure on education, information, and communication. Enhanced prenatal care and comprehensive emergency obstetric care are assumed to require additional expenditures on training, assumed to be 10 percent of total personnel costs. We assumed that the additional costs of basic emergency obstetric care compared with obstetric first aid are largely due to providing doctors at each health center. We also assumed that 8 percent of mothers require cesarean section as a result of either maternal or

perinatal complications. About 2 percent of mothers are assumed to require treatment for preterm delivery, and 1 percent for premature rupture of membranes.

In practice, the proportion of women with serious complications receiving comprehensive emergency obstetric care varies widely, from 3 percent in Cameroon to 75 percent in Sri Lanka (Averting Maternal Death and Disability Working Group on Indicators 2003). The scenarios considered in this chapter assume that either 20 or 50 percent of women with serious complications reach secondary care, and that 50, 70, 80, or 90 percent of those women receive the elements of comprehensive emergency obstetric care that they need, depending on which intervention package is being considered. For the sensitivity analysis, we used low values of 30, 50, 60, and 70 percent and high values of 70, 80, 90, and 95 percent. We assumed that ambulances are available, so that when the proportion of mothers with severe complications reaching secondary care is increased, the additional costs are only the additional driver time and the increased costs of running and maintaining the vehicle.

The prevalence and incidence of different maternal conditions are taken from the WHO mother-baby package (WHO 1994). World Health Organization estimates of the burden of different maternal and perinatal conditions (WHO 2004d) have been applied to a population of 1 million, with a particular crude birth rate to generate an estimate of the potential number of deaths that could be avoided, the years of life that could be saved, and the DALYs that could be averted. The assumptions regarding the effectiveness of the interventions with respect to maternal and perinatal conditions were based primarily on the WHO's mother-baby package and a review of the literature; they are shown in table 26.A2. We assumed that each intervention has the same effect on the number of deaths, years of life saved, and DALYs. The effectiveness of interventions is assumed to be additive.

ACKNOWLEDGMENTS

We would like to thank the many individuals who helped prepare this chapter. In particular, we acknowledge the expert input regarding perinatal conditions from Joy Lawn and Jelka

Zupan. Thanks are also given to our colleagues at the University of Aberdeen, particularly Joyce Boor, Julia Hussein, Emma Pitchforth, Nara Tagiyeva-Milne, and Karen Witten. We acknowledge and thank our colleagues Paul McNamee and Rodolpho Hernandez from the Health Economics Research Unit at the University of Aberdeen for their thorough review of the cost-effectiveness analysis. Thanks also to our expert panel members: Deanna Ashley, Gary Darmstadt, Catherine Hauptfleisch, Jilly Ireland, Joy Lawn, Cecil Klufio, Elizabeth Molyneux, Ashalata Shetty, Sribala Sripad, Vijay Kumar Tandle, Sumesh Thomas, and Jelka Zupan.

NOTES

1. *Antecedent* is here defined as a factor that changes the probability of an adverse outcome or sequela, either positively (protecting) or, more usually, negatively (aggravating). A risk factor may be a leading contributor to the global burden because of high prevalence in the population or because of a large increase in the probability of adverse outcomes (WHO 2002).

2. Afghanistan, Angola, Bangladesh, China, the Democratic Republic of Congo, Ethiopia, India, Indonesia, Kenya, Nigeria, Pakistan, Tanzania, and Uganda.

3. We use a simple three-way distinction for levels of evidence. *Level A* refers to evidence from randomized clinical trials or systematic overviews of trials; *level B* relates to nonrandomized studies, often with multivariate

analyses; and *level C* is assigned to case series, case studies, or expert opinion.

4. This chapter does not deal with tertiary and specialist levels of care or with rehabilitative care or care for chronic conditions.

5. The six functions of BEmOC are (a) administering antibiotics intravenously or intramuscularly, (b) administering oxytocics intravenously or intramuscularly, (c) manually removing the placenta, (d) administering anticonvulsants intravenously or intramuscularly, (e) carrying out instrumental delivery, and (f) removing retained products of conception. The two additional functions in CEmOC are blood transfusion and cesarean section. For a facility to be regarded as a BEmOC or CEmOC site, respectively, it must perform all six or all eight functions regularly and must be assessed every three to six months (UNFPA 2003).

Chapter 27

Newborn Survival

Joy E. Lawn, Jelka Zupan, Geneviève Begkoyian,
and Rudolf Knippenberg

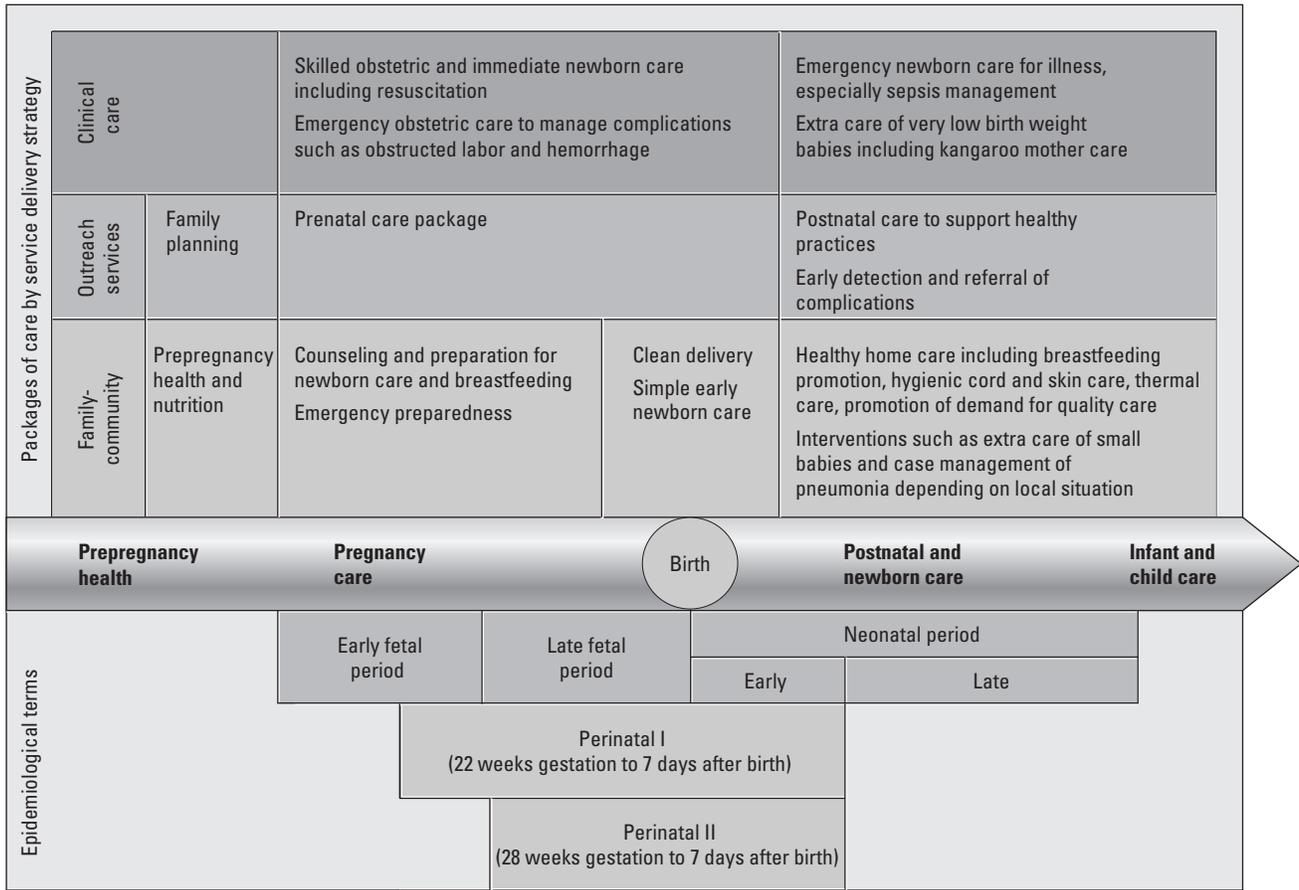

The second half of the 20th century witnessed impressive reductions in the risk of under-five child mortality, which was halved between 1960 and 1990. The greatest reduction was for children after the first month of life, with relatively little decrease in the neonatal period (the first 28 days of life). Neonatal deaths, estimated at approximately 4 million annually, now account for 38 percent of the world's deaths of children under five. The fourth Millennium Development Goal (MDG) aspires to a global target, by 2015, of reducing the under-five mortality rate by two-thirds, which implies approximately 30 deaths per 1,000 live births for children under five. Currently, there are an estimated 30 deaths per 1,000 live births in the neonatal period alone. Thus, the fourth MDG cannot be achieved without substantial reduction in neonatal deaths (Lawn, Cousens, and Zupan 2005).

Addressing neonatal mortality requires links within the continuum of care from maternal health through pregnancy, childbirth, and early neonatal care, and into child health programs. Such services can be delivered through a combination of care at the family-community level, outreach, and clinical care (figure 27.1). Yet neither child survival nor safe motherhood programs have adequately addressed newborn deaths. The first week of life, when 75 percent of neonatal and 50 percent of maternal deaths occur, is associated with low health care coverage, particularly in poor communities. Investing in maternal, neonatal, and child health (MNCH) services will improve the survival of newborns and reduce stillbirths and maternal and child deaths. The first weeks of life are also a time of behavioral transition, representing an opportunity to promote healthy behaviors that have benefit beyond the neonatal period.

This chapter provides an overview of neonatal deaths, presenting the epidemiology as a basis for program priorities and summarizing the evidence for interventions within a health systems framework, providing cost and impact estimates for packages that are feasible for universal scale-up. The focus of the chapter is restricted to interventions during the neonatal period. The priority interventions identified here are largely well known, yet global coverage is extremely low. The chapter concludes with a discussion of implementation in country programs with examples of scaling up, highlighting gaps in knowledge.

NEONATAL DEATHS

One reason neonatal survival has received little attention relative to the huge number of deaths is the invisibility of those deaths. Most deaths during the neonatal period occur at home and are often unregistered even in transition countries (Lumbiganon and others 1990). Social invisibility is linked to an expectation of high mortality; many traditional societies do not name newborns for up to six weeks. Data presented here are derived from full-coverage vital registration for 72 countries, which cover less than 4 percent of all neonatal deaths; demographic and health surveys, which cover 75 percent of global neonatal deaths; and statistical modeling, for the 20 percent of neonatal deaths in countries without data (WHO forthcoming). Population-based data on neonatal morbidity or long-term disability in low- and middle-income countries (LMICs) are scarce. The World Health Organization (WHO) has estimated that three conditions (birth asphyxia, prematurity,

Note: International Classification of Diseases version 10 recommends perinatal I for national data collection. The World Health Organization recommends perinatal II for international comparisons of data.

Figure 27.1 The Continuum of Care for Mothers, Newborns, and Children, Showing Epidemiological Terms around the Time of Birth and Packages of Care Relevant to Newborn Health, According to Service Delivery Level

and “other perinatal causes”), collectively termed *perinatal causes*, contribute to 6.3 percent of global disability-adjusted life years (WHO 2003a). Although these causes represent only part of the neonatal burden, the WHO estimate is more than triple that of HIV, yet receives remarkably little attention.

Where Do Newborns Die?

Only 1 percent of neonatal deaths occur in high-income countries. These countries have average neonatal mortality rate (NMR) of 4 per 1,000 live births, whereas in LMICs the average NMR is 33 per 1,000 live births, with a range of 2 to 70 (table 27.1). The highest number of neonatal deaths occur in South Asia because of the large populations of this region. The six countries with the highest numbers of neonatal deaths in 2000 include the populous nations of India (1.09 million neonatal deaths annually), China (416,000), Pakistan (298,000), Nigeria (247,000), Bangladesh (153,000), and Ethiopia (147,000). Of the 20 countries with the highest NMRs, 80 percent are in Sub-Saharan Africa. The highest rates occur in countries there that have experienced recent civil unrest, such as Liberia (65 per 1,000 live births), Sierra Leone

(60 per 1,000 live births), Mozambique (55 per 1,000 live births), and Ethiopia (52 per 1,000 live births).

When Do Newborns Die?

Each year 3 million newborns die during their first seven days of life, accounting for 75 percent of all neonatal deaths. At least 1 million babies die during their first 24 hours of life (Lawn, Cousens, and Zupan 2005). If mortality rates during the first five years of life are adjusted to rates per week, the risk in the first week of life is massively higher than during any other time of life: 24 per 1,000 in the first week compared with 3 per week for the rest of the first month and only 0.12 per week after the first year of life. Yet the first week is the very period in the continuum of care when services are most likely to be lacking, particularly in poor communities, where most deaths occur.

Time Trends in Neonatal Mortality

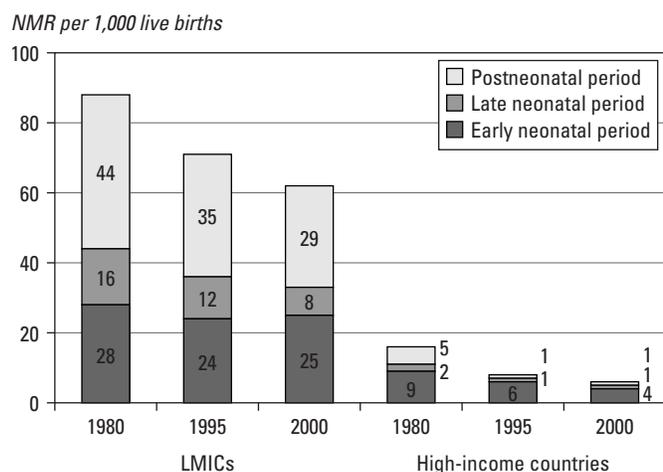

As shown in figure 27.2, the disparity in NMRs between LMICs and high-income countries is increasing over time, especially during the early neonatal period, which saw an almost 60 percent reduction in high-income countries between 1983 and

Table 27.1 NMRs and Neonatal Deaths by Region for 2000, and Variation in NMR by Income Quintile and by Region

Region	NMR per 1,000 live births (range across countries)	Median NMR by income quintile by region		Number (percentage) of neonatal deaths (thousands)	Percentage of deaths during the neonatal period among children under five

Figure 27.2 Trends in Early and Late Neonatal and Postneonatal Mortality, by Country Income Levels

2000, compared with about a 15 percent reduction in LMICs. There has been no measurable decline in the regional average NMR for sub-Saharan Africa. However some regions have made significant progress in reducing NMRs, particularly Latin America and the Western Pacific. Some low-income countries such as Bangladesh, Indonesia, and Sri Lanka have achieved NMR reductions of 40 to 50 percent. In South Asia and Sub-Saharan Africa, the decline in late neonatal deaths was influenced by the halving of neonatal tetanus deaths that occurred during the 1990s as a result of increased tetanus toxoid protection and clean delivery practices. By 2000, two-thirds of LMICs had eliminated neonatal tetanus and an additional 22 countries were nearing this goal.

Historical data also show more rapid reductions in postneonatal mortality, steady reductions in late neonatal mortality, and slower reductions in early neonatal deaths. In England, the NMR fell from more than 30 per 1,000 live births in 1940 to 10 per 1,000 in 1975. This fall occurred before intensive care, which was introduced only when the NMR had fallen below 15 per 1,000. The greatest reduction of NMR coincided with the introduction of free prenatal care, high coverage of skilled childbirth care, and the availability of antibiotics. Although the number of postneonatal and late neonatal deaths is amenable to public health interventions (such as immunization and improved hygiene and nutrition), larger reduction of early neonatal deaths and of maternal deaths requires a system that provides effective clinical care—particularly during childbirth, which is more challenging.

Direct Causes of Neonatal Death

Fewer than 3 percent of the world's neonatal deaths occur in countries that have vital registration data that are reliable enough to use in cause-of-death analysis. Population-based information in high-mortality settings often depends on verbal autopsy tools of variable quality. The Child Health Epidemiology Reference Group undertook an extensive exercise to derive global estimates for program-relevant causes of neonatal death, including preterm birth, asphyxia, sepsis/pneumonia, neonatal tetanus, diarrhea, and other causes, with the latter including specific but less prevalent causes such as jaundice. For low-mortality countries, vital registration data from 45 countries with full vital registration coverage (cumulative sample size of 96,797) were included. For high-mortality countries, studies were identified through extensive systematic searches, and a meta-analysis was performed after applying inclusion criteria

and using standard case definitions (56 studies, cumulative sample size of 13,685). Models were developed to simultaneously estimate the seven selected causes of death by country (Lawn, Cousens, and Wilczynska forthcoming).

Three causes of death—infections (pneumonia, diarrhea, and tetanus) (36 percent), preterm birth (28 percent), and asphyxia (23 percent)—account for the majority of neonatal deaths. Causes of death vary between the early and late neonatal periods, with deaths caused by preterm birth, asphyxia, and congenital defects occurring predominantly during the first week of life and infection being the major cause of neonatal deaths thereafter. Neonatal tetanus, a totally preventable condition, still accounts for more than a quarter of a million deaths, even after the second global elimination deadline has passed. Most neonatal tetanus deaths occur in 20 countries in South Asia and Sub-Saharan Africa, all of which have very high NMRs. Variation in causes of neonatal death is seen between and within countries, closely associated with the NMR level. Where the NMR is high (more than 45 per 1,000 live births), more than half of neonatal deaths are due to infections; where the NMR is low, prematurity and congenital abnormalities are the major causes of death (Lawn, Cousens, and Zupan 2005). Hence, information regarding the local epidemiology is important in prioritizing interventions.

Indirect Causes of Neonatal Death

An estimated 20 million low birthweight (LBW) infants (that is, weighing less than 2,500 grams), are born each year—25 percent of them in South Asia (Blanc and Wardlow 2005). Although globally only 16 percent of newborns have LBW, 60 to 80 percent of neonatal deaths occur in LBW infants (Lawn, Cousens, and Wilczynska forthcoming). LBW is due to short gestation (preterm birth), intrauterine growth restriction (IUGR), or both. Globally, almost one-third of neonatal deaths are directly attributable to preterm birth. In contrast, an analysis of vital registration data for 45 countries and of five population-based studies suggests that a maximum of 1 to 2 percent of neonatal deaths are directly attributable to IUGR in full-term neonates (Lawn, Cousens, and Wilczynska forthcoming). Prematurity and full-term IUGR are also indirect causes or risk factors for neonatal deaths, particularly deaths resulting from infection. The relative risk among preterm infants is much higher than for full-term IUGR infants (Yasmin and others 2001). Complex technology is not necessary to avoid most deaths in moderately preterm newborns. Extra attention to warmth and feeding and to prevention or early treatment of infections is crucial (Lawn, McCarthy, and Ross 2001).

Maternal health and health care are important determinants of neonatal survival. Neonatal outcomes are affected by female health throughout the life cycle, from child, through adolescence, and into pregnancy (Pojsda and Kelley 2000). In general, intrapartum risk factors are associated with greater increases in

risk of neonatal death than factors identified during pregnancy, which are in turn associated with greater increases in risk than prepregnancy factors (Lawn, Cousens, and Zupan 2005). Obstructed labor and malpresentation present the highest risk and require skilled intervention. The mother's death substantially increases the risk of death for her child. Greenwood and others (1987) report that of mothers who died in labor ($N = 8$), all the babies died within one year.

Delays in access to care for severely ill young infants are common. Peterson and others (2004), in a study in Uganda, find that almost 80 percent of the caregivers of severely ill young infants did not comply with recommended referrals to a health facility. The reason given in 90 percent of the cases was lack of money, underscoring the need for pro-poor financing mechanisms and promotion of community demand for care. This recalls the “three delays” model for maternal deaths, which outlines delays in recognition of illness and in access to care and provision of care once at a health facility (Thaddeus and Maine 1994).

Poverty is the root cause of many maternal and neonatal deaths, either because it increases the prevalence of risk factors such as maternal infections or because it reduces access to care. An analysis of 50 demographic and health surveys between 1995 and 2002 reveals that, within regions, the poorest quintiles have an NMR that is, on average, 20 to 50 percent higher than that for the highest income quintile (table 27.1). Deliberate programmatic focus is required to ensure that care reaches poor families.

Applying Lessons from Epidemiology to Programs

There are almost 4 million neonatal deaths annually. Given that the proportion of child deaths that occur during the neonatal period (currently 38 percent) will increase over time, the MDG for child survival cannot be met without a significant reduction in the NMR. Most neonatal deaths are in Sub-Saharan Africa and South Asia and are due to preventable causes. Historical data demonstrate that the NMR can be reduced to 15 per 1,000 without intensive care.

Priority should be given to two main gaps in the provision of care. The first is the continuum of care by time. The period through pregnancy and childbirth into infancy contains a gap at childbirth and during the first week of life, when most neonatal deaths—and also most maternal deaths—occur. Addressing this gap will involve strengthening safe motherhood and child survival services and institutionalizing links at the subnational, national, and global levels. The second gap is between levels of care (figure 27.1)—particularly with the family-community level, since poor and rural communities account for the majority of neonatal and maternal deaths. Approaches are needed to better link homes and health care, supplying care closer to such communities, increasing demand for skilled care, and empowering communities, including poor communities, to make healthful decisions.

INTERVENTIONS

We undertook literature searches and categorized interventions by time period (during pregnancy, and intrapartum and postnatal or neonatal periods) (table 27.2). We focus on interventions delivered during the neonatal period that are likely to reduce neonatal deaths, as opposed to those delivered during the neonatal period that yield later benefits (for example, prevention of mother to child transmission of HIV). Although rigorous evaluation of evidence is vital, evidence is not available for some well-established interventions. In the case of neonatal resuscitation, for example, a randomized controlled trial is impossible for ethical reasons, yet the intervention is a cornerstone of neonatal care in high-income settings. Some important practices, such as cleanliness, have undergone little rigorous evaluation but are obviously beneficial (Bhutta and others 2005). On the basis of level of evidence and feasibility of implementation, we grouped interventions into three categories:

- Universally applicable interventions are selected on the basis of mortality impact, cost, and feasibility. Some of these interventions are feasible only after skilled care is available. Other interventions are feasible immediately, even in the absence of skilled care. A particular example is improved family care practices. Interventions may apply to different newborns as follows:
 - essential newborn care for all babies at all levels
 - extra newborn care for babies with specific risk factors, such as LBW
 - emergency newborn care for babies who are ill, particularly those with infections.
- Additional interventions should apply where neonatal mortality is lower and capacity is greater. These interventions are more complex, requiring more skilled staff members and additional commodities, and therefore cost more for less reduction in mortality. Universal scaling up cannot be recommended at present, but these interventions become important for further reduction of mortality and disabilities after universal care packages are in place.
- Situational interventions are necessary because of locally prevalent risk factors, such as HIV or malaria.

The packages of newborn care selected for universal scale-up are summarized in table 27.3 and discussed in the following subsections, starting with family-community interventions and followed by essential, extra, and emergency newborn care packages.

Family-Community Care of the Newborn

Family care of the newborn is important for all newborns. It includes promoting positive behaviors such as breastfeeding and demand for health care throughout the neonatal period

and afterward (WHO 2003c). Cleanliness (for example, cord care and hand washing), warmth provision, and exclusive breastfeeding reduce neonatal illnesses, especially infection. Implementation of this package will depend on the setting, the coverage of facility delivery, and the availability of community workers or other channels but is feasible even in poorly developed health systems (Knippenberg and others 2005). The role and value of the mother are central.

Although much has been written to describe traditional newborn care practices, few studies assess behavior change. An exception is the study by Meegan and others (2001) of the Masai in Kenya, where behavioral messages about cord care practices were associated with the virtual elimination of neonatal tetanus—with no increase in tetanus toxoid immunizations. The Warmi Project in rural Bolivia demonstrated that raising community awareness of maternal, fetal, and neonatal health issues through women's community groups increased family-planning coverage, attendance at prenatal and postnatal services, and the presence of trained traditional birth assistants at childbirth, resulting in a 62 percent reduction of perinatal mortality (O'Rourke, Howard-Grabman, and Seoane 1998). A cluster randomized trial in rural Nepal, where 90 percent of women deliver at home, also used female facilitators working with women's groups. Comparing the 12 intervention villages with their paired villages showed a 30 percent reduction in the NMR (mainly late NMRs) mediated through increased health seeking and improved home behaviors (such as doubling the rates of practices such as hand washing and use of clean delivery kits) and strengthening of the health system (Manandhar and others 2004).

A family-community package promoting good home care of the newborn—particularly cleanliness, warmth, and exclusive breastfeeding—would have an expected reduction in the NMR of 10 to 40 percent, varying with the baseline NMR and the potential for accessing care. The effect might be greater if the package successfully addressed harmful local practices. The effect of early care seeking for illness will depend on the capacity of the primary and referral health care levels to manage neonatal illness. Thus, community-level interventions with no supply-side strengthening will have only a limited effect. Many questions remain about how best to work with families and communities, given widely differing cultures and behaviors and the varying capacities of existing community health workers (Darmstadt and others 2005), and about the wider application of demand subsidies.

Essential Newborn Care at the Time of Birth

WHO (2003d) defines essential newborn care as the care of the newborn at birth, including cleaning, drying, and warming the infant; initiating exclusive breastfeeding early; and caring for the cord. Essential care of the newborn is necessary for all

Table 27.3 Packages for Universal Scale-up of Newborn Care

Intervention package	Contents	Number of target population per year (millions)	Implementation strategy	Estimated current coverage (percent)		Reduction in all-cause NMR (percent)	Comments on evidence
				South Asia	Sub-Saharan Africa		
Family-community care of the newborn at home after birth	Healthy home care practices (exclusive breastfeeding, warmth protection, clean cord care, care seeking for emergencies); if birth outside a facility, then clean delivery kit.	All newborn infants: World 130 South Asia and Sub-Saharan Africa 63	Women's groups and community health workers doing postnatal visits, with links to the formal health care system, including support for referral. If appropriate, extra care of moderately small babies at home and community-based management of acute respiratory infections.	36	28	10–40	Mortality reduction based on studies in high NMR settings with weak health systems. Extra care of LBW infants and community management of acute respiratory infections not included in range shown.
Essential newborn care at the time of birth	Immediate drying, warmth, early breastfeeding, hygiene maintenance, and infection prevention	All newborn infants: World 130 South Asia and Sub-Saharan Africa 63	Skilled attendant, or if no skilled attendant available, some simple postnatal practices are feasible at home with other cadres of workers.	11	14	20–30	Based on conservative combining of single interventions (for example, breastfeeding) in the package.
Neonatal resuscitation	Resuscitation after birth if required	Newborns not breathing at birth: World 6.5 South Asia and Sub-Saharan Africa 3.2	Skilled attendant.	3	3	10–25	Limited studies, mainly from lower NMR settings with high percentage of asphyxia deaths, so range from studies was reduced.
Extra care of small newborns	Extra support for warmth (kangaroo mother care), feeding, and illness identification and management	LBW neonates: World 20.0 South Asia and Sub-Saharan Africa 10.7	Facility-based care for severely preterm babies. Community-based care is effective for moderately preterm babies.	<10	<10	20–40	Most studies are nonrandomized controlled trials at the community level in settings with extremely high LBW rates. Effect depends on baseline NMR and LBW rates.
Emergency care of ill newborns	Management of ill infants, especially those with neonatal infections	Neonates with illnesses: World 13.0 South Asia and Sub-Saharan Africa 6.3	Facility-based care with antibiotics and supportive care. Community-based management with oral antibiotics for acute respiratory infections.	<20	<20	20–50	Meta-analysis of effect on the NMR of oral antibiotic management of acute respiratory infections in the community in high-mortality settings.
Neonatal packages plus MCH package	Neonatal packages as above, in addition to family planning, prenatal care, and comprehensive obstetric care packages	All newborn infants: World 130 South Asia and Sub-Saharan Africa 63	Supply of care throughout pregnancy, childbirth, and postnatal period with increased demand and improved referral systems.	<5	<5	—	No study data identified. Marginal budgeting for bottlenecks tool suggests 58 percent in South Asia and 71 percent in Sub-Saharan Africa.

Note: The range of reduction of all-cause NMRs given for each package is independent of the others; hence, the total is greater than 100 percent.

infants and is ideally provided by a skilled attendant, but in the absence of skilled care, many of the tasks can be carried out at home by alternative cadres of workers. WHO's essential care package includes resuscitation, which we consider separately because the skill level required is more complex.

Clean care of the umbilical cord (clean blade and tie) is important in reducing the incidence of neonatal tetanus and umbilical sepsis, but evidence for topical treatment of the cord remains unclear (Zupan and Garner 2000). Hand washing is important at all levels of care. Hypothermia is an important and preventable contributor to morbidity and mortality, especially in preterm babies. The so-called warm chain involves ensuring that childbirth takes place in a warmed room, drying the newborn, encouraging skin-to-skin contact between the newborn and the mother, and avoiding bathing for at least 12 hours (Lawn, McCarthy, and Ross 2001). In hospitals in LMICs, many newborns are hypothermic, and staff knowledge and practices could be improved (Dragovich and others 1997).

The effects of exclusive breastfeeding have been intensively studied, and the positive effect on infant mortality is unequivocal, although studies often do not specify the effect on neonatal mortality and morbidity. The WHO collaborative trial found the risk of mortality in nonbreastfed neonates to be 2.5 to 7.0 times greater than for breastfed neonates (WHO Collaborative Group 2000). The practice of keeping well babies close to their mothers and allowing feeding on demand increases breastfeeding rates, reducing both hypothermia and nosocomial infections (WHO 1998b). Unfortunately, as exemplified by the low proportion of hospitals that are certified as baby friendly, this practice is poorly implemented. Supportive policy, such as the International Code of Marketing of Breastmilk Substitutes, is also important at the national level.

The effect of essential newborn care has not been formally tested as a package, although exclusive breastfeeding, cleanliness, infection control measures, and hypothermia avoidance all individually reduce neonatal mortality and morbidity.

Nevertheless, only 11 percent of babies in South Asia and 14 percent in Sub-Saharan Africa are exclusively breastfed to three months. The Bellagio group estimated a 15 percent reduction in the NMR through 99 percent coverage of exclusive breastfeeding and an 11 percent impact reduction through clean delivery (Jones and others 2003). Conservatively, an essential newborn care package may result in a 10 to 25 percent reduction in the NMR, but field trials of a combined package are still required. No economic assessments were identified.

Newborn Resuscitation

Approximately 5 to 10 percent of newborns do not breathe spontaneously and require stimulation. About half of those have difficulty initiating breathing, requiring resuscitation (WHO 1998a). The major reasons for failure to breathe include preterm birth and acute intrapartum events resulting in hypoxic brain injury. Basic resuscitation using a self-inflating bag and air is effective for the majority of these newborns, although some may be too premature or have already experienced severe hypoxic brain injury and die despite resuscitation.

Monitoring labor and providing effective obstetric care can reduce the need for resuscitation (Dujardin, Sene, and Ndiaye 1992), but resuscitation may be required even with good obstetric care. Therefore, every skilled attendant should be competent in newborn resuscitation (box 27.1).

For most babies who do not breathe at birth, ventilation with a self-inflating bag and mask is lifesaving, and the time to first breath differs little between use of a self-inflating bag and mask and use of endotracheal intubation. Evidence is growing that most newborns can be successfully resuscitated without the use of oxygen (Saugstad 2001), although a small proportion of infants require such advanced resuscitation techniques as endotracheal intubation, oxygen, chest compression, or drugs. Such advanced resuscitation is appropriate only in institutions that provide ventilation. In the 1980s, the high cost of a self-inflating

Box 27.1

Institutionalizing a Neonatal Resuscitation Program in a Chinese Province

A hospital-based study from China reports baseline surveillance of 1,722 newborns followed by a two-year prospective assessment of 4,751 newborns, while instituting standardized resuscitation guidelines. Previous traditional resuscitation involved infusing central stimulants plus vitamin C and 50 percent glucose; wiping the baby with alcohol; and pressing the philtrum. Health professionals recognized that asphyxia was the leading cause of

neonatal death and the second leading cause of infant death nationally. They also recognized that child survival goals could not be met unless asphyxia was addressed. They developed and implemented an evidence-based neonatal resuscitation program, training staff in using the new guidelines. The early NMR fell significantly—by 66 percent, to 3.4 per 1,000.

Source: Zhu and others 1997.

bag and mask led to the development of a prototype mouth-to-mask device operated by blowing expired air. A study by Massawe and others (1996) in two teaching hospitals, one in Tanzania and the other in India, found that resuscitators using this device could maintain a maximum of only 20 breaths per minute, one-third of the recommended rate. Low-cost (less than US\$5) versions of the bag and mask are now available, and it is the recommended device for resuscitation.

Although small-scale studies show that nonprofessional cadres can learn the technique of resuscitation (Bang and others 1999; Kumar 1995), a significant effect on mortality has not been demonstrated, and the feasibility of maintaining competency and the cost-effectiveness of training such cadres have yet to be ascertained. If traditional birth assistants attend, say, 20 deliveries a year, they would encounter a baby requiring resuscitation an average of only once a year, so the effect would be lower, and the cost per life saved higher, compared with a facility-based midwife who does 200 or more deliveries a year. Thus, more research is required before home resuscitation by traditional birth assistants can become a widespread policy. In the meantime, it should be ensured that where skilled attendants exist, they have the skills and equipment to perform neonatal resuscitation.

Because a randomized controlled trial would be considered unethical, the studies identified apply a before-and-after comparison. No cost assessments were identified. Achieving wider coverage of resuscitation is a challenge, especially for the 47 percent of the world's babies born at home.

Extra Care for Small Babies

Because 60 to 80 percent of neonatal deaths occur in LBW babies, targeting this group for additional preventive and early curative care is a logical approach to mortality reduction. Addressing deaths among severely preterm infants (fewer than 32 weeks of gestation) is more complex, but most preterm infants are moderately preterm (33.0 to 36.9 weeks). Excess mortality from acquired infections and other complications can largely be prevented or managed without intensive care.

A number of community-based studies have undertaken simplified identification of small babies and provided extra care at home, especially feeding (including the use of a dropper or cup feeding if required), warmth promotion, and cord cleanliness. The reported NMR reductions range from 25 percent (Pratinidhi and others 1986) to 42 percent (Daga and others 1988). Datta (1985) applied a comprehensive approach, including weighing all babies and providing extra home support to LBW infants through feeding counseling and early recognition of and referral for illness, alongside strengthening of local health systems. Compared with a control area, the NMR was reduced by more than 30 percent, with the greatest reduction among the group of 1,500- to 2,500-gram babies. In Bang and others' (1999) study, 90 percent of neonatal deaths were in LBW

infants, and all LBW babies were targeted for increased home visits. Special sleeping bags were provided for warmth, and support was given for breastfeeding and early treatment of possible infections. The NMR fell by 87 percent in the moderately preterm group (35 to 37 weeks) (Bang and others 1999).

So-called kangaroo mother care involves continuous skin-to-skin contact between mother and baby to provide thermal stability and promote exclusive breastfeeding for clinically stable preterm infants. The published evidence relates to facility-based care with or without kangaroo mother care after discharge. Mortality impact data for kangaroo mother care are lacking, but a review by Conde-Agudelo, Diaz-Rossello, and Belizan (2000) that included three randomized controlled trials found that serious morbidity was reduced by about 60 percent at the six-month follow-up visit. Although cost has not been formally evaluated, it must be considerably less than for incubator care. The lack of assessments of kangaroo mother care at community level is a research gap.

A few studies in health facilities in LMICs have reported increased survival of LBW infants with improved care. One from Papua New Guinea demonstrated a 56 percent reduction in the NMR with the introduction of standards for care and of basic technology (Duke, Willie, and Mgone 2000). Data from Ghana showed a 28 percent reduction in mortality for LBW infants with support for breastfeeding, attention to warmth, and early management of infections and jaundice using standard protocols (Lawn, McCarthy, and Ross 2001).

The reported effect for extra care of LBW babies in the community varies between 20 and 40 percent, excluding Bang and others' (1999) study because additional interventions were involved. Given the high LBW prevalence in these studies, the effect may be less in other settings with a lower LBW prevalence. Data from facilities that do not offer intensive care suggest a similar or slightly larger effect. Cost-effectiveness assessments were not identified.

Emergency Care for Ill Newborns

For many of the world's 4 million neonatal deaths, the immediate cause is a neonatal illness presenting as an emergency either soon after birth (such as complications of preterm birth and asphyxia) or later (because of neonatal tetanus or community-acquired infections). Other important but less prevalent conditions include jaundice and hemorrhagic disease of the newborn. Long-term disability follows many neonatal conditions, but it is poorly documented. Many serious neonatal problems present with similar signs: inability to feed, breathing difficulty, and temperature instability. All those conditions have high fatality rates, particularly neonatal tetanus (Institute of Medicine 2003) and neonatal encephalopathy (Ellis and others 1999), and preventive interventions may be the most realistic option in those conditions. Early phototherapy for jaundice reduces both mortality and chronic disability subsequent to

kernicteris and is feasible in facilities (WHO 2003b). We focus on the clinical neonatal management of infection, which is the most prevalent neonatal illness and the most feasible to scale up.

A meta-analysis of community-based trials of case management of pneumonia in Africa and Asia yields a summary estimate for NMR reduction of 27 percent (Sazawal and Black 2003). The antibiotic regime used was mainly oral cotrimoxazole, although two studies included injectable penicillins. Bang and others' (1999) study in rural India reports a 62 percent reduction in the NMR with a home-based package for neonatal sepsis that included injectable gentamicin, although this reduction may be related to a number of simultaneously introduced interventions in addition to the gentamicin.

The effect of emergency care on neonatal sepsis can be assumed to be similar to the range in Sazawal and Black's (2003) meta-analysis: 20 to 60 percent. Published cost data were not identified apart from the Bang and others (1999) study, which indicated a cost of US\$5.30 per neonate treated. This cost estimate includes the time of community health workers and the cost of equipment and drugs, but not associated supervision or system costs.

MARGINAL IMPACT AND COST OF SCALING UP UNIVERSAL NEONATAL PACKAGES

Because newborn health depends on services in the continuum of care for mother, newborn, and child, a vertical program would be duplicative, expensive, and inappropriate (Tinker and others 2005). Hence costing and impact estimates will be based on marginal additions of neonatal-specific packages to existing maternal and child health (MCH) services (table 27.4). This scenario reflects the reality in many South Asian and Sub-Saharan African contexts, where MCH services exist but do not yet include newborn interventions. We will cost packages, because packages are more cost-effective than single interventions, and the emphasis is on the packages described for universal scale-up (table 27.3). The benefits take into account only neonatal deaths averted, whereas many of the interventions will also reduce maternal deaths, stillbirths, and childhood morbidity and disability—and therefore the benefits underestimate gains for both the fourth and the fifth MDGs.

Costing and impact simulations are provided using the “marginal budgeting for bottlenecks” tool, a prioritization tool developed by the United Nations Children's Fund (UNICEF), the World Bank, and WHO. The inputs for the analysis presented here are as follows:

- *Baseline epidemiology* uses NMRs from the latest demographic and health surveys by country or state and recent local relevant demographic data, such as crude birth rates.
- *Cause-specific neonatal mortality estimates* by country are from the Child Health Epidemiology Reference Group's

neonatal estimates by country (Lawn, Cousens, and Wilczynska forthcoming).

- *Baseline coverage estimates* for the neonatal packages presented in table 27.3 are taken from local data, if available (for example, exclusive breastfeeding prevalence), or drawn from coverage estimates in the *Lancet* newborn series (Darmstadt and others 2005; Knippenberg and others 2005; Lawn, Cousens, and Zupan 2005).
- *Impact estimates* for neonatal mortality are from the literature, as presented in this chapter. The range uses the 95 percent confidence interval, rounded to the nearest 5 percent where available (table 27.3). If the data were from an efficacy trial or a before-and-after trial, the range in the literature was reduced to reflect the expected effectiveness, based on expert opinion. Cause-specific mortality was used to allow combinations of effects across packages, and the assumptions applied were aligned with those used in the *Lancet* neonatal series (Darmstadt and others 2005)—although the packages here differ, because this chapter is restricted to the neonatal period. The assumptions for cause-specific impact are detailed at <http://www.fic.nih.gov/dcpp>. The effect for outcomes other than neonatal ones was based on data in the marginal budgeting for bottlenecks tool, primarily from the *Lancet* Bellagio series (Jones and others 2003) and Cochrane reviews. Effects are combined in a residual manner; for example, deaths averted by preventive strategies are removed from the pool before curative approaches are applied, and hence the total effect is less than the sum of the effects. Years of life lost were calculated using local average life expectancy discounted at 3 percent per year. This measure equates to the fatal outcome component of disability-adjusted life years, as described in chapter 15.
- *Specific costs of adding the intervention packages* are calculated on the basis of the cadre of worker, additional personnel time, in-service training, supervision, performance incentives, travel and subsistence costs for referral care, drugs, and equipment. Demand promotion and community mobilization are included. The costs of time, training, and incentives are based on national salary levels, using real country data or World Bank databases. The costs of commodities are based on the UNICEF supply system (<http://www.supply.unicef.dk/Catalogue/>). The cost of strengthening health systems, including improving management and logistics, constructing new facilities, and deploying and training new cadres of workers, is included in the comprehensive MCH package.

Table 27.4 presents the estimated NMR effects and per capita costs, in selected Indian states and Sub-Saharan African countries, of strengthening health systems to increase coverage with existing MCH packages (without neonatal care after birth). It then presents the additional specific costs of including

Source: Estimates by authors, using the “marginal budgeting for bottle-necks” tool as detailed in the text.

YLL = years of life lost. YLL includes neonatal fatal outcomes only and is based on local life expectancy discounted at 3 percent per year.

Scenario 1: increasing coverage by 20 percent.

Scenario 2: meeting fourth MDG, necessitating about 45–60 percent NMR reduction, depending on the percentage of under-five mortality that is neonatal.

Note: No specific neonatal outreach package is shown, because this is in prenatal care as part of the MCH package or home postnatal visits in the family-community package.

a. Five states in India are represented: Gujarat, Madhya Pradesh, Orissa, Rajasthan, and West Bengal.

b. Five countries in Sub-Saharan Africa are represented: Benin, Ethiopia, Madagascar, Mali, and Rwanda.

c. The MCH package consists of family planning, prenatal and obstetric care, and child health services (comprehensive integrated management of infant and childhood illness including prevention and community activities) and includes system strengthening costs.

d. Includes interventions listed in table 27.3 under family-community package plus extra care of moderately small babies at home and community-based management of acute respiratory infections.

e. Includes clinical care packages listed in table 27.3 (essential newborn care, neonatal resuscitation, extra care of small newborns, and emergency care of ill newborns).

neonatal packages at the family-community level and in clinical services and, finally, the combined costs for comprehensive MNCH. Results are shown for two coverage scenarios:

- *Scenario 1:* increasing coverage of the interventions by 20 percent from the baseline
- *Scenario 2:* increasing coverage to the level required to meet the fourth MDG, necessitating about a 45 to 60 percent reduction in NMR, depending on the baseline percentage of under-five mortality that is neonatal.

Table 27.4 shows that the addition of neonatal packages will reduce neonatal deaths at an average cost of about US\$0.50 per capita per year for up to a 15 percent reduction in NMR at the family-community level and about US\$0.20 per capita for a 22 percent NMR reduction at the clinical care level. Although the cost per capita is low for clinical care, the cost per case treated is higher, and the lag time to scale up is longer. The family-community neonatal package in India is estimated to cost US\$100 to US\$257 per year of life saved (table 27.4), which corresponds to about US\$2,800 to US\$7,800 per death averted. That is similar to the results of US\$3,442 per neonatal death averted or US\$111 per life year saved in a community participatory package in Nepal (US\$4,397 and US\$142, respectively, with health system strengthening) (Manandhar and others 2004).

The comprehensive MNCH package (the MCH package plus integrated neonatal packages) is more expensive than the neonatal packages alone: US\$2.40 to US\$2.80 per capita and per year for a 20 percent increase in coverage, and US\$5.50 to US\$5.70 to achieve the mortality reduction necessary to meet the fourth MDG (including the health system strengthening and demand-side approaches required). However, the effect of the MNCH packages on the NMR is more than double that of the neonatal packages alone—for example, a reduction of up to 58 percent in NMRs in Africa, compared with up to 22 percent using interventions in the neonatal period only. This finding emphasizes the advantages of a comprehensive approach across the continuum of care. Hence, the average cost per year of life saved is still low at US\$380 (India) and US\$432 (Sub-Saharan Africa) for a 20 percent increase in coverage, including costs of system strengthening. If the coverage of the MCH plus neonatal packages were to reach 90 percent, those packages would avert up to 71 percent of neonatal deaths in the African countries and up to 76 percent in the Indian states.

In settings where the current coverage of skilled care is low, opportunities exist to start with family care and extra care of LBW babies while building toward more challenging clinical packages. Some clinical care packages—such as simple extra care of the small baby or the provision of oral antibiotics for pneumonia later in the neonatal period—can be adapted for delivery through community health systems. Varying the cadres of worker involved or the level of health system at which

the package is delivered may reduce the cost of the package, but it also necessitates extra supervision and attention to links with the formal health system. Box 27.2 describes the projected effect and cost of various packages in Ethiopia for a 12-year program to improve maternal and child survival targeted at achieving the fourth MDG by 2015. Outreach services such as prenatal care alone have an effect of about 10 percent on NMRs, but when they are combined with a family package using community health promoters, an additional 30 percent reduction in the NMR is projected in Ethiopia.

Outreach and family care options are more feasible initially. Yet if commitment toward moving to strengthen the clinical care system is lacking, the potential reduction in NMRs over time from those options is limited, and the cost per death averted is higher. Although the estimated cost (averaged over 12 years, with gradually increasing amounts) is low, the input is higher than the current government and donor health expenditure of the countries examined. Thus, spending in India would have to be doubled, and in some African countries probably tripled. Considerable new funding is required at the national and international levels, as well as more efficient allocation and absorption of existing funds (Martines and others 2005).

IMPLEMENTATION

Effective interventions exist and are low cost, especially when added to existing programs, but current coverage is low, especially for the poor, who have the highest mortality risk. Approximately 53 percent of women worldwide deliver with a skilled attendant: fewer than 30 percent in the poorest countries and more than 98 percent in the richest countries. In Sub-Saharan Africa, average coverage with skilled care has increased at only 0.2 percent per year in the past decade; without faster progress, coverage of skilled attendance will still be less than 50 percent in 2015. Analysis in 50 low-income countries showed that the richest 20 percent of women were, on average, almost five times as likely to use a skilled attendant as the poorest 20 percent (Knippenberg and others 2005). Hence, coverage is low, progress is slow, and inequity is high.

Each country or decision-making unit starts with a different epidemiology and varying coverage and capacity in its health system. No single recipe for strengthening newborn care in health systems is available. Scaling up MNCH care will involve systematic steps to assess local situations and opportunities, improve care within current constraints, and overcome supply and demand constraints—especially for the poor. No country or program can achieve multiple new interventions at once, and scaling up human resources takes time. Therefore, phasing approaches is essential not only to allow faster approaches to reach the poor soon, but also to allow consistent strengthening of the health system (Knippenberg and others 2005).

Box 27.2

Steps to Increase Coverage of Key MNCH Interventions in Ethiopia

Ethiopia is one of the poorest countries in the world, with gross national income of US\$100 (in 2000), less than half the average for Sub-Saharan Africa. Neonatal deaths of some 135,000 a year account for 29 percent of child deaths. According to a 2000 demographics and health survey, coverage of care is extremely low: only 6 percent of women deliver with a skilled attendant present and only 8 percent receive postnatal care within 48 hours of delivery. The poor and those in rural areas have even lower coverage. Health professionals are in short supply. At the same time, obstetric services may be unused even when accessible because of issues of affordability and acceptability (most health workers are male).

In 2004, the government and major stakeholders held a national partnership conference to develop a national plan for scaling up child survival interventions. The government decided on a health extension package that would deploy two female health extension workers to each *kebele* (commune of 5,000 inhabitants). Those workers are mainly responsible for MNCH interventions, such as immunization, micronutrient supplementation, and family planning, but they also have other public health and some clinical responsibilities. In addition, one primary

Source: Knippenberg and others 2005.

school graduate per 50 families will be trained to promote healthy family behaviors.

Estimates based on the marginal budgeting for bottlenecks tool suggest that, during the first eight years, progressive scaling up of the health extension and health promoters packages, together with some upgrading of clinical services, will cost an additional US\$4 per person per year. That effort could result in a 30 percent reduction in the NMR, attributable mostly to improved behaviors, such as clean delivery and exclusive breastfeeding, and to increased demand for care. Increased coverage with family planning and tetanus toxoid vaccination through the health extension package accounts for about 10 percent of the NMR reduction. By the end of the 12-year period, an additional 30 percent reduction in NMR is expected from strengthening clinical services. A comprehensive package of family-based, outreach, and clinical services is projected to reduce the NMR by nearly 50 percent, associated with a 25 percent reduction in the maternal mortality ratio—as compared with a less than 5 percent reduction in the maternal mortality ratio with family and outreach care alone. The incremental annual cost of almost US\$10 per person is more than three times current public spending on health of US\$2.70.

Step 1: Assess the Situation and Advocate for Action for Newborn Health

Careful examination of local data is required (Lawn, McCarthy, and Ross 2001). Newborn health should be included in general health sector and public sector planning—for instance, for education and transportation. When governments set mortality reduction targets for children under five, they should consider setting simultaneous targets for reducing NMRs (Martines and others 2005). The level of participation—involving multiple stakeholders, including women and communities—and the political will to implement and finance such plans are also crucial to success. Reaching every pregnant woman and every newborn with effective care involves everyone: the family and community provide home care and advocate for access to preventive and curative care; the health system supplies care during normal pregnancy, childbirth, and postnatal care, along with emergency obstetric and young infant care services if required; and the government and global policy makers provide supportive policy and resources, in particular to ensure that there are enough health care providers, such as

midwives. National champions can be effective in promoting progress. Global partnerships may also play a role in facilitating broad national plans and promoting donor convergence in implementation (Tinker and others 2005).

The government of Nepal recently held a series of stakeholder meetings and developed a plan for a national newborn health strategy. Representatives from such diverse backgrounds as neonatology, safe motherhood programs, and community mobilization efforts met over a five-month period to create an operational plan for newborn care through 2017 (Khadka, Moore, and Vikery 2003).

Step 2: Achieve Optimal Newborn Care within the Constraints of the Current Health System

Because situations vary even within countries, data-driven prioritization and good leadership are crucial to using resources well (Lawn, McCarthy, and Ross 2001). Program areas related to newborn health include safe motherhood, child survival, immunization, family planning, and nutrition, along with management of sexually transmitted diseases, prevention of

Box 27.3

Adding Newborns to IMCI in India

An estimated 1.1 million neonatal deaths occur annually in India—approximately 28 percent of the world's total. Between 1960 and 1990, India achieved a 50 percent reduction in infant mortality, but in the 1990s, the decline in the infant mortality rate slowed, partially because of the increasing proportion of infant deaths during the neonatal period. The government looked for ways to add to existing programs and to increase coverage of services, especially given that most neonatal deaths occur in the first few days of life in home settings.

Two major adaptations have been made to the standard IMCI approach:

- Integrated management of neonatal illness was introduced into the global generic guidelines for IMCI, which do not cover illness in the first week of life.
- Focus on outreach services and family care, taking the program into communities to achieve higher coverage, is being promoted through a variety of strategies, namely:
 - three home visits in 10 days for normal weight babies, with a further three in the subsequent three

Source: Adapted from K. Suresh, M. Babille, and V. K. Paul, personal communication, April 2004.

weeks if the infant is LBW, to provide essential newborn care, extra care of the LBW infant, and early identification and referral for sepsis

- improved coordination between auxiliary nurse-midwives and community health workers to assist with the integration of health and nutrition services at household levels.

The marginal cost of adding N (for neonatal) into IMCI in relation to clinical care is estimated at less than US\$0.10 per person, given the existence of traditional IMCI programs. Training the health and nutrition workers (2 per 1,000 population) and providing home visits is estimated to cost US\$0.22 per person. In 2002, the government began to test the integrated management package in 50 districts of United Nations Children's Fund areas of programming. This initiative has prompted policy makers to scale up implementation throughout the country during the 2005–10 phase of its Reproductive and Child Health Program.

maternal-child transmission of HIV, and prevention of malaria during pregnancy. The reality is that such interventions have not reached most women and children and that existing services fail to coordinate along the continuum of care. This situation results in gaps in service and missed opportunities. In Africa, for example, the regional average for prenatal care coverage is 64 percent, yet coverage of tetanus toxoid immunization is 42 percent (Knippenberg and others 2005). Syphilis treatment is another opportunity that frequently is missed during prenatal care (Gloyd, Chai, and Mercer 2001). Including the newborn in transport and funding programs that currently address only maternal emergencies may be of little marginal cost for significant benefit. In India, where integrated management of infant and childhood illness (IMCI) is being scaled up, the marginal cost of adding selected neonatal conditions to the clinical care component of IMCI is low, estimated at less than US\$0.10 per capita (box 27.3).

In many settings in South Asia and Sub-Saharan Africa, even where midwives are in place they do not have the skills required for newborn care. Competency-based training in neonatal resuscitation is a rarity and must be incorporated into preservice as well as in-service training (box 27.1). India's National Neonatology Forum identified birth asphyxia as a leading

cause of neonatal deaths and launched the Neonatal Resuscitation Program, developing a course with standard guidelines and certification of competency (Deorari and others 2001). Between 1990 and 1992, more than 12,000 physicians and nurses were trained. The effect of the program was evaluated in 14 teaching hospitals in India. Changes in resuscitation practices were noted, and asphyxia-related mortality fell significantly. The prevalence of survivors with disabilities was not assessed.

An alternative model of skill strengthening has been tested in South Africa, where significant improvements in knowledge and skills have been documented as a result of the Perinatal Education Programme, a distance-run self-taught course (Woods and Theron 1995). More than 30,000 midwives in South Africa have passed the examinations, and the program's manuals are used in many undergraduate medical and nursing schools.

Numerous publications have detailed suboptimal hospital management of women in labor or newborns, variously reported as contributing to 10 to 75 percent of all perinatal deaths (Lawn and Darmstadt forthcoming). Thus, there is scope for improving outcomes and client satisfaction in virtually all settings. For example, in much of Sub-Saharan Africa, a

Box 27.4

South Africa and the Perinatal Problem Identification Programme: Locally Owned Data for Decision Making

Care for pregnant women and newborns in South Africa ranges from unattended childbirth in rural mud huts to advanced obstetric and intensive neonatal care. National perinatal mortality is estimated at 40 per 1,000 live births, with regional and racial disparities. During the 1990s, growing awareness of the importance and preventability of newborn deaths resulted in the development of the Perinatal Problem Identification Programme. Under the program, basic data are entered into a computer program that calculates perinatal mortality, supporting the identification of avoidable factors to aid the prioritization of actions to address key problems. More than 44 sites across the country use the Perinatal Problem Identification Programme, covering almost 80,000 births annually, or approximately 10 percent of deliveries, with 3,045 perinatal deaths (2000). Avoidable factors were identified in 83 percent of deaths, with half of these being patient related, such as a delayed response to complications. A

further 14 percent of avoidable factors were administrative and, in particular, were related to transportation and lack of staff members. About 25 percent of the avoidable factors involving health workers pertained to intrapartum care, especially poor monitoring (not using the partograph) and inadequate response to problems identified during labor. Half of the cesarean sections were delayed by an hour or more.

The program identified the following national priorities to reduce perinatal deaths:

- reducing intrapartum asphyxia, especially in rural areas—for instance, using maternity waiting homes and addressing transport delays
- improving intrapartum management by means of protocols (partograph and effective monitoring), competency-based training, and ongoing audit
- implementing syphilis screening and treatment more effectively.

Source: Authors, based on data from Pattinson 2002.

significant proportion of women deliver in facilities that collect data that could be used to identify achievable improvements in care (box 27.4).

Step 3: Phase the Systematic Scaling-Up of Newborn Care

Although some resource-poor countries have succeeded in building functional systems (box 27.5), the process, especially for clinical care, takes time. Professional care during childbirth and childhood illnesses is the ideal, but significant costs are involved in increasing the numbers of professionals and retaining them, especially in rural posts. Even maintaining current staff presents challenges, given low pay and high frustration. To markedly increase coverage requires new commitment now to a massive expansion in the number of midwives and to innovative approaches to retain staff, especially in hard-to-serve areas. Supply constraints must be systematically identified and targeted—notably, human resources, accessibility to facilities, financial barriers, and supply of commodities and drugs (Knippenberg and others 2005). Demand-side strategies are also important, including consideration of subsidies for preventive care or transport for emergency care.

In the meantime, most neonatal deaths continue to occur in underserved and poor communities that will wait the longest for access to skilled care. Each year, 60 million women deliver without skilled care present. There is a moral imperative to

reach those women now. Feasible strategies to reduce NMRs exist (for example, efforts to improve family behaviors, tetanus toxoid immunization campaigns, and community-based management of acute respiratory infections) and have been demonstrated in poorly developed health care systems. Interim strategies are available, such as linking a group of traditional birth attendants with skilled attendants (Koblinsky, Campbell, and Heichelheim 1999) or medical assistants to perform cesarean sections. Policy conflicts between skilled and community approaches are not helpful. Both approaches are required. With phased program planning, community services can be used now while professional care is being strengthened. The community services can then promote demand for skilled care (Knippenberg and others 2005).

Step 4: Monitor Coverage and Measure Effect and Cost

In most high-mortality countries, NMRs are measured only intermittently (typically every five years through demographic and health surveys). Tracking of coverage indicators, and especially equity of coverage, is important for managing program decision making. Information is lacking, and the information that is available is often not used to improve care. Governments must be encouraged to report funding, coverage, and outcomes related to national plans for maternal, neonatal, and child survival. Donors should also be accountable for reporting funding

Box 27.5

Reducing Newborn Deaths Is Possible in Low-Income Countries

Sri Lanka achieved neonatal mortality of 11 per 1,000 live births in 2000 despite a low gross national product per capita of US\$800 and less than US\$1.50 per capita per year of health spending on maternal and neonatal health. In 1959, maternal and neonatal mortality were high, with an NMR of 50 per 1,000 live births, and gross national product per capita was US\$290. Maternal and infant mortality were halved by 1980 because skilled childbirth care was scaled up and because prenatal, childbirth, and postnatal and newborn care services were provided close to commu-

nities and without user charges. The period 1980–2000 saw a further 50 percent reduction in the NMR without the use of intensive care, apart from one unit in the capital.

Malaysia also followed a policy of rapid scale-up of the coverage of skilled care at birth. It trained large numbers of midwives and encouraged collaboration with traditional birth attendants to promote a gradual transition to skilled care over several decades. The NMR is now 6 per 1,000 live births, and 95 percent of women deliver with a skilled attendant.

Source: Adapted from Koblinsky 2003.

flows and ensuring that commitments are kept (Martines and others 2005).

RESEARCH PRIORITIES

The overwhelming priority in newborn health research remains how to reach underserved populations. This effort involves demonstrating the effect, cost, and scaling up process for packages of interventions. The processes of adapting effective packages to different settings using various cadres of health workers and of identifying indicators of successful implementation that are replicable are all basic to scaling up yet have been little studied. Costing of newborn health interventions is a major gap. Virtually no published examinations of the marginal benefits and costs of adding neonatal interventions to existing programs aimed at safe motherhood, IMCI, HIV/AIDS, malaria, and sexually transmitted diseases are available. A demonstration of such synergies will help influence policy makers to incorporate neonatal issues into these and other programs. Testing innovative approaches to protect poor families from user costs is also important.

Given that preterm birth accounts for almost 30 percent of neonatal deaths and contributes indirectly to many more deaths, reducing the incidence of preterm birth and decreasing deaths among preterm infants are important areas for study. Low-tech extra care of small babies has the potential to reduce deaths significantly, but the effectiveness of various home and facility packages, including the potential of emollients for preventing infections, needs to be tested. A large industry is developing high-tech devices for newborn care to address the 2 percent of neonatal deaths in rich countries. Yet there is little investment in the development and testing of low-cost, simple, robust devices in the settings where most fetal and neonatal deaths occur.

Understanding is lacking of the effects of maternal infections, particularly of synergies between HIV, malaria, and sexually transmitted diseases (Ticconi and others 2003) as well as the potential synergy between maternal infections and apparent asphyxial injury to neonates (Peebles and Wyatt 2002).

Incidence and intervention data regarding neonatal morbidity and disability at the population level are entirely lacking in LMICs. Improved tools for assessing cause-specific mortality and morbidity outcomes are required to advance answers to many of these questions (Lawn, Cousens, and Wilczynska forthcoming).

CONCLUSIONS

Reductions in neonatal mortality are necessary to meet the fourth MDG. High-impact, low-cost, feasible interventions are available. They could avert approximately 70 percent of the world's 4 million neonatal deaths, according to analysis presented here, an estimate similar to the estimates in the *Lancet* neonatal series (Darmstadt and others 2005). Large gains in neonatal survival are linked to other health gains, such as reduced childhood morbidity and disability, prevention of stillbirths, and improved maternal survival, thus contributing also to the achievement of the fifth MDG.

The success of some low-income countries is encouraging, but in South Asia and Sub-Saharan Africa, coverage is generally low, progress is slow, and inequity is high. While countries continue to move toward a more comprehensive health care system, simpler approaches at family-community level and through outreach services can save many lives now, even in the poorest settings. Well-known interventions, such as neonatal resuscitation and case management of infections, can be added to other programs, particularly safe motherhood and IMCI

programs, at low marginal cost. However, to reach the MDGs, skilled care is required. Scaling up coverage to ensure professional midwives reach those in underserved areas will require major new investment to generate and retain more skilled staff members, along with the necessary supportive infrastructure. This investment will involve increased spending, which—as shown here—may double current national health expenditures per capita in Asia and triple them in many African countries. Even if poor countries spend more and spend better, outside funding will be required.

Current investment in MNCH by most national governments and international donors is utterly inadequate compared with investment in conditions that have higher profiles yet lower mortality rates. The deaths of 10,000 newborns each day are unconscionable when most could be saved now at relatively low cost if the political will to do so existed.

Stunting, Wasting, and Micronutrient Deficiency Disorders

Laura E. Caulfield, Stephanie A. Richard, Juan A. Rivera, Philip Musgrove, and Robert E. Black

Undernutrition and micronutrient deficiencies contribute substantially to the global burden of disease (Ezzati and others 2002). Impoverished communities experience high rates of undernutrition and increased exposure to infectious diseases caused by crowding and inadequate sanitation. Women of reproductive age and children experience devastating health consequences as a result of limited resources, cultural influences, and biological vulnerabilities. Undernutrition and infectious diseases exist in a baleful synergy: undernutrition reduces immunological capacity to defend against diseases, and diseases deplete and deprive the body of essential nutrients. Undernutrition and infectious diseases further exacerbate poverty through lost wages, increased health care costs, and—most insidiously—impaired intellectual development that can significantly reduce earning potential. Health experts have recently recognized the long-term effects of early undernutrition and inadequate infant feeding for obesity and chronic diseases, including diabetes and cardiovascular diseases. This chapter summarizes the problems of undernutrition and vitamin A, iron, zinc, and iodine deficiencies in young children and current programmatic efforts to prevent and treat them.

NATURE, CAUSES, AND BURDEN OF UNDERNUTRITION

The following section describes the magnitude, distribution, and etiology of growth faltering and specific micronutrient deficiencies in young children.

Growth Faltering

Because nutritional inputs are necessary for children's growth, undernutrition is generally characterized by comparing the weights or heights (or lengths) of children at a specific age and sex with the distribution of observed weights or heights in a reference population of presumed healthy children of the same age and sex and then calculating *z*-scores, that is, the difference between a child's weight or height and the median value at that age and sex in the reference population, divided by the standard deviation (SD) of the reference population. A child whose height-for-age is less than -2 SD is considered stunted, because the chances of the child's height being normal are less than 3 percent. A child whose weight-for-age is less than -2 SD is considered underweight, and one whose weight-for-height is less than -2 SD is deemed wasted. *Stunting* results from chronic undernutrition, which retards linear growth, whereas *wasting* results from inadequate nutrition over a shorter period, and *underweight* encompasses both stunting and wasting. Typically, growth faltering begins at about six months of age, as children transition to foods that are often inadequate in quantity and quality, and increased exposure to the environment increases their likelihood of illness.

Although knowledge about the prevalence of stunting and wasting is preferred, information about underweight is more available globally. The high correlation between stunting and underweight and the low prevalence of wasting mean that the prevalence of underweight directly describes the magnitude of the problem of growth faltering and stunting in young children. About 130 million children under the age of five are

underweight, with the highest prevalences in South Asia and Sub-Saharan Africa (table 28.1). The prevalence of stunting, underweight, and wasting is decreasing in most areas of the world; however, in most of Africa, stunting is increasing.

Childhood malnutrition diminishes adult intellectual ability and work capacity, causing economic hardships for individuals and their families. Malnourished women tend to deliver premature or small babies who are more likely to die or suffer from suboptimal growth and development (Allen and Gillespie 2001). Poor early nutrition leads to poor school readiness and performance, resulting in fewer years of schooling, reduced productivity, and earlier childbearing. Thus, poverty, undernutrition, and ill-health are passed on from generation to generation. Undernutrition impedes economic progress in all developing countries.

Undernutrition raises the likelihood that a child will become sick and will then die from the disease. Morbidity and mortality are highest among those most severely malnourished; however, given the high prevalence of mild to moderate underweight, the mildly or moderately underweight individuals experience

the greatest total burden of disease (Fishman and others 2004). Children whose weight-for-age is less than -1 SD are also at increased risk of death, and undernutrition is responsible for 44 to 60 percent of the mortality caused by measles, malaria, pneumonia, and diarrhea. Overall, eliminating malnutrition would prevent 53 percent of deaths in young children, with most of those deaths occurring in South Asia and Sub-Saharan Africa (table 28.2).

Morbidity attributable to undernutrition depends on the nature of the illness. Susceptibility to a highly infectious disease such as measles is unlikely to be affected by nutritional status: all individuals are equally likely to become infected if they are unvaccinated and naive. However, 5 to 16 percent of pneumonia, diarrhea, and malaria morbidity is attributable to moderate to severe underweight (Fishman and others 2004). As table 28.3 shows, the number of disability-adjusted life years (DALYs) attributable to undernutrition is high and, as with mortality, is concentrated in South Asia and Sub-Saharan Africa. The tremendous costs associated with the care and treatment of childhood diseases that could be partially

Table 28.1 Estimated Prevalence of Selected Nutritional Deficiencies in Children Ages Birth through Four, by Region (percent)

a. Only considers DALYs directly attributable to iron deficiency anemia. Not included are DALYs due to perinatal deaths attributable to maternal iron deficiency anemia.

prevented through improvements in child nutrition have not been quantified.

Evidence is accumulating that early malnutrition increases the risk of numerous chronic diseases later (Caballero 2001; Gluckman and Hanson 2004). Associations of early undernutrition with diabetes, hypertension, renal disease, and cardiovascular disease mean that child undernutrition also leads to high adult health care costs.

Vitamin A Deficiency

Vitamin A deficiency (VAD) is a common cause of preventable blindness and a risk factor for increased severity of infectious disease and mortality (Rice, West, and Black 2004). One of the first symptoms of marginal VAD is night blindness. If VAD worsens, additional symptoms of xerophthalmia arise, eventually resulting in blindness. A child who becomes blind from VAD has only a 50 percent chance of surviving the year. Even if children survive, blindness severely diminishes their economic potential. VAD may cause anemia in some regions, but it does not appear to impair children's growth (Ramakrishnan and others 2004).

Increased mortality is associated with VAD, most likely because of the detrimental effects on the immune system, which result in increased severity of illness (Sommer and West 1996). According to Rice, West, and Black (2004), VAD is responsible for almost 630,000 deaths each year from infectious disease (table 28.2), accounting for 20 to 24 percent of the mortality from measles, diarrhea, and malaria (Rice, West, and Black 2004). Attributable fractions are highest where VAD is prevalent and mortality is high. Linking morbidity with VAD is far more difficult. Vitamin A supplementation decreases the severity of diarrhea and complications from measles, but in some trials, supplementation has been associated with increased lower respiratory infections.

VAD results from inadequate intakes of vitamin A because of low intakes of animal foods; inadequate intakes of nonanimal sources of carotenoids that are converted to vitamin A; and

inadequate intakes of fat, which facilitates the absorption of carotenoids. Dietary sources of preformed vitamin A include liver, milk, and egg yolks. Dark green leafy vegetables such as spinach, as well as yellow and orange noncitrus fruits (mangoes, apricots, papayas) and vegetables (pumpkins, squash, carrots), are common sources of carotenoids (vitamin A precursors), which are generally less bioavailable than preformed vitamin A but tend to be more affordable.

Table 28.1 shows recent estimates of the prevalence of VAD in young children (Rice, West, and Black 2004). Of those affected, 250,000 to 500,000 each year will lose their sight as a result. The overall prevalence of VAD is decreasing markedly because of increased awareness of VAD as a public health problem and increased measles immunization and vitamin A supplementation or fortification programs. However, the prevalence of VAD is increasing or is unknown in some regions because of political instability, high rates of infectious disease, and increasing poverty.

Iron Deficiency

More than 2 billion people, mostly women and young children, are thought to be iron deficient (Stoltzfus and Dreyfuss 1998). Iron is found in all plant foods but is more plentiful and bioavailable in meat. Deficiency results from insufficient absorption of iron or excess loss. Absorption is tightly regulated in the intestines, depending on the iron status of the individual, the type of iron, and other nutritional factors. Once iron is absorbed, it is well conserved. Iron is depleted primarily through blood loss, including from parasitic infections such as schistosomiasis and hookworm.

Mainly found in hemoglobin, iron is essential for the binding and transport of oxygen, as well as for the regulation of cell growth and differentiation (Beard 2001). Iron deficiency is the primary cause of anemia, although vitamin A deficiency, folate deficiency, malaria, and HIV also result in anemia. Iron deficiency anemia is most prevalent in South Asia and Sub-Saharan

Africa, but it is not limited to developing countries (table 28.1). Iron deficiency results in neurological impairment, which may not be fully reversible (Grantham-McGregor and Ani 1999). Finally, iron deficiency is known to decrease immune function, but some investigators have also hypothesized that deficiency protects against infectious disease or that iron supplementation increases infectious disease (Caulfield, Richard, and Black 2004). Iron deficiency and anemia do not appear to contribute to growth faltering (Ramakrishnan and others 2004).

Stoltzfus, Mullany, and Black (2004) find that iron deficiency anemia was an underlying factor in 841,000 deaths per year resulting from maternal and perinatal causes, and it directly causes the deaths of 134,000 young children annually (table 28.2). Worldwide, iron deficiency is a substantial contributor to DALY losses (table 28.3).

Iodine Deficiency

Iodine is necessary for the thyroid hormones that regulate growth, development, and metabolism and is essential to prevent goiter and cretinism. Inadequate intake can result in impaired intellectual development and physical growth. A range of impairments resulting from iodine deficiency are referred to as iodine deficiency disorders (IDD) (Hetzel 1983) and can include fetal loss, stillbirth, congenital anomalies, and hearing impairment. The vast majority of deficient individuals experience mild mental retardation. This decrease in mental ability and work capacity may have significant economic consequences. Iodine deficiency has not, however, been associated with the incidence or severity of infectious disease, and studies implicating deficiency as an underlying cause of mortality are limited. Because of this, few child deaths can be attributed to iodine deficiency, but the directly attributable DALY losses remain considerable (table 28.3).

The prevalence of iodine deficiency is often estimated from the prevalence of palpable goiter, but this method is not sensitive to milder expressions of deficiency. Iodine deficiency is thought to be a public health problem in a community if goiter is detected in more than 5 percent of the school-age population. A prevalence greater than 30 percent means that the deficiency is severe. According to World Health Organization (WHO) estimates, goiter rates among school-age children exceed 5 percent in 130 countries, putting 2,225,000 people at risk of IDD. A high prevalence of IDD occurs in Eastern Europe and Central Asia, the Eastern Mediterranean and North Africa, South Asia, and Sub-Saharan Africa (WHO 1999). Iodized salt programs are decreasing iodine deficiency in many regions; however, this reduction is offset by apparent increases in other regions, where public health officials are now aware of the problem because of increased surveillance.

Switzerland and the United States embarked on iodine fortification programs in earnest in the early 1920s. Success resulted in enthusiastic political and financial support for increased

global coverage, and control of IDD through salt iodation represents a great achievement in international public health. Nevertheless, significant numbers of people remain at risk.

Zinc Deficiency

Zinc is ubiquitous within the body and is vital to protein synthesis, cellular growth, and cellular differentiation. Studies in children have demonstrated important roles for zinc in relation to immune function, growth, and development (Brown and others 2002; Shankar and Prasad 1998).

Zinc deficiency results from inadequate intakes and, to some extent, increased losses. Only animal flesh, particularly oysters and shellfish, is a good source of zinc, and fiber and phytates inhibit absorption. Thus, as with iron deficiency, populations consuming a primarily plant-based diet are susceptible. Deficiency can also result from losses during diarrheal illness.

Consensus is currently lacking on how to measure zinc deficiency in individuals. The International Zinc Nutrition Consultative Group recommended using serum or plasma zinc concentrations to identify the risk of deficiency at the population level. In addition, the group used information on absorbable zinc in the food supplies of 176 countries to estimate the proportion of each national population at risk of inadequate intake (table 28.1). This information was used to calculate the burden of disease (table 28.2) associated with zinc deficiency in young children. Prevalence is not expected to decrease unless the implementation of zinc-related interventions increases substantially (Caulfield and Black 2004).

The health consequences of severe zinc deficiency have been elucidated over the past 40 years, whereas the health risks of mild to moderate deficiency have been described only recently. Clinical presentations of severe deficiency include growth retardation, impaired immune function, skin disorders, hypogonadism, anorexia, and cognitive dysfunction. Mild to moderate deficiency increases susceptibility to infection, and the benefits of zinc supplementation on the immune system are well documented (Shankar and Prasad 1998). Zinc can prevent and palliate diarrhea and pneumonia (Zinc Investigators' Collaborative Group and others 1999, 2000) and also may reduce malaria morbidity in young children (Caulfield, Richard, and Black 2004). Improvements in growth have been demonstrated (Brown and others 2002), which may operate directly or indirectly through increased immune function and decreased infectious disease.

Zinc deficiency is estimated to be responsible for about 800,000 deaths annually from diarrhea, pneumonia, and malaria in children under five (table 28.2). Sub-Saharan Africa, the Eastern Mediterranean, and South Asia bear the heaviest attributable burden of pneumonia and diarrhea, with Sub-Saharan Africa accounting for nearly the entire attributable malaria burden.

INTERVENTIONS

Clearly, growth faltering and micronutrient deficiency disorders are prevalent, have deleterious consequences for children's health and development, and are primary contributors to the global burden of disease. Economic development is not the only path to solving childhood undernutrition. Improvements in family income may not translate into increased food intakes because the income elasticity for caloric intake is relatively low. The effects on micronutrient deficiencies might be greater if the food sources of those nutrients (meat, seafood, eggs, fortified food products) were more sensitive to income increases and if children had access to those foods. Price subsidies may reduce undernutrition in young children if targeted to foods consumed by them; the potential contribution of price subsidies to family nutrition is discussed elsewhere (see chapter 11). This chapter focuses on specific public health measures that are intended to address the problems directly. Progress has been made in some areas, but the current magnitude of the problems and of the associated disease burden underscore the need for more investment in nutritional interventions.

Growth Faltering and Childhood Stunting

Infants and young children falter in their growth because of inadequate dietary intakes and recurrent infectious diseases, which reduce appetite, increase metabolic requirements, and increase nutrient loss. Even though this problem is understood, progress to reduce malnutrition has been slow. Over time, thinking on how to reduce growth faltering and childhood stunting has shifted. Whereas previous efforts focused almost exclusively on identifying and rehabilitating severely malnourished children, current efforts emphasize prevention through combined nutritional and disease prevention and treatment interventions.

Initially, these efforts to prevent undernutrition focused on diseases rather than on improved child feeding practices as such. However, according to Becker, Black, and Brown (1991), despite the devastating effects of illness on nutritional status, improving dietary intakes is more effective than disease prevention efforts in reducing undernutrition. Because of dramatic reductions in appetite during illness, efforts to improve dietary intakes initially focused on maintaining energy intakes despite anorexia and on increasing intakes during recuperation, when appetite may be normal or high. More recent interventions aim at feeding healthy children optimal diets, which includes paying attention to dietary quality. Finally, some have argued that, for nutritional advice to be effective, it needs to be provided alongside growth monitoring and promotion; however, it is increasingly recognized that messages for prevention are largely universal and that integrated growth monitoring and promotion are not the only model for service delivery.

Promotion of Optimal Feeding of Infants and Young Children. Much of the early focus on optimal feeding was on breastfeeding, which should be immediate and exclusive until six months of age. At that time nutritious and safe foods should be added to a diet that is still based on breast milk until early in the second year of life. A consensus has been reached that six months is the recommended duration of exclusive breastfeeding (WHO 2002) and that the total duration is a decision left to the mother.

Multiple approaches exist to promote the initiation of breastfeeding and to prolong exclusive breastfeeding—health education; professional support; lay support; health sector changes (for example, infant friendly hospitals); and media campaigns—through health facilities and community programs. A recent Cochrane review estimates the potential effectiveness of these approaches (Sikorski and others 2002). Women who received any form of support for breastfeeding were 22 percent less likely to stop exclusive breastfeeding, and women who received lay support, in particular, were 34 percent less likely to stop exclusive breastfeeding. Substantial evidence indicates that interventions can be effective in prolonging breastfeeding and exclusive breastfeeding and that operational research is needed for program implementation and sustainability. If such programs were fully successful, they would reduce deaths in children under five by 13 percent (Jones and others 2003).

Complementary feeding is the process of introducing other foods and liquids into the child's diet when breast milk alone is no longer sufficient to meet nutritional requirements. According to Brown, Dewey, and Allen (1998), complementary feeding practices are suboptimal from several perspectives:

- Complementary foods are introduced too early or too late.
- Foods are served too infrequently or in insufficient amounts, or their consistency or energy density is inappropriate.
- The micronutrient content of foods is inadequate to meet the child's needs, or other factors in the diet impair the absorption of foods.
- Microbial contamination may occur.

In addition, because children often do not eat all the food offered to them, interaction between the caregiver and the child, along with other psychosocial aspects of care during feeding, requires attention. The amount of complementary food a child needs depends on breast milk intake. Guidelines are available for determining energy and nutrient intakes from complementary foods, given breast milk intakes (Dewey and Brown 2003).

Several reviews of the multiple approaches to improving infant and young child feeding practices are available (Allen and Gillespie 2001; Caulfield, Huffman, and Piwoz 1999; Dewey 2002; Hill, Kirkwood, and Edmond 2004; Swindale and others 2004). Caulfield, Huffman, and Piwoz (1999) review

16 programs in 14 countries to improve dietary intakes of infants 6 to 12 months of age. The programs were designed to promote exclusive breastfeeding and appropriate feeding during illness up to age three, and the content and approaches reflected current thinking regarding nutrition and behavior change. The approaches employed included using the mass media to reach both caregivers and the population as a whole to change cultural norms about complementary feeding and using one-on-one or small group interactions with community health workers to provide individualized information and support.

Most of the projects achieved good coverage (50 to 70 percent), with rates varying depending on the communication strategy. They resulted in large shifts in maternal knowledge and attitudes and changes in infant feeding practices. In the few programs assessing dietary intakes, intakes improved by 70 to 165 kilocalories per day. Differences in nutritional status at 12 months indicated weight-for-age and height-for-age gains of 0.24 to 0.87 SD. Even with a 50 percent overestimation of the effects, the effect of such programs could translate into tangible reductions in malnutrition and attributable mortality. In addition, these calculations do not consider the cumulative reduction in malnutrition from programs that benefit children's growth into the second and third years of life. Jones and others (2003) use the results of the analysis, along with knowledge of the relationship between underweight and child mortality, to estimate that programs to promote complementary feeding could reduce by 6 percent the deaths of children under five in developing countries.

Many programs provide supplemental food to participants either to provide them an incentive for participating in other activities (to offset time costs and increase consumer demand for preventive services) or to rehabilitate severely malnourished children. Although the latter approach is traditionally considered for supplemental food programs, the former approach is more common. Indeed, India's Integrated Child Development Services Program, the world's largest supplemental food program, plans to shift from rehabilitation to the use of supplemental food as a "magnet" for providing other integrated child development services (Kapil 2002). No consensus exists on when or how to include supplemental food to reduce undernutrition, and inefficient targeting is frequently a key constraint to effectiveness. Swindale and others' (2004) review of the effectiveness of food-assisted child survival programs concludes that such programs are reducing malnutrition by 2.0 to 2.5 percent per year.

Despite evidence of the effectiveness of nutritional interventions in improving feeding practices and preventing undernutrition, few programs take a comprehensive approach toward optimizing infant feeding, perhaps because of a lack of consensus on the key components of a comprehensive strategy. In 2002, participants at a WHO consultation developed 10 guiding

principles for optimal feeding of the breastfed child (PAHO and WHO 2003). These principles, outlined in box 28.1, build on lessons from previous programmatic efforts such as those reviewed here and provide a basis for designing comprehensive programs to reduce malnutrition. The international public health community faces the challenge of implementing and evaluating these approaches.

Disease Control and Prevention. Interventions to prevent or decrease malnutrition or infectious disease are expected to decrease child mortality, and interventions that accomplish both will have the greatest effect (Pelletier, Frongillo, and Habicht 1993). This subsection considers the potential for disease control and prevention efforts to reduce undernutrition in young children.

Malaria is responsible for a large portion of childhood mortality in Sub-Saharan Africa. The effect of undernutrition on susceptibility to malaria has been discussed at length elsewhere (Caulfield, Richard, and Black 2004), but the nutritional deficiencies resulting from malaria have been insufficiently explored. Insecticide-treated bednets have been shown to prevent clinical episodes of malaria and decrease the prevalence of anemia in children (Lengeler 2003). Improvements in growth have also been documented.

Water, sanitation, and hygiene interventions decrease childhood malnutrition primarily by preventing diarrheal disease (Checkley and others 2004). Hand-washing interventions can reduce the risk of diarrheal diseases by about 45 percent. Hand-washing interventions can be included in water and sanitation programs or can exist as a single intervention, and they are both effective and cost-effective (Borghi and others 2002).

Vitamin A Deficiency

Even though the consequences of VAD had been defined by 1920, it was 1986 when vitamin A interventions were rigorously studied in a large, controlled community trial (Sommer and West 1996). A number of other community trials soon also demonstrated a significant decrease in child mortality with vitamin A supplementation (Beaton and others 1993). Supplementation can alleviate acute VAD quickly, whereas long-term strategies incorporate fortification and dietary diversification.

Supplementation can be either a curative or a preventive measure. If an individual presents with ocular symptoms of VAD, supplementation is part of the usual standard of care. Beyond the use of supplementation for symptoms that result directly from deficiency, its use as part of the treatment regimen for measles or severe malnutrition can improve health outcomes. In deficient areas, high-dose oral supplementation is recommended every four to six months for children under five and is highly efficacious in reducing ocular effects as well as

Box 28.1

Guiding Principles for Complementary Feeding of the Breastfed Child

1. Practice exclusive breastfeeding from birth to six months of age and introduce complementary foods at six months of age (180 days) while continuing to breastfeed.
2. Continue frequent, on-demand breastfeeding until two years of age or beyond.
3. Practice responsive feeding, applying the principles of psychosocial care. Specifically, do the following:
 - Feed infants directly and assist older children when they feed themselves, being sensitive to their hunger and satiety cues.
 - Feed slowly and patiently; encourage children to eat, but do not force them.
 - Experiment with different food combinations, tastes, textures, and methods of encouragement if children refuse many foods.
 - Minimize distractions during meals if the child loses interest easily.
 - Remember that feeding times are periods of learning and love, and talk to children during feeding, including making eye contact.
4. Practice good hygiene and proper food handling:
 - Wash hands before food preparation and eating (both caregivers and children).
 - Store foods safely and serve foods immediately after preparation.
 - Use clean utensils to prepare and serve food.
 - Use clean cups and bowls when feeding children.
 - Avoid the use of feeding bottles, which are difficult to keep clean.
5. Start at six months of age with small amounts of food and increase the quantity as the child gets older, while maintaining frequent breastfeeding. According to average breast milk intakes in developing countries, infants' needs from complementary foods are approximately 200 kilocalories per day at 6 to 8 months, 300 kilocalories per day at 9 to 11 months, and 550 kilocalories per day at 12 to 23 months.
6. Increase food consistency and variety gradually as the infant gets older, adapting to the infant's requirements and abilities. Infants can eat pureed, mashed, and semisolid foods beginning at six months. By eight months most infants can also eat finger foods—that is, snacks that they can eat unaided. By 12 months, most children can eat the same types of foods that the rest of the family consumes, keeping in mind the need for nutrient-dense foods. Avoid foods that cause choking.
7. Increase the frequency with which the child is fed complementary foods as he or she gets older. The appropriate number of feedings depends on the energy density of local foods and the usual amounts consumed at each feeding. For the average healthy, breastfed infant, meals should be provided two or three times a day at 6 to 8 months of age and three or four times a day at 9 to 23 months of age, with additional snacks.
8. Feed a variety of foods to ensure that nutrient needs are met. The child should eat meat, poultry, fish, or eggs daily, or as often as possible. Vegetarian diets cannot meet nutrient needs at this age unless nutrient supplements or fortified products are used.
9. Use fortified complementary foods or vitamin and mineral supplements for the infant, as needed. In some populations, breastfeeding mothers may also need vitamin and mineral supplements or fortified products for their own health and to ensure normal concentrations of certain nutrients in their breast milk.
10. Increase fluid intake during illness, including more frequent breastfeeding, and encourage the child to eat soft, varied, appetizing, favorite foods. After illness, give food more often than usual, and encourage the child to eat more.

Source: PAHO and WHO 2003.

mortality (Sommer and West 1996). A meta-analysis of controlled trials in children demonstrated a 23 percent reduction in mortality (Beaton and others 1993). High-dose vitamin A supplements are considered safe for infants younger than six months. Several studies suggest that giving vitamin A within 48 hours of birth reduces mortality in the first three months by 21 to 74 percent (D. Ross 2002).

A variety of foodstuffs have been fortified with vitamin A, including oil, monosodium glutamate, butter, wheat flour, sugar, and rice. Fortified white sugar has been successful in reducing VAD prevalence in Central America. In El Salvador and Guatemala, where fortified sugar is the primary source of vitamin A, it accounts for approximately 30 percent of the recommended dietary intake (RDI). Fortification of monosodium

glutamate with vitamin A has been demonstrated to be biologically efficacious. Even though program implementation was flawed by unacceptable cost, discoloration of the monosodium glutamate, and packaging problems, indicators of VAD declined significantly during periods of fortification in both Indonesia and the Philippines (Dary and Mora 2002).

Vitamin A intakes can also be improved through dietary diversification, either by educating communities about important sources of vitamin A and beta-carotene that are available in the local diet or by increasing economic prosperity so that individuals have additional funds to spend on a wider variety of food. Education alone has not been demonstrated to affect the degree of VAD in a community, but it can be a powerful tool when incorporated in a broader strategy that also includes supplementation and fortification (Sommer and West 1996).

Iron Deficiency

Despite the public health community's enduring interest in preventing and treating iron deficiency anemia, little evidence suggests that the problem has been reduced. Indeed, in some regions the opposite may be true. From the 1970s to the 1980s, the iron density of people's diets decreased in every region except the Near East and North Africa as iron-poor cereals displaced legumes. During much of this period, iron deficiency anemia increased in South Asia and Sub-Saharan Africa, where the problem is most severe (Stoltzfus, Mullany, and Black 2004). Goals for reducing iron deficiency anemia were articulated for the 1990s at the 1990 World Summit for Children, and many countries adopted policies for providing supplementation for young children; however, few large programs have been developed to eliminate the problem.

The explanations for this failure to act include doubts among both scientific program planners and policy makers about the causes and consequences of iron deficiency and anemia; lack of political commitment; inadequate program planning, including mobilization and training of health staff members; insufficient community involvement; and, in particular, inherent difficulties with prolonged adherence to daily supplementation (Stoltzfus, Mullany, and Black 2004). Despite this bleak picture, guidelines for supplementation have been formulated for children ages 6 to 24 months and for low birth-weight infants beginning at 2 months (Stoltzfus and Dreyfuss 1998). Also, various scientific documents synthesize and communicate current knowledge about the consequences of iron deficiency anemia and programming efforts.

Ample evidence indicates that iron deficiency is the principal cause of anemia in children; that iron supplements are efficacious in preventing and treating iron deficiency anemia, increasing hemoglobin concentrations by about 1 gram per deciliter on average in controlled trials; and that supplements reduce severe anemia even in malarious areas. The contribution of parasitic

infections such as malaria and hookworm to anemia does not negate the usefulness of iron supplements; rather it underscores the need for multiple inputs to prevent severe anemia, given the risks of transfusion. Although current recommendations indicate daily supplements, less frequent delivery, such as intermittently or weekly, is commanding interest. Beaton and McCabe's (1999) meta-analysis concludes that both daily and weekly supplementation are efficacious if adherence is good.

In many countries, iron fortification of foods is the principal strategy for reducing iron deficiency and anemia. Fortified foodstuffs include wheat and maize flours, noodles, sugar, condiments, and complementary foods and milk for infants and children. Efficacy studies indicate the potential of fortification to increase iron intakes and reduce anemia, and effectiveness trials in Chile (dry milk for infants), Ghana (complementary food for young children), Guatemala (sugar), India (salt), Mexico (fortified weaning food and dry milk), and República Bolivariana de Venezuela (maize and wheat) have found improvements in hemoglobin concentration or reductions in anemia prevalence (Allen and Gillespie 2001; Rivera and others 2004). Nevertheless, few national iron fortification programs have evaluation results that are without controversy. Yip and Ramakrishnan (2002) argue that the strongest examples of the potential for fortification are found in the Chilean program of fortified dry milk for infants and in the U.S. program of iron-fortified infant cereals. A randomized trial in Mexico of a poverty alleviation program that distributes a complementary food fortified with multiple micronutrients, including iron, found positive effects on anemia rates (Rivera and others 2004). Evaluations of newly implemented iron fortification programs should gauge their contribution to anemia prevention.

Newer strategies, such as sprinkles (powders), spreads, or foodlets (a hybrid of a food and a tablet), appear promising, particularly for regions where the infrastructure will not support more traditional forms of fortification (Zlotkin and others 2003). Processed complementary foods and beverages offer additional vehicles for reducing iron and other micronutrient deficiencies and promoting well-being (Solon and others 2003). Implementing such strategies and documenting their cost-effectiveness are important activities for the next few years.

In many settings, promoting iron-rich organ meats and animal products and undertaking other food-based strategies may increase iron intakes and contribute to anemia reduction. Such approaches have been promoted for many years, but research is still needed to document their efficacy and effectiveness (Ruel and Levin 2000).

Iodine Deficiency Disorders

Interventions to diminish iodine deficiency using either supplementation or fortification are both efficacious and inexpensive, and WHO, the United Nations Children's Fund, and

the International Council for the Control of Iodine Deficiency Disorders have pledged to eliminate iodine deficiency and the spectrum of IDD.

For regions with severe endemic iodine deficiency, high-dose iodine supplementation is indicated while longer-term solutions are put into place. Iodized oil and iodide tablets are the most common means of direct administration. Injections of iodized oil have been used with much success to decrease the prevalence of IDD and have been shown to be effective for three to four years, depending on the dosage (Hetzel 1989). Although injected oil is effective, it is also expensive, requires trained personnel to administer, and carries the risk of infectious disease transmission from contaminated needles. Because of those drawbacks, researchers began exploring oral administration as an alternative. Oral administration of iodized oil in liquid and tablet form has been successful in the long-term correction of clinical deficiency, and in Indonesia, oral administration was associated with a reduction in infant mortality (Cobra and others 1997).

Iodized or iodated salt is the primary strategy for correcting iodine deficiency because of the nearly universal consumption of salt regardless of socioeconomic status; the lack of an effect on consistency, color, or taste from the addition of iodine; and the limited number of producers in many countries. Large-scale salt fortification has been highly successful in many countries, and of the 130 countries with iodine deficiency, 75 percent have laws mandating salt iodization. The goal of universal salt iodization for consumption by both humans and livestock in all countries with endemic iodine deficiency was set at the 1990 World Summit for Children (WHO, UNICEF, and ICCIDD 2001). Some populations do not easily embrace salt iodization because of cultural preferences or because they have an ample supply of unprocessed salt, so other means of fortification are needed. One promising option is to add potassium iodate to irrigation water.

Zinc Deficiency

Although zinc deficiency is likely widespread and even mild deficiency probably has significant health consequences, few interventions have been developed to combat it in developing countries. Possible interventions include supplementation, fortification, and dietary diversification or modification. The strong evidence that the use of zinc supplements given during and for a short time after diarrhea improves the outcome of that episode and prevents future episodes has led to the recommendation that zinc, along with increased fluids and continued feeding, be used to treat all episodes of acute diarrhea (WHO and UNICEF 2004). Substantial efforts are under way to initiate programs in developing countries. Prophylactic zinc supplementation also improves growth and reduces diarrhea incidence (International Zinc Nutrition Consultative Group 2004).

Fortification interventions include the traditional method of adding zinc to a commercial food, consumer fortification using sprinkles, and plant-breeding techniques. For example, Mexico has introduced several large-scale programs, including the fortification of maize and wheat flours and the distribution of fortified complementary food and fortified milk to low-income children (Rivera and Sepulveda 2003). Researchers are investigating the possibility of home fortification of food using sprinkles containing iron and zinc (Zlotkin and others 2003), but further research is needed to determine whether sprinkles are a viable option. Through plant breeding and genetic engineering, staple crops may be made to contain more zinc or less phytate, resulting in increased zinc bioavailability (Ruel and Bouis 1998). Other dietary strategies target food preparation techniques, such as fermentation of unrefined flour to increase zinc bioavailability.

INTERVENTION COSTS AND COST-EFFECTIVENESS

Multiple strategies exist for preventing malnutrition in young children in the short and long term. This section considers the costs and cost-effectiveness of these interventions for preventing malnutrition or deaths attributable to each nutritional problem. Table 28.4 presents a compendium of cost information, including, where possible, the costs of preventing a child death or saving a DALY.

Horton and others (1996) use data from Brazil, Honduras, and Mexico to estimate the costs and cost-effectiveness of hospital-based programs to promote breastfeeding. Using standard costing methods, they examine the costs of breastfeeding promotion activities in each program and the additional inputs, as well as the savings. Savings accrued from the removal of infant formula where it was currently used. Using data on infant feeding practices and morbidity and mortality from Brazil, they estimated the costs of the programs per birth, per diarrhea case averted, and per death averted. As table 28.4 shows, the costs of such programs range from US\$0.30 to US\$0.40 per child, and from US\$100 to US\$200 per death averted, making them comparable in cost-effectiveness to measles and rotavirus vaccination. Assuming that deaths would otherwise have occurred around age one, and using average Latin American life expectancy at that age, yields a cost per DALY gained of only US\$3 to US\$7.

In many community-based strategies, multiple organizations work through a variety of communication channels to promote exclusive breastfeeding. Two studies in Ghana and Madagascar provide cost estimates for such programs (Chee, Makinen, and Sakagawa 2002; Chee and others 2003). The programs cost US\$4 to US\$16 per child, and given the effect on mothers' practices, the cost ranged from US\$5 to

Table 28.4 Costs and Cost-Effectiveness of Nutrition Interventions

Type of deficiency and intervention	Source	Year	Country	Costs (US\$)		
				Per child or per outcome	Per death averted	Per DALY gained
<i>Underweight</i>						
Breastfeeding support	Horton and others 1996	1996	Brazil, Honduras, Mexico	0.30–0.40 per birth; 0.65–1.10 per diarrhea case averted	100–200	3–7
Breastfeeding promotion	Ross, Loening, and Mbele 1987	1987	Mali	2–3 per child	282	11

— = Source did not include data from which to estimate deaths averted (and DALYs gained).

Note: Deaths prevented by promoting or supporting breastfeeding are assumed to occur around age one. Deaths prevented by other programs to reduce underweight and all programs to reduce micronutrient deficiency are assumed to occur between ages one and five. Authors' estimates of costs per DALY (in parentheses) using region-specific life expectancies at ages one and five, reflect this range.

a. Assumes that all the DALY gains come from preventing deaths.

b. Assumes that an undernourished child has a chance of 1 in 16 to 1 in 12 (6 to 8 percent) of dying before age five, the same as estimated for child survival programs.

US\$58 per adopter of exclusive breastfeeding. In Ghana, an estimated 883 deaths were averted, yielding a program cost of US\$7.80 per DALY gained or US\$203 per death prevented. The range of costs within each program depended on the baseline prevalence of the behavior, the population density, and the characteristics of the implementing organizations themselves. Programs will be more cost-effective when the baseline prevalence is lower; the population density is higher; and the organizations involved are focused, highly motivated, and well organized.

Less information is available on the costs of community-based nutrition programs to prevent growth faltering, to control morbidity, and to improve survival. The costs of a program in Mali (Ross, Loening, and Mbele 1987), which included promotion of breastfeeding, counseling, and education on optimal child feeding; prevention of diarrheal disease; and growth monitoring, were estimated to be US\$282 per death averted and US\$11 per DALY gained. This estimate is consistent with others that nutrition programs cost US\$2 to US\$10 per child, depending on the intensity of nutrition counseling, including Fiedler's (2003) study of the Integrated Community Child Care Program in Honduras, which had an estimated cost of US\$4 per child. (For a fuller analysis of such programs, including contextual and programmatic characteristics that affect outcomes, see chapter 56.)

In the past five years, investigators have undertaken several cost analyses of national programs to distribute vitamin A capsules. Two reports from Ghana and Zambia are particularly informative (Rassas, Hottor, and others 2004; Rassas, Nakamba, and others 2004). As table 28.4 shows, such programs cost US\$0.90 to US\$1.23 per child, with the costs per death averted ranging from US\$162 to US\$277. (Deaths from micronutrient deficiencies are assumed to occur between ages one and five, and estimates of cost per DALY ranging from US\$6 to US\$11 reflect this range, as well as region-specific life expectancies at those ages.) These costs are comparable with estimates of a vitamin A program in Nepal that cost US\$1.25 per child and US\$327 per death averted (Fiedler 2000). Ching and others (2000) examine the costs of incorporating vitamin A capsule distribution into immunization campaigns in 50 countries in 1998 and 1999. Their analysis finds that the total costs per death averted ranged from about US\$150 to US\$600, with the incremental costs for vitamin A distribution amounting to only about US\$30 to US\$150 per death averted. The costs per death averted depended on the country setting, the program's coverage, the delivery of vitamin A (one or two doses), and the underlying level of mortality. The incremental cost per DALY gained could be as low as US\$1 or as high as US\$6.

Fewer examples of vitamin A fortification programs are available, with the only clear example being sugar fortification

in Central America. In 1994, estimates indicated that a program in Guatemala cost US\$0.17 per child, and US\$1,000 per death averted. Counting only the losses from mortality, the cost of saving a DALY was US\$33 to US\$35. However, for each death prevented, there were probably several cases of eye damage prevented and of improved general health; thus, taking full account of nonfatal effects would reduce the cost per DALY somewhat.

Iron supplementation is more costly than distribution of vitamin A capsules, as it involves a daily supplement over an extended period. Estimates indicate that such programs cost US\$3.17 to US\$5.30 per child. Numerous cost estimates are available for iron fortification programs, because these programs have been the principal strategy to prevent and control iron deficiency anemia. Such programs have traditionally cost US\$0.09 to US\$1.00 per child, depending on the country and the vehicle for fortification. These estimates are based on elemental iron as the fortifier. Even though this is the cheapest form available, critics have questioned the bioavailability of elemental iron, and many researchers now advocate using other forms of iron.

Iodine fortification programs cost little, about US\$0.02 to US\$0.05 per child. Iodized oil injections are more costly at US\$0.80 to US\$2.75 per beneficiary, but these programs may be recommended for settings where people consume little commercialized and easily fortified food.

Currently, no examples of zinc intervention programs are available from which to estimate cost-effectiveness. However, Robberstad and others' (2004) simulation analysis examines the potential costs and cost-effectiveness of providing zinc as an adjunct to oral hydration salts in treating diarrhea in young children. Providing zinc as part of case management carries an estimated incremental cost of US\$0.47 per treatment, ranging from US\$0.33 to US\$0.62. Given the relationship between zinc provision and mortality risk, this addition to current management programs would cost, on average, US\$2,100 per death averted and US\$73 per DALY gained.

Despite the enormity of the nutritional problems, the associated loss of DALYS, and the existence of programs to combat malnutrition, surprisingly little data on the costs or cost-effectiveness of nutritional programs are available. This problem represents a serious gap in information for health planning, implementation, and advocacy. Nonetheless, considerable evidence indicates that when programs to promote breastfeeding or child growth or to correct micronutrient deficiencies are delivered to populations with a relatively high prevalence of malnutrition, the cost per participating child is usually so low that deaths can be averted at a cost per DALY that is less than US\$100, and often less than US\$10, even in regions with low life expectancy. Few health interventions are comparably cost-effective.

ECONOMIC BENEFITS OF INTERVENTION

The previous sections outlined the costs to society in terms of deaths and disabilities resulting from growth faltering and micronutrient malnutrition, as well as the costs and cost-effectiveness of options for their alleviation and prevention; however, DALYs do not capture the full range of potential benefits to society from effective nutrition programs. For example, even though the effect of iron deficiency on mental retardation in children contributes to the attributable DALYs (Stoltzfus, Mullany, and Black 2004), the negative effects of iron deficiency on cognition that do not constitute retardation are not considered. Other effects of malnutrition on cognitive and physical functioning that ultimately affect labor productivity are also not considered, nor are other long-term health consequences of child undernutrition. Finally, because undernutrition increases the frequency and severity of disease, undernutrition is associated with considerable health care costs, which are also not captured in burden estimates.

Malnutrition and Human Capital Formation

Researchers have studied cognitive function using global measures of development and intelligence, such as IQ, along with school performance and more narrowly defined intellectual, psychomotor, and behavioral skills. A large body of research has examined whether undernutrition causes lasting cognitive deficits in later life and whether potential deficits are amenable to subsequent nutritional interventions. Acute malnutrition is associated with negative neuroanatomical, emotional, and behavioral effects on children's development. After recovery, results of behavioral and developmental tests generally improve, but the long-term developmental implications remain unclear. Many studies find IQ scores 8 to 18 points lower in children who suffered from severe malnutrition (Fishman and others 2004). Studies of chronic undernutrition also report deficits in IQ and school performance with stunting during early childhood. Evidence from nutritional interventions among high-risk or undernourished children suggests that early supplementary feeding (but no sooner than two years of age) improves developmental scores during the intervention, with some evidence of long-term benefits. For example, follow-up of Guatemalan children exposed to prenatal and early postnatal supplementation demonstrated long-term cognitive benefits even after adjusting for socioeconomic factors and educational experience (Pollitt and others 1995). These results argue strongly for preventing acute severe malnutrition and generalized growth faltering that leads to stunting in children.

Nutritional interventions may preserve or improve cognitive function through mechanisms other than preventing growth faltering or acute malnutrition. For example, breastfeeding confers some cognitive benefits. Anderson, Johnstone,

and Remley's (1999) meta-analysis estimates gains of 3.5 IQ points, adjusting for important covariates.

Iron deficiency has long been associated with developmental delays, and iron supplementation studies have demonstrated improvements in cognitive function. Whether the negative effects of iron deficiency and anemia on development are reversible remains controversial, which implies the need for strong preventive measures. More research is needed to learn about the effects of iron deficiency on development and to develop measures for evaluating programs that provide iron.

Multiple lines of evidence indicate that zinc influences development (Black 1998). Despite a clear biological role, epidemiological studies provide insufficient evidence to draw conclusions on the gain in human capital if zinc deficiency were reduced through public health interventions. Research to address this gap is under way.

The public health community has long recognized that iodine deficiency is the most common cause of preventable mental retardation. Even though the problem of maternal iodine deficiency and cretinism in the offspring is well recognized, evidence also suggests that deficiency in children is negatively associated with cognitive abilities. Bleichrodt and Born's (1994) meta-analysis finds losses of 13.5 IQ points in those with iodine deficiency. Some of these effects occur in the absence of goiter, the hallmark of IDD. More research is needed to fully understand the human consequences of milder forms of iodine deficiency that are probably still prevalent in developing countries.

Malnutrition and Loss of Productivity

Abundant evidence demonstrates that both anemia and iron deficiency decrease fitness and capacity for aerobic work by decreasing oxygen transport and respiratory efficiency in muscles. The consequences of iron deficiency are thus measurable in terms of loss of economic productivity. Aguayo, Scott, and Ross's (2003) case study in Sierra Leone estimates that anemia among women is associated with agricultural productivity losses of US\$19 million per year. For children, the economic costs are not as clear, but those costs may be substantial depending on the children's ages and the types of work they perform.

Growth faltering that leads to stunting in early childhood translates into shortened adult stature. Adult height is related not only to total food consumption but also to protein intake (Jamison, Leslie, and Musgrove 2003), which reinforces the importance of dietary quality. Multiple levels of evidence link adult stature and worker productivity (Martorell 1996). Haddad and Bouis (1991) estimate that a 1 percent decrease in adult stature is associated with a 1.4 percent decrease in productivity. Others find that a 1 percent increase in adult stature is associated with a 2.0 to 2.4 percent increase in wages or earnings. Other things being equal, current programs to prevent

stunting in early childhood can deliver about a third to a half of that 1 percent increase in adult stature. Thus, a lifetime of economic loss results from a failure to prevent stunting in early childhood and accompanying deficits in adult stature, and strategies to reduce this tremendous loss are available.

In addition, the impacts of malnutrition on cognitive development translate indirectly into deficits in productivity in adulthood. Children who are malnourished are more likely to start school late, to perform less well, and to stay in school for a shorter time (Behrman, Alderman, and Hoddinott 2004). Studies suggest that improvements in nutrition within the current range of benefits of programs for young children can lead to substantial increases in rates of school initiation and to more years of schooling (Alderman, Hoddinott, and Kinsey 2003; Alderman and others 2001; Behrman and others 2003). Both years of schooling and school performance affect wages and economic productivity. Alderman, Hoddinott, and Kinsey (2003) calculate that the effects of malnutrition during early childhood, with the accompanying effects on schooling, lead to a 12 percent reduction in lifetime earnings in Zimbabwe. Current programming could restore a significant proportion of those lost wages.

Resource Allocation

Malnutrition increases the likelihood that a child will be sick and, when sick, will become seriously ill. Thus, resources must be allocated to health care services to deal with the increased frequency and severity of illness caused by undernutrition and micronutrient deficiencies. To our knowledge, this increase in likelihood and severity of illness has never been quantified, but it is likely to be high, considering not only the costs of health care infrastructure, but also the time costs and costs of lost wages or schooling borne by the family for each episode of illness. Furthermore, to the extent that undernutrition or micronutrient deficiencies lead to deficits in cognitive development, resources need to be allocated to special education, rehabilitation, and vocational services. The costs associated with not providing such services are ultimately paid in mortality and economic statistics.

Adult Disease and Disability

In the past 10 years, a growing literature has identified associations between small size at birth; early patterns of postnatal growth; and adult conditions as diverse as diabetes, cardiovascular disease, and schizophrenia. More research is needed to provide evidence of causality for such associations and to create the evidence base for attributing those effects to malnutrition in burden-of-disease calculations. Given current knowledge, health care budgets in developing countries will likely be strained to deal with the burden of chronic diseases of adulthood caused by the failure to prevent maternal and child undernutrition.

PROGRAM IMPLEMENTATION: LESSONS OF EXPERIENCE

For decades, countries have implemented programs to alleviate growth faltering and micronutrient deficiencies in children; therefore, it is timely to consider what has been accomplished and what can be learned from successes and failures. The task is difficult, because nutrition programs are diverse, ranging from the simple fortification of salt with iodine to multifaceted programs to improve dietary intakes and prevent growth faltering. Nonetheless, some general statements about the state of programming in this area are possible.

Success in conceptualizing and implementing programs to reduce growth faltering by combining disease control strategies with the promotion of breastfeeding and optimal complementary feeding has been demonstrable. The focus has shifted away from growth monitoring and promotion (counseling) strategies to population-based assessment with more generalized dissemination of key messages for behavior change. Available data suggest high cost-effectiveness for such programs. Key challenges involve scaling up and sustainability, as well as strengthening of monitoring and evaluation systems. A gap in this knowledge concerns optimal feeding in the presence of HIV infection, and testing options and designing programs in such settings are of the highest priority.

Iodine fortification has been a clear success over decades, which underscores the need for continued and consistent funding and advocacy for such programs. Even when universal access to iodine becomes a reality, policy and programmatic supports will be necessary to maintain it.

The success of iodine fortification contrasts with other examples of fortification that have made slow and uneven progress. Fortification of foodstuffs with vitamin A is limited geographically, and even though many countries have embarked on iron fortification, these programs lag because of controversies about the effectiveness of existing programs, the evaluation methods used, and the lack of infrastructure for fortification in some settings. Concerted efforts to address the controversies and to provide evidence of the effectiveness of fortification in controlling iron deficiency are under way. In addition, recognition that fortification should address multiple micronutrient deficiencies, chiefly the B vitamins and zinc, has grown.

Programs to distribute vitamin A capsules twice a year are a reality in many areas characterized by VAD. Jones and others (2003) estimate that current coverage of supplementation for children living in areas with VAD is 55 percent. In the past few years, studies have provided solid data on the costs and cost-effectiveness of such programs in diverse settings.

In contrast, despite concerns about the health and developmental consequences of iron deficiency and anemia, few examples are available of even small-scale iron supplementation programs for young children. Supply and adherence continue to

constrain progress, with adherence depending on program workers' and families' perceptions of benefits and their reluctance to continue the long-term use in children of what are often considered to be medicines. Similar constraints apply to programs to provide iron supplements to pregnant women, but operational research has overcome many obstacles, and the hope is that the lessons learned can inform the design and implementation of iron supplementation programs for young children.

Food-based strategies, particularly dietary diversification and the promotion of specific food groups for preventing micronutrient malnutrition, are less advanced than other programs. In part, this lack of advancement reflects the diverse nature of the behaviors to be changed and of the available options. Given this diversity and the fact that such strategies are more setting specific than, for example, capsule distribution, the lack of summary estimates of effectiveness is not surprising. Consensus is growing that improving dietary intakes through agricultural innovations and dietary diversification represents long-term answers to micronutrient malnutrition, but progress is slow because of the urgency of alleviating deficiencies in the short term. More research is needed to define the policies that will promote these strategies.

Research over the past decade has articulated a strong case for interventions to prevent zinc deficiency, with supplementation and fortification identified as important approaches. Experiences with zinc supplementation or fortification programs are needed to provide estimates of costs and cost-effectiveness. If the costs of providing zinc supplements to young children are in line with those reported earlier, then such programs would be highly cost-effective, considering the prevalence and burden of disease associated with zinc deficiency.

Child malnutrition results from multiple factors, and even though each context has its own unique features, the etiology has many more commonalities. Thus, for program planners and policy makers intent on alleviating malnutrition to begin designing and implementing programs in their particular settings from scratch is strikingly inefficient. In the past decade, this point has been recognized, and documents that articulate processes for program implementation and evaluation have mushroomed. These "road maps" permit policy makers and program planners to capitalize rapidly on interest in addressing nutrition problems. The road maps also communicate a sense of feasibility by streamlining the complex processes of program design and evaluation. Thus, their use can reduce the likelihood that programs will be diffuse (too many inputs), will be culturally inappropriate, will have unrealistic expectations, and will have no possibility of sustainability and no plans for process or impact evaluation.

Demonstrating that nutrition programs are effective is key to translating scientific findings into policies and programs as well as to ensuring the continuity and expansion of funding.

Despite decades of nutrition programs, with identifiable successes, uncertainty about their effectiveness persists. The value of publishing solid process and outcome evaluations in the scientific literature in addition to project reports has only recently been recognized and cannot be overstated. Whereas outcome evaluations provide data on program effects, process evaluations provide key information to maintain quality assurance and to support the plausibility of key outcomes. Consensus is growing on the need to evaluate a package of services rather than use complex strategies to tease apart the effects of specific program elements. Well-designed programs with process evaluation efficiently provide this information.

Although following standard scientific approaches to establish program effectiveness has enabled progress in many interventions, alternative designs can and should be used for this purpose. Scientists traditionally argue that randomized controlled trials are needed to establish causal evidence of effectiveness and that multiple trials are needed in diverse settings, perhaps followed by pooled or meta-analyses to provide summary estimates. Others argue that designs that provide plausible evidence of program effects or adequate information to support continued funding should be recognized as valid by funders and publishers in refereed journals and should be implemented more broadly (Victora, Habicht, and Bryce 2004).

RESEARCH AND DEVELOPMENT AGENDA

Despite progress, much work remains unfinished. Other chapters focus on research and development needs in relation to packaging services, scaling up, and ensuring sustainability. Here the focus is on research for strengthening the database for policy making.

Gaps in knowledge remain with respect to recognized strategies for intervention programs. Often information on intervention efficacy exists, yet little scientific literature on program effectiveness is available. Key gaps include the following:

- evaluation of the effectiveness of national iron fortification programs to reduce iron deficiency anemia
- implementation and evaluation of the effectiveness of iron supplementation programs for young children
- evaluation of the effect on child mortality of multifaceted programs to reduce child undernutrition
- evaluation of the effectiveness of programs based on the new guiding principles for reducing undernutrition and micronutrient malnutrition in young children
- implementation and evaluation of the effectiveness of food-based strategies to reduce micronutrient malnutrition
- implementation and evaluation of the effectiveness of early postnatal vitamin A supplementation to reduce infant mortality.

Costing studies should accompany the evaluations to allow estimates of cost-effectiveness for decision making.

Because of the logistical difficulties in developing fortification approaches in settings with little industry infrastructure, alternative fortification approaches are needed, such as micronutrient sprinkles or foodlets. In addition, operational research is needed to develop, implement, and evaluate programs to improve zinc status. Never has so much evidence been amassed on the consequences of a deficiency disorder without programmatic application. The challenge now is to develop and implement programs for preventing and treating zinc deficiency and to evaluate their effectiveness for child growth, health, and survival. The International Zinc Nutrition Consultative Group (2004) has laid out a research agenda with these aims in mind.

CONCLUSIONS

Undernutrition is a major cause of death and disability in young children. When ranked among other causes, growth faltering and micronutrient deficiencies figure prominently, both because they are prevalent and because their consequences are devastating. Not included in the numbers, however, are the losses of lifetime productivity associated with early malnutrition and the resources that must be allocated to confront the developmental and morbidity consequences of child malnutrition, which last a lifetime.

Success has been achieved in preventing and controlling iodine deficiency, and palpable progress has been made in the past 20 years in correcting vitamin A deficiency and promoting breastfeeding; however, for iron, articulated goals have not been translated into programs, and the problem has remained the same or worsened. Zinc deficiency is now recognized as an important new challenge.

As shown here, solid evidence shows that nutrition programs can be effective at addressing nutritional problems in young children. Increasingly available cost data, when combined with outcome evaluations, demonstrate that nutritional interventions rank favorably in terms of cost-effectiveness when compared with competing interventions. The case that further investment in nutrition interventions is warranted is thus compelling.

Chapter 29

Health Service Interventions for Cancer Control in Developing Countries

Martin L. Brown, Sue J. Goldie, Gerrit Draisma, Joe Harford,
and Joseph Lipscomb

INTRODUCTION

Cancer imposes a major disease burden worldwide, with considerable geographic variations in incidence; mortality; survival; overall disease burden; causative environmental factors; and mix of prevention, detection, treatment, and palliative programs that make up a country's cancer control strategy. Unless cancer prevention and screening interventions effectively reduce the incidence of cancer, the number of new cancer cases will increase from an estimated 10 million cases in 2000 to 15 million in 2020, 9 million of which would be in developing countries. By 2050, the cancer burden could reach 24 million cases per year worldwide, with 17 million cases occurring in developing countries (Parkin, Bray, and Devesa 2001).

Researchers have made numerous efforts to quantify the global burden of cancer and to estimate site-specific cancer mortality and morbidity (see, for example, Ferlay and others 2004; Parkin, Bray, and Devesa 2001). A recent report from the International Agency for Research on Cancer provides estimates of cancer incidence for Africa by site and country (Parkin and others 2003). In general, however, data on cancer incidence, prevalence, and mortality are less complete and less accurate in developing countries than in developed countries, because the latter have more resources to invest in population-based cancer registries and the infrastructure to maintain such registries.

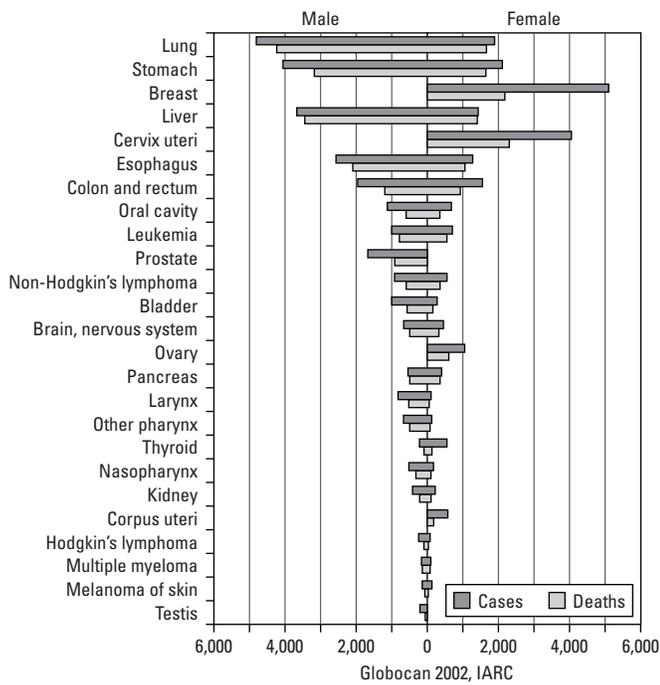

Despite the limitations of current data for developing countries, the epidemiology of cancer in developing countries clearly differs from that in developed countries in some important respects. Developed countries often have relatively high rates of lung, colorectal, breast, and prostate cancer because of the

earlier onset of the tobacco epidemic, the earlier exposure to occupational carcinogens, and the Western diet and lifestyle in such countries. In contrast, up to one-fourth of cancers in developing countries are associated with chronic infections. Liver cancer is often causally associated with infection by the hepatitis B virus (HBV), cervical cancer is associated with infection by certain types of human papillomavirus (HPV), and stomach cancer is associated with *Helicobacter pylori* infection.

This chapter focuses on interventions for controlling seven cancers that impose a particularly heavy burden of disease on developing countries: cervical cancer, liver cancer, stomach cancer, esophageal cancer, lung cancer, colorectal cancer, and breast cancer. In 2000, these seven types of cancer accounted for approximately 60 percent of all newly diagnosed cancer cases and cancer deaths in developing countries (Ferlay and others 2001). Four of the seven cancers—cervical, liver, stomach, and esophageal—have elevated incidence and mortality rates in developing countries. The other three—lung, colorectal, and breast—have lower incidence and mortality rates than the other four cancers, but they nonetheless impose a heavy disease burden and are increasing because of demographic and industrial transitions. Pediatric cancers and HIV-related cancers, two topics that are of great importance and concern, are beyond the scope of this chapter.

BURDEN OF CANCER IN DEVELOPING COUNTRIES

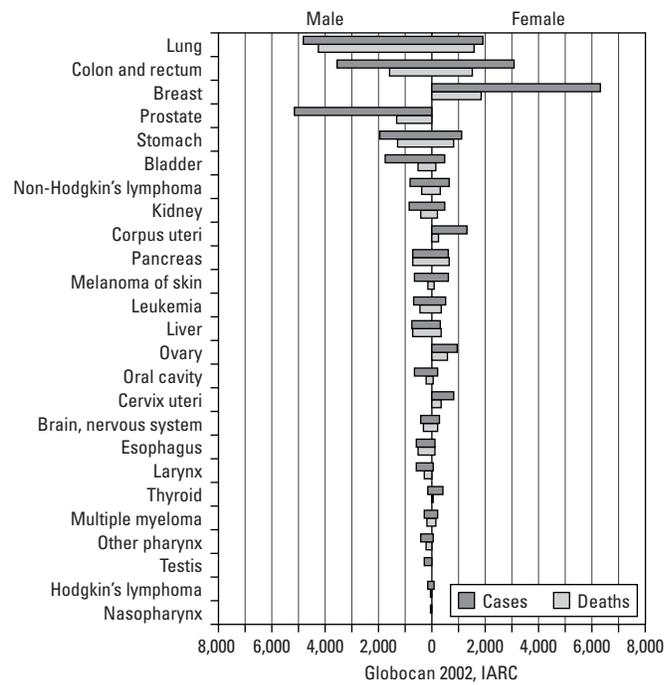

Data from Ferlay and others (2004) clearly illustrate the differing patterns of cancer incidence in developing and developed

Source: Ferlay and others 2004.

Figure 29.1 Estimated Number of Cancer Cases of All Ages, Developing Regions, 2002 (hundreds)

countries (figures 29.1 and 29.2). In developing countries, the top five female cancers in rank order of incidence are breast, cervical, stomach, lung, and colorectal cancer; however, cervical cancer still accounts for more deaths than breast cancer in developing countries. The top five male cancers are lung, stomach, liver, esophageal, and colorectal cancer (figure 29.1). The incidence of cancers of the lung and breast is relatively high in both developed and developing countries. Colorectal cancer accounts for a smaller share of the burden in developing countries than in developed countries, but cancer of the stomach accounts for a higher share. Some cancers that are more common in developing than in developed countries, including stomach, liver, and cervical cancer, are related to the absence of a well-developed public health infrastructure for the control of cancer-causing infectious agents and contaminants, the lack of basic preventive health care and screening services for much of the population, and the poor-quality diets available to the most economically disadvantaged members of society in many developing countries. Cancer of the esophagus, also relatively common in developing countries, may reflect, in part, the consumption of traditional beverages at extremely high temperatures. Some cancers that are increasingly common in developing countries, including lung, breast, and colorectal cancer, may reflect the increasing Westernization of lifestyles, longer life expectancy, and globalization of markets for tobacco products.

Figure 29.2 Number of Cancer Cases of All Ages, Developed Regions, 2002 (hundreds)

For some cancers, including esophageal, liver, lung, and pancreatic cancer, survival rates vary little between developing and developed countries (Sankaranarayanan, Black, and Parkin 1998). Currently available methods of early detection and treatment have not been demonstrated to be effective for these cancers, so primary prevention remains the most practical intervention for control. For a second group of cancers, including large bowel, breast, ovarian, and cervical cancer, proven methods of early detection, diagnosis, and treatment are available that can, in principle, be delivered through district health care facilities. For these cancers, survival rates vary both between developing and developed countries as a whole and between specific countries within each of these groups. For a third group of cancers, including testicular cancer, leukemia, and lymphoma, the variability in survival between developing and developed countries is tremendous. Even though relatively effective treatments are available for these cancers, they are multimodal treatments that require a relatively high level of medical resources, a good health care infrastructure, and a level of sophisticated knowledge, which low- and middle-income developing countries may not have.

Table 29.1 shows estimated cancer deaths and the estimated disease burden in terms of disability-adjusted life years (DALYs) lost as a result of various types of cancers in developing and developed countries and by region in 2001. As the table

Note: For an explanation of how DALYs are computed, see chapter 15 of this volume.

shows, the seven types of cancer that are the focus of this chapter account for seven of the first eight cancer sites ranked by number of deaths in developing countries. Considerable heterogeneity in the pattern of cancer burden across the six regions is apparent, and additional heterogeneity is apparent within these regions. Deaths from liver cancer are relatively high in East Asia and the Pacific and in Sub-Saharan Africa, probably because of the high prevalence of chronic HBV infection and the lack of adequate resources for food storage and preservation in those regions (Parkin and others 2003). The number of deaths from colorectal and breast cancer, as a proportion of all cancer deaths, is relatively high in Europe and Central Asia and in Latin America and the Caribbean, probably because those regions have increasingly adopted more Western lifestyle patterns of reproductive behavior, diet, and physical activity. The number of deaths from oral cancer is particularly high in South Asia, where the use of betel quid is common.

TYPES OF INTERVENTIONS FOR CANCER CONTROL

The World Health Organization (WHO) emphasizes that, when developing national strategies for controlling cancer, countries should consider the following four broad approaches (WHO 2002):

- *Primary prevention.* The goal of primary prevention is to reduce or eliminate exposure to cancer-causing factors, which include environmental carcinogens and lifestyle factors related to nutrition and physical activity. For the seven cancers considered here, approaches to primary prevention include immunization against, or treatment of, infectious agents that cause certain cancers; use of tobacco control programs; reduction of excessive alcohol consumption; dietary intervention; and pharmacological intervention.
- *Early detection and secondary prevention.* The main objective of early detection or secondary prevention through population-based screening programs is detection at a stage at which curative treatment is possible. Interventions for the early detection of cancer can help reduce mortality from cancer only if they are part of a wider cancer control strategy that includes effective diagnostic follow-up procedures and treatment (Anderson and others 2003). For cervical, colorectal, and breast cancer, effective methods of early detection and treatment are available, but their implementation has been uneven (Sankaranarayanan, Black, and Parkin 1998).
- *Diagnosis and treatment.* The primary modalities of cancer treatment are surgery, chemotherapy, and radiotherapy, and these modalities may be used alone or in combination.

There is increasing emphasis worldwide on the development of specialized cancer centers that apply evidence-based multimodal therapies, including rehabilitation and palliative care.

- *Palliative care.* The scope of palliative care has been expanded in recent years to encompass the alleviation of symptoms and treatment during all phases of disease—from diagnosis to death—and to address matters related to the psychological and quality-of-life aspects of disease, as well as the physiological aspects. Furthermore, palliative care has been expanded to include consideration for the well-being of the patient's family members as well as for the patient (Singer and Bowman 2002).

The discussion in this chapter focuses primarily on health service interventions for controlling the seven cancers that are the subject of this chapter. Other chapters deal with broad public health interventions involving the control of occupational and environmental exposures; health education; policy interventions such as regulation, labeling, and taxation related to tobacco consumption; diet; and physical activity.

COST-EFFECTIVENESS OF CANCER CONTROL INTERVENTIONS

There is a growing literature on the cost-effectiveness of interventions within each of the four categories above. In this section, we review published studies of the cost-effectiveness of health services-based cancer control interventions, and we present new analyses of the cost-effectiveness of screening interventions for cervical and breast cancer.

Primary Prevention

This subsection reviews studies of the effectiveness and cost-effectiveness of several interventions for the primary prevention of cancer.

Immunization against—or Treatment of—Infectious Agents That Cause Certain Cancers.

Infectious agents are causally associated with three of the seven cancers that are the focus of this chapter—liver cancer (HBV), cervical cancer (HPV infection), and stomach cancer (*H. pylori* infection)—so eliminating these agents through immunization or other means offers hope for preventing such cancers.

The HBV vaccine was designed to prevent liver cancer and is currently the only such vaccine in widespread use. Long-term protection against acute and chronic infection has been demonstrated with the HBV vaccine in a wide range of settings (Coursaget and others 1994; Viviani and others 1999), and recent data support a reduction in hepatocellular carcinoma (Lee, Hsieh, and Ko 2003).

Infection with specific high-risk types of HPV plays a key role in causing cervical cancer. A double-blind placebo-controlled trial of an HPV 16 vaccine reported encouraging efficacy results in young female volunteers who had been fully vaccinated (three doses of vaccine or placebo) over a 1.7-year follow-up period (Koutsky and others 2002). In a more recent study, a bivalent HPV 16/18 vaccine prevented approximately 95 percent of persistent infections with HPV 16 and 18 (Harper and others 2004).

Several modeling studies have explored the potential benefits of HPV vaccination at the population level (Goldie and others 2003; Hughes, Garnett, and Koutsky 2002; Kulasingam and Myers 2003) and have elucidated several priorities for future research, including a better understanding of the heterogeneity of vaccine response and the effects of type-specific vaccination on other HPV types.

Hughes, Garnett, and Koutsky (2002) evaluate the potential effectiveness of HPV vaccination using a dynamic transmission model and find that, when both men and women were vaccinated—assuming 90 percent coverage, 75 percent effectiveness, and 10-year immunity—type-specific HPV prevalence was reduced by 44 percent. When only women were vaccinated, the reduction was 30 percent. The authors show that, if the vaccine targeted only certain types of high-risk HPV, cervical cancer incidence was not reduced proportionally because other high-risk types of HPV progressed to invasive cancer.

Goldie and others (2003) assess the impact of a type-specific HPV 16/18 vaccine calibrated to population-based data for Costa Rica. They find that a vaccine that prevented 98 percent of persistent HPV 16/18 was associated with an approximate equivalent reduction in HPV 16/18-associated cancer and a 51 percent reduction in total cervical cancer. The effect on total cancer was attenuated because of the competing risks associated with oncogenic types of HPV other than HPV 16/18.

Three studies have evaluated the potential cost-effectiveness of HPV vaccination in countries with cervical cancer screening programs (Goldie, Kohli, and others 2004; Kulasingam and Myers 2003; Sanders and Taira 2003). In general, these studies indicate that a program of HPV vaccination that permits a later age of screening initiation and a less frequent screening interval is likely to be a cost-effective use of health care resources in developed countries.

In Fujian province, China, a region of high mortality attributable to stomach cancer, a recently completed randomized controlled trial of *H. pylori* eradication with antibiotics provides some evidence that this approach may be effective in preventing stomach cancer in the subgroup of *H. pylori* carriers without precancerous lesions at the time of treatment (Wong and others 2004). A recent randomized trial of *H. pylori* eradication in Chiapas, Mexico, which used preneoplastic conditions as surrogate markers for the development of gastric cancer, found some evidence for the effectiveness of this treatment (Ley and others 2004).

Several studies, most of them in developed countries, have assessed the potential cost-effectiveness of screening individuals for infection with *H. pylori* and then eradicating *H. pylori* with antibiotic therapy as a means of preventing the later occurrence of stomach cancer. Roderick and others (2003) examine the cost-effectiveness of an *H. pylori* screening program conducted in the United Kingdom. Discounting costs and benefits at 6 percent, they find that the cost-effectiveness ratio for screening for *H. pylori*, initiated at age 40, is approximately US\$28,000 per year of life saved (YLS). Optimal cost-effectiveness was not achieved until the *H. pylori* screening program had run for at least 40 years. Harris and others (1999) estimate the cost-effectiveness ratio associated with one-time screening for *H. pylori* at age 50 to be approximately US\$50,000 per YLS (in 1995 dollars, 3 percent discount rate) when treatment for *H. pylori* infection results in a 15 percent reduction in stomach cancer risk. Assuming a 30 percent reduction, the figure was US\$25,000 per YLS for the United States, but only a few hundred dollars per YLS in Colombia, which has a much higher rate of stomach cancer and lower health care costs.

Tobacco and Alcohol Control Programs. Tobacco consumption is the most important cause of lung and other cancers of the respiratory system, as well as of esophageal cancer, and may be a contributing factor for several other cancers. The most effective national tobacco control programs combine health promotion, education, and health service interventions with policies. Policy instruments include regulating tobacco advertising and promotion; enacting smoking bans in workplaces, restaurants, and public buildings and on public transportation; and increasing excise taxes on tobacco products (Fiore, Hatsukami, and Baker 2002; WHO 2002). Decreased rates of smoking uptake by children and adolescents would result in the greatest potential gain in life years. The WHO Framework Convention on Tobacco Control (WHO 2003b) summarizes tobacco control policies and programs related to regulation, taxation, and education. Da Costa e Silva (2003) shows prioritized treatment approaches for tobacco cessation, based on countries' levels of resources.

Excessive alcohol use accounts for 20 to 30 percent of liver and esophageal cancer (WHO 2001b). Interventions to reduce excessive consumption of alcohol have many principles in common with tobacco control, including the effectiveness of regulatory and taxation measures along with health promotion and addiction treatment programs.

Dietary and Related Interventions. The dietary ingestion of substances produced by the mold *Aspergillus flavus*, specifically aflatoxin B1, is causally associated with hepatocellular carcinoma. Exposure to aflatoxins may be synergistic with HBV

infection in the development of this cancer. Effective means are available for preventing the contamination of grains and other types of food with aflatoxin during the growth, harvest, storage, and processing of such products (Kensler and others 2003; Turner and others 2002). Furthermore, chlorophyllin supplements have been found to reduce the carcinogenic properties of aflatoxin. That finding provides additional evidence for current dietary guidelines that meals should contain foods rich in chlorophylls—for example, spinach and other green, leafy vegetables (Kensler and others 2003).

Among those infected with *H. pylori*, diet is thought to play a critical role in the progression of superficial gastritis to chronic atrophic gastritis. Prolonged consumption of foods rich in salted, pickled, and smoked products increases the risk of stomach cancer, and increased consumption of fresh fruit and vegetables likely decreases the risk. Obesity is also a well-established risk factor for several cancers (Vainio and Bianchini 2002b). For that reason, WHO recommends that governments seeking to ensure compliance with nutritional objectives conduct appropriate school and public education campaigns on diet and work with the food and agriculture sectors (WHO 2002).

Pharmacological Interventions. *Chemoprevention* is defined as the reduction of the risk of cancer development through the use of micronutrients or pharmaceuticals. Clinical trials among high-risk individuals to establish the efficacy of chemoprevention via micronutrients (for instance, carotenoids and retinoids) and dietary fiber have been mainly negative (Alberts and others 2000; ATBC 1994; Omenn and others 1996; Schatzkin and others 2000). However, several ongoing clinical studies are examining the potential cancer preventive effects of calcium, vitamin D, folic acid, selenium, and vitamin E (Christensen 2004).

Both case-control and cohort studies show a reduced risk for colorectal cancer after prolonged use of aspirin (Vainio and Morgan 1999). Additional evidence indicates that aspirin has a preventive effect on several other types of cancer, including hormone receptor–positive breast cancer (Terry and others 2004), but questions remain about the balance between the clinical benefits and adverse side effects of long-term aspirin therapy, including gastrointestinal bleeding and hemorrhagic stroke (Imperiale 2003).

Some evidence suggests that the antiestrogen drug tamoxifen may reduce the risk of breast cancer (Gail and others 1999), but there is also conflicting evidence (Powles and others 1998; Veronesi and others 1998). The potential for primary prevention using other selective estrogen receptor modulators is a topic of current clinical research (Lippman, Lee, and Sabichi 1998). Preliminary analyses indicate that the use of tamoxifen to prevent breast cancer could be cost-effective in the United States (T. Smith and Hillner 2000).

Early Detection and Secondary Prevention

This subsection looks at studies of the effectiveness and cost-effectiveness of several interventions for the early detection and secondary prevention of cancer.

Screening for Liver Cancer. Screening methods for early detection of liver cancer include serum assays for alpha-fetoprotein and, potentially, ultrasound. A recently completed randomized controlled trial of liver cancer screening in China evaluated the use of two or six alpha-fetoprotein assays over a period of four years among men age 30 to 69 with chronic HBV (Chen and others 2003). Screening resulted in earlier diagnosis of liver cancer, but because treatment for established liver cancer is largely ineffective, screening did not reduce overall mortality.

Randomized trials that include ultrasound screening for liver cancer and that incorporate recent advances in antiviral preventive treatment have yet to be conducted. Sarasin, Giostra, and Hadengue's (1996) model-based cost-effectiveness analysis explores whether biannual screening of patients with Child-Pugh class A cirrhosis, under a set of assumptions systematically favorable to screening, would be cost-effective. The authors conclude that, even under best-case conditions, screening for liver cancer is not likely to be cost-effective.

Screening for Stomach Cancer. Mass screening programs for the early detection of invasive stomach cancer using radiological or endoscopic techniques have been widely implemented in Japan, where incidence rates of stomach cancer are high.

Babazono and Hillman (1995) compare the cost-effectiveness of three methods for the early detection of stomach cancer in the context of mass screening programs in Japan: indirect radiology (barium meal plus photofluoroscopy), direct radiology, and endoscopy. When screening for stomach cancer was started late in life, indirect radiology was the most cost-effective screening method. This analysis supports an increase in the recommended age for initiating screening for stomach cancer from age 40 to 50.

Screening for Lung Cancer. Investigators have carried out several cost-effectiveness analyses of the screening of high-risk individuals, such as current and former smokers, for lung cancer using helical computed tomography (Chirikos and others 2002; Mahadevia and others 2003; Marshall and others 2001). The results of these studies vary widely from quite favorable (US\$19,000 per YLS) to extremely unfavorable (more than US\$100,000 per YLS). The main reason for the wide variation in these studies is different assumptions about the clinical nature of early lung lesions detected by helical computed tomography—specifically, whether a large proportion of these

Table 29.2 Estimates of the Cost-Effectiveness of Colorectal Cancer Screening Interventions, United States (cost-effectiveness ratios expressed as 2000 US\$/YLS)

Colorectal screening test	Wagner and others 1996	Frazier and others 2000	Khandker and others 2000	Sonnenberg, Delco, and Inadomi 2000	Vijan and others 2001

small lung nodules represents “pseudo-disease” that will never progress to clinical lung cancer (Marcus and others 2000). The National Lung Cancer Screening Trial, currently under way (van Meerbeeck and Tournoy 2004), hopes to answer this question. Until results from the trial are available, no definitive statement can be made about the effectiveness or cost-effectiveness of lung cancer screening.

Screening for Colorectal Cancer. Screening methods for early detection of colorectal cancer include fecal occult blood testing, sigmoidoscopy, barium enema, and colonoscopy. Several studies of the cost-effectiveness of colorectal cancer screening in developed countries have been published (Pignone and others 2002). Table 29.2 presents estimates of the cost-effectiveness of colorectal cancer screening in the United States. Cost-effectiveness ratios for various modalities of colorectal cancer screening range from almost US\$6,000 to about US\$40,000 per YLS. Using models closely linked to European trials of biennial fecal occult blood testing to screen for colorectal cancer, Whynes and Nottingham Faecal Occult Blood Screening Trial (2004) report favorable cost-effectiveness ratios ranging from US\$2,500 to US\$4,000 per YLS. Studies of the cost-effectiveness of colorectal cancer screening in developed countries consistently conclude that such screening is cost-effective, but they do not totally agree on the relative rankings of different colorectal screening strategies (Pignone and others 2002).

Screening for Cervical Cancer. Cytology-based screening using the Papanicolaou smear has been the main screening method used for the secondary prevention of cervical cancer worldwide. In many low-income countries, however, cytology screening has proved difficult to sustain because of its reliance on highly trained cytotechnologists; good-quality laboratories; and infrastructure to support up to three visits for screening, evaluation of cytologic abnormalities with colposcopy, and treatment (Sankaranarayanan, Budukh, and Rajkumar 2001). Two alternative screening approaches replace the Pap smear

with simple visual screening methods, such as visual inspection after application of an acetic acid solution (VIA), or with HPV DNA testing (Denny and others 2000; Sankaranarayanan and others 1999; Schiffman and others 2000; Wright 2003; Wright and others 2000; Zimbabwe Project 1999). These newer options also eliminate colposcopy, potentially allowing screening and treatment to be performed during the same visit. In middle-income countries where cytology screening is available but cervical cancer mortality has not been reduced, key questions center around improving the quality of cytology-based programs; such improvement includes having adequate colposcopy and biopsy facilities and accessible treatment (Lazcano-Ponce and others 1999); making use of HPV DNA testing technology in a cost-effective manner; and targeting the appropriate age group for cervical cancer screening more accurately. The vast majority of published cost-effectiveness analyses of population-based cervical cancer screening performed during 1980–2003 focused on high-income countries. (A list of the 39 studies reviewed is available from the authors.) The detailed results of each study are somewhat difficult to compare. The types of costs included in each study varied substantially (patient time costs and programmatic costs often were omitted), studies frequently did not discount costs and benefits or did not note the discount rate used, and sensitivity analyses were not conducted consistently on all relevant variables. Despite those limitations, several themes emerge. The incremental cost-effectiveness of screening in the general population becomes increasingly less favorable as programs are intensified by shortening the screening interval. For example, Mandelblatt and others (2002) reported that for conventional cytology and HPV testing, compared with cytology alone, the incremental cost was more than US\$300,000 when conducted annually compared to US\$15,400 per YLS when conducted every 10 years. Maxwell and others (2002) reported that liquid-based cytology and HPV testing for equivocal results cost US\$231,300 per YLS if conducted annually incremental to 14,300 per YLS if conducted every three years. Kim, Wright,

and Goldie (2002) reported similar results for this same strategy (US\$20,300 per YLS conducted every five years, US\$59,600 per YLS every three years, and US\$174,200 every two years). The analyses, which included strategies that employed both frequent screening and screening tests with higher sensitivity, often found the cost-effectiveness of frequent screening to be even less attractive. For example, Goldie, Kim, and Wright (2004) reported annual screening with combined cytology and HPV DNA testing in women over age 30 exceeded US\$1 million per YLS compared to every two years. Although many analyses find that extending the age range to the very young, the very old, or both can be less cost-effective, for certain women in high-risk groups, including older, uninsured women who have never been screened, screening for cervical cancer at older ages can be cost-effective.

The analyses conducted in low-income countries focused on assessing the cost-effectiveness of an expanded set of strategies that included alternatives to conventional cytology. In addition, these analyses—unlike those in developed regions—often raised issues of feasibility, affordability, cultural context, accessibility, and equity.

In one of the earliest stochastic modeling evaluations of cervical cancer screening programs in developing regions, Sherlaw-Johnson, Gallivan, and Jenkins (1997) explored the effectiveness of cytology and HPV testing in the context of infrequent screening. They reported that the most efficient use of resources would be to concentrate cervical cancer screening efforts on women age 30 to 59 at least once per lifetime, because such blanket screening would reduce the incidence of invasive cervical cancer by up to 30 percent.

In an analysis focused on cervical cancer control in Vietnam, Suba and others (2001) reported that, because of the low direct medical costs associated with Vietnam's cervical cytology program, such a program appeared to be attractive for that country. They found that total costs to establish a nationwide Pap screening program based on five-year intervals averaged less than US\$148,000 annually during the 10 years the authors assumed would be necessary to develop the program. Assuming 70 percent participation in the program, the authors found the cost-effectiveness ratio for cervical cytology screening, compared with no screening, to be US\$725 per discounted YLS.

Goldie and others (2001) assessed the cost-effectiveness of several cervical cancer screening strategies in previously unscreened 30-year-old South African women. Screening tests included VIA, cytology, and HPV DNA testing. Strategies differed by the number of clinic visits required, frequency of screening and individual's age at the time of screening, and response to a positive test result. The authors found that when all strategies were considered to be equally available and were compared incrementally, HPV DNA testing was always more effective and less costly than cytology and generally more effective

but more costly than VIA. They found that, in comparison with no screening, a single lifetime VIA screen at age 35, coupled with immediate treatment of women with positive results, resulted in a cost saving of US\$39 per YLS as compared with a two-visit HPV, although programmatic costs were not considered. Using sensitivity analysis, the authors find the choice between using HPV DNA testing or VIA depended on the relative costs and sensitivity of the two tests and on the percentage of women lost to follow-up between the first and second visit.

Mandelblatt, Lawrence, Gaffikin, and others (2002) used a simulation model to compare seven cervical cancer screening techniques in Thailand. Comparing each strategy to the next less expensive alternative, the authors found that VIA performed at five-year intervals in women age 35 to 55, followed by immediate treatment of abnormalities, was the least expensive option and saved the greatest number of lives.

The Alliance for Cervical Cancer Prevention used primary data from studies conducted in India, Kenya, Peru, South Africa, and Thailand to develop a series of standardized, country-specific cost-effectiveness analyses. The costs and benefits associated with alternative strategies to reduce cervical cancer mortality were estimated for these five countries with different epidemiological profiles by integrating country-specific data from each site and using a standardized set of assumptions agreed on by an expert panel with experience in each country (Goldie, Gaffikin, and others 2004). In all five countries, lifetime cancer risk was reduced by approximately 25 to 35 percent with a single lifetime screen using either one-visit VIA or two-visit HPV DNA testing targeted at women age 35 to 40. Risk was reduced by more than 50 percent if screening was performed two or three times per lifetime. Although the cost of screening differed considerably between the countries, strategies were identified that, when performed two or three times per lifetime, would be considered extremely cost-effective depending on the individual country's per capita gross domestic product.

We conducted an exploratory analysis to evaluate the potential cost-effectiveness of cervical cancer screening strategies in Brazil, Madagascar, and Zimbabwe using computer-based simulation models calibrated to age-specific cervical cancer incidence and mortality in each country, along with published data. We evaluated once-in-a-lifetime screening between age 35 and 40 with (a) one-visit VIA, with screening and treatment conducted during the same visit; (b) two-visit HPV DNA screening, with HPV DNA testing during the first visit followed by treatment of screen-positive women during the second visit; and (c) three-visit cervical cytology screening, with a cytology sample obtained during the first visit, colposcopy for screen-positive women conducted during the second visit, and treatment provided during the third visit. We assumed that for the one- and two-visit strategies, women who screened positive and were eligible for cryotherapy were treated immediately, but

those ineligible for cryotherapy were referred for colposcopy and diagnostic workup.

We estimated direct medical costs using data from the literature and unit costs provided by the volume editors and WHO. All costs for the analysis are presented in 2000 dollars. We estimated patients' time costs and direct nonmedical costs using our own previous work and wage estimates based on World Bank data on per capita gross national income (WHO n.d.) and wage estimate regressions developed by the U.S. Department of Commerce. Table 29.3 presents the results of our analysis.

Lifetime costs per individual screened are given in international dollars. Cost-effectiveness ratios are provided in U.S. dollars as well as international dollars to facilitate comparison to other studies. The available data show that cervical cancer screening conducted once, twice, or three times in a lifetime can have a significant effect on the lifetime risk of cervical cancer compared with no screening. For countries with limited resources, screening efforts should target women age 35 or older; strategies should focus on screening all women at least once in their lifetime before increasing the frequency of screening; and countries should consider alternative approaches to the conventional three-visit cervical cytology screening techniques—for example, single-visit

VIA, followed by immediate treatment, or HPV DNA testing or cervical cytology followed by treatment at a second visit. Note that all screening tests may not be equally available in low-resource settings and that certain screening tests may be selected because of cultural preferences or for programmatic reasons. Implementing cervical cancer screening programs on the basis of VIA, HPV DNA testing, or cytology requires different types of resources, and the relative availability of these resources in different settings will affect the choice of strategy.

Screening for Breast Cancer. Methods for early detection of breast cancer include screening by mammography, clinical breast examination (CBE), and breast self-examination. Screening by mammography, CBE, or both may decrease breast cancer mortality, but uncertainty about the magnitude of the benefit remains because the quality of the evidence varies and results are inconsistent (Humphrey and others 2002). Recent controlled studies of organized breast self-examination programs indicate that this approach is not effective (Semiglazov and others 1999; Thomas and others 2002).

A randomized controlled trial of CBE screening for breast cancer began in Manila in 1995, but the intervention was

discontinued after the first round because compliance with referral among women who were found to have a breast lump was extremely low (21 percent) and attempts to improve compliance failed. Analysis of the incidence of cancer cases in 1999 shows that the screening intervention succeeded in detecting more localized breast tumors, but the low compliance with referral and low yield of early cancers meant that the early detection program could not succeed in preventing deaths from breast cancer (International Agency for Research on Cancer n.d.).

Numerous cost-effectiveness studies of breast cancer screening programs have been conducted in developed countries (Vainio and Bianchini 2002a). Most cost-effectiveness studies of mammography screening in Europe yield cost-effectiveness ratios in the range of US\$3,000 to US\$10,000 per YLS, whereas those in the United States yield far less favorable cost-effectiveness ratios, ranging from US\$20,000 to US\$100,000 per YLS (table 29.4).

To investigate the potential cost-effectiveness of CBE and mammography for India, we used a microsimulation model of breast cancer screening (van Oortmarssen and others 1990). The model simulates individual life histories of disease states, and consequences of screening are calculated by comparing the histories with and without screening intervention for each individual. For our purposes, we assumed a population of 1 million Indian women with the age distribution of the country

in 2000 (United Nations Population Division 2003). We assumed that the screening program would last for 25 years and would have an attendance rate of 100 percent. We expressed the effects of screening as the reduction in the number of deaths caused by breast cancer and the number of life years gained because of the screening program. Costs and effects were discounted at a rate of 3 percent.

We estimated the model's parameters using data from Dutch screening projects (Collette and others 1992; Vervoort and others 2004). We used trial results to estimate the effectiveness of mammography in reducing breast cancer mortality (de Koning and others 1995). We based sensitivity estimates of CBE on data from Rijnsburger and others (2004) and based alternative (lower) estimates on data from Bobo, Lee, and Thames (2000) and Rijnsburger and others (forthcoming). We calibrated the model so that it would correctly predict the age-specific incidence and mortality of breast cancer in India (Ferlay and others 2001) and its stage distribution at clinical diagnosis (Sankaranarayanan, Black, and Parkin 1998). Details of these methods are available elsewhere (Lamberts and others 2004).

We calculated total costs by comparing the differential costs of breast cancer screening, diagnosis, initial therapy, adjuvant therapy, follow-up, and advanced disease in the case of screening versus no screening. We calculated component costs by multiplying the estimated resource use by the estimated costs per unit for each health care input. Reliable cost data for India were limited, so we extrapolated estimates from Dutch unit costs (Mulligan and others 2003). For the analysis discussed above, we calculated costs based on a market-basket approach.

The overall incidence of breast cancer is lower in India than in Western countries. The relationship between the incidence of breast cancer and age also differs: in Western countries, the incidence of breast cancer increases with age, whereas in India, it decreases with age, beginning at age 50. Investigators have generally attributed this finding to a cohort effect: breast cancer is more common among younger cohorts than older cohorts. The stage at which breast cancer is diagnosed is much less favorable in India than in Western countries.

Table 29.5 presents the results of our exploratory cost-effectiveness analysis of various breast cancer screening programs involving CBE or mammography for a population of 1 million women in India. As the table shows, biennial CBE from age 40 to 60 costs US\$2.6 million, averts 358 breast cancer deaths, prevents the loss of 4,896 life years, and has a cost-effectiveness ratio of US\$522 per YLS in comparison with no screening. Biennial CBE from age 50 to 70 is less favorable in terms of cost-effectiveness: US\$582 per YLS.

The cost-effectiveness ratios for biennial mammography screening are not as favorable as those for biennial CBE screening. Annual CBE screening results in almost the same number of life years saved as biennial mammography screening at 36 percent of the cost.

Table 29.4 Estimates of the Cost-Effectiveness of Breast Cancer Screening Every Two Years for Women in Selected Developed Countries

Country	Age of women being screened (years)	Cost-effectiveness ratio (US\$/YLS) ^a
Australia (de Koning 2000)	50–69	7,680

Table 29.6 shows the results of our sensitivity analysis for the exploratory cost-effectiveness analysis of breast cancer screening in India. Cost-effectiveness ratios are lower when the incidence of cancer is higher, as in Bombay. Cost-effectiveness ratios are 32 and 16 percent higher, respectively, with a lower sensitivity of CBE and when the averted costs of palliative treatment are not included. Using alternative approaches to estimate screening program costs has a major effect, resulting in cost-effectiveness estimates 6 to 11 times higher than the base case analysis. This result underlines the need for economic studies that can obtain reliable data from primary sources on the true resource costs of cancer control interventions in developing countries. With data from such studies, researchers would not have to continue to rely on extrapolating cost estimates from data in developed countries.

These results depend critically on assumptions about the efficacy of CBE, for which the evidence is limited, highlighting the need for controlled studies of CBE in developing countries. Our estimates indicate that the cost-effectiveness of screening mammography in India compares favorably, in absolute terms, with breast cancer screening in developed countries. Nevertheless, screening mammography for breast cancer is likely to be less cost-effective in a country such as India than is screening for cervical cancer.

Cancer Treatment and Palliative Care

Barnum and Greenberg (1993) used an indirect approach to estimate the cost-effectiveness of initial cancer treatment in developing countries. They assumed that they could estimate the effectiveness of initial cancer treatment by comparing cancer survival in the United States for the period 1975–80 with the period 1940–45. The logic of such a comparison is that major advances in cancer diagnosis, surgery, radiation, and chemotherapy occurred during the intervening period, and thus survival in the 1940–45 period could be equated to outcomes expected to result from no treatment or ineffective treatment. Barnum and Greenberg's results indicated a cost-effectiveness ratio of the following:

- US\$1,300 to US\$6,200 per YLS for initial treatment of the more treatable cancers, that is, cervical, breast, oral cavity, and colorectal cancer
- US\$53,000 to US\$163,000 per YLS for initial treatment of the less treatable cancers, that is, liver, lung, stomach, and esophageal cancer.

The following subsections review cost-effectiveness studies performed on selected adjuvant or palliative cancer treatments that have been studied extensively in controlled clinical trials.

Breast Cancer Treatment Interventions. The following paragraphs review studies of the cost-effectiveness of adjuvant systemic therapy for early-stage breast cancer and of radiation therapy following mastectomy and chemotherapy to treat node-positive breast cancer in premenopausal women.

T. Smith and Hillner (2000), relying on results from the Early Breast Cancer Trialists' Collaborative Group (EBCTCG 1998), modeled the natural history of breast cancer in premenopausal 45-year-old women in the United States who were diagnosed with early-stage breast cancer and treated with tamoxifen, chemotherapy, or both. Table 29.7 summarizes the

cost-effectiveness of various breast cancer treatments. Smith and Hillner's cost-effectiveness estimates for single-modality systemic adjuvant therapy for breast cancer are about the same order of magnitude as Barnum and Greenberg's (1993) estimates of cost-effectiveness for initial therapy of breast cancer (about US\$7,300 per YLS in 2000 dollars). Other studies (Malin and others 2002; Norum 2000) have yielded cost-effectiveness estimates for chemotherapy and hormonal therapy two to three times more favorable than Smith and Hillner's estimates. The more favorable estimates are probably the result of the investigators' use of a discount rate of 3 percent instead

of 5 percent and their assumption that the benefits of treatment continue over a longer period of time.

Two U.S. studies (Lee and others 2002; Marks and others 1999) have estimated the cost-effectiveness ratio for radiation therapy following mastectomy and chemotherapy for node-positive breast cancer in premenopausal women to be in the range of US\$22,600 to US\$43,000 per quality-adjusted life year (adjusted to 2000 U.S. dollars, with a discount rate of 3 percent). Results were sensitive to treatment costs, survival benefit, and patient time costs.

The clinical trials of postmastectomy radiation on which the two U.S. studies are based compared radiation following surgery plus chemotherapy with surgery plus chemotherapy alone. Love and others (2003), however, offer observational evidence that radiation treatment may also extend survival for Chinese and Vietnamese women when administered to patients with one to three positive nodes following mastectomy alone or mastectomy combined with oophorectomy and tamoxifen. If these benefits were confirmed, postmastectomy radiation might be cost-effective in developing countries, where the cost of radiation treatment is lower than in most developed countries.

Colorectal Cancer Treatment Interventions. As concerns colorectal cancer, investigators have carried out cost-effectiveness studies on surgical techniques, adjuvant treatment, follow-up monitoring for recurrence, and treatment of advanced disease (van den Hout and others 2002). Brown, Nayfield, and Shibley (1994) estimate that the cost-effectiveness of adjuvant chemotherapy for stage three colon cancer ranges from US\$3,000 to US\$7,000 per YLS (adjusted to 2000 U.S. dollars, with a discount rate of 6 percent). R. Smith and others' (1993) study conducted in the Australian health care setting obtains similar results in terms of cost per YLS but yields substantially higher costs per quality-adjusted life year.

Dahlberg and others' (2002) cost-effectiveness study, which relies on cost and clinical outcome data from the Swedish Rectal Cancer Trial (1997), demonstrates that rectal cancer patients receiving preoperative radiation therapy had improved cancer-specific and overall survival rates, as well as reduced local rectal cancer recurrence rates. They estimate the overall cost-effectiveness of preoperative radiation therapy for rectal cancer patients to be US\$3,654 per YLS (in 2001 U.S. dollars, using a discount rate of 3 percent). In a sensitivity analysis, which varied the rates of local rectal cancer recurrence and the survival advantage with and without radiation treatment, cost-effectiveness ratios for preoperative radiation therapy for patients with rectal cancer ranged from US\$908 to US\$15,228 per YLS.

Cervical Cancer Treatment Interventions. Five recent phase 3 trials indicate that a new alternative therapy—cisplatin-based

chemoradiation—is more effective than standard therapy using radiation alone in the treatment of advanced cervical cancer (Rose and Lappas 2000). Using an economic model, Rose and Lappas apply unit costs to resource allocation data derived from the cisplatin-based chemoradiation arms of the five randomized trials and examine the benefits in terms of increased median survival time. Costs per YLS for cisplatin-based chemoradiation regimens varied from US\$2,384 to US\$28,770 on the basis of published survival and from US\$308 to US\$3,712 on the basis of estimated survival. Although chemoradiation for advanced cervical cancer would probably be considered cost-effective in most developed countries, analyses that take local treatment settings into account are needed to determine if this result also holds for developing countries.

Palliative Care Interventions. The most basic approach to palliative care for terminally ill cancer patients, especially in low-resource settings, involves using inexpensive oral analgesics, ranging from aspirin to opiates, depending on individual patients' needs. Unfortunately, sufficient supplies of opioid drugs for use in palliative care are often not available in developing countries because of regulatory or pricing obstacles, ignorance, or false beliefs (for more information see <http://www.medsch.wisc.edu/painpolicy/index.htm> and chapter 52).

Appropriate palliative care for cancer patients may involve a variety of other treatment modalities, including antiemetic drugs to relieve the side effects of chemotherapy, radiation to effect temporary tumor regression, and physical therapy to alleviate disability related to lymphedema following breast cancer surgery. Berthelot and others' (2000) study combines information from several clinical trials and Canadian treatment cost information to perform cost-effectiveness analyses of different ambulatory chemotherapy regimens used for patients with metastatic non-small-cell lung cancer to palliate symptoms and modestly improve survival. They report that vinblastine plus cisplatin resulted in both better survival and lower health care expenditures than best supportive care because it resulted in fewer episodes of rehospitalization.

Van den Hout and others' (2003) study examines the cost-effectiveness of single-fraction versus multiple-fraction radiotherapy for palliative treatment of cancer patients with painful bone metastases. They find that overall medical and social costs for single-fraction radiotherapy for palliative therapy—US\$1,144 per patient in medical costs and US\$1,753 per patient in total social costs—were lower than comparable costs for multiple-fraction radiotherapy, despite the higher rate of retreatment associated with single-fraction radiotherapy. Whether those results are directly applicable to radiation treatment in developing countries, where single-fraction radiation treatment may be relatively less effective, is unknown. Nonetheless, the results strongly suggest that single-fraction

radiotherapy may be an acceptable, if not preferred, choice of palliative treatment in settings where resources for radiation treatment are relatively scarce and the need for palliative treatment is relatively high.

APPLICABILITY OF COST-EFFECTIVENESS STUDIES FROM DEVELOPED TO DEVELOPING COUNTRIES

Many of the cost-effectiveness studies of cancer control interventions (prevention, screening, and treatment) have been performed in the context of high-income, developed countries; thus, the question arises whether such studies are applicable to health care delivery settings in developing countries. No simple rule is available to indicate how the results of cost-effectiveness studies in developed countries might translate to health care delivery settings in developing countries, but disease incidence and time horizon are major pertinent considerations in relation to cancer prevention and screening interventions. In relation to cancer treatment, other considerations have to be taken into account.

Factors Affecting the Applicability of Cost-Effectiveness Studies of Prevention and Screening

Cost-effectiveness analyses of cancer prevention and screening interventions are complex. Several parameters have a large influence on the results of these studies, including the following:

- age-specific cancer incidence
- all-cause life expectancy and temporal trends of major epidemics
- population age structure
- availability, effectiveness, and costs of cancer treatment
- health system costs of the prevention or screening intervention.

As illustrated by the several examples described in this chapter, those parameters are likely to vary widely between developed and developing countries.

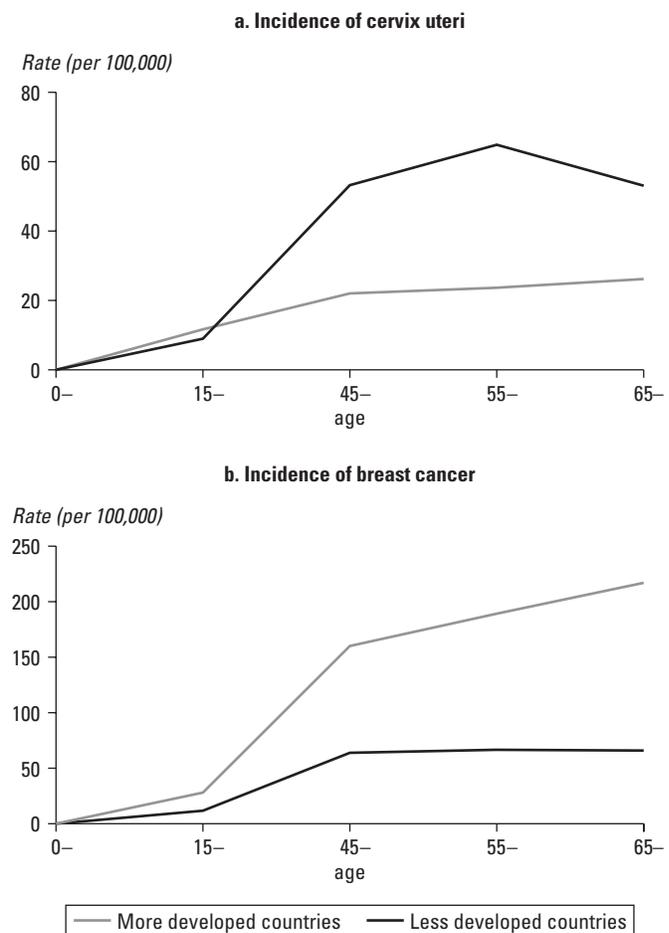

For example, age-specific cancer incidence in the absence of a preventive or screening intervention can have a major influence on the potential cost-effectiveness of a cancer prevention or screening intervention. Generally, the higher the background incidence of the cancer, the more cost-effective the cancer prevention or screening intervention will be. For that reason, the relative cancer incidence patterns in developed and developing countries for the cancer screening interventions described earlier need to be considered.

Figure 29.3 shows age-specific cancer incidence patterns for cervical and breast cancer for developed and developing

countries. As the figure shows, the incidence of cervical cancer in developing countries is relatively high in comparison with the incidence of these cancers in developed countries, whereas the incidence of breast cancer is relatively low in developing countries compared with that in developed countries. Given the relatively high incidence of cervical cancer in developing countries, interventions for cervical cancer prevention and screening are likely to be more cost-effective in developing countries rather than developed countries, compared with interventions for breast cancer, all else being equal.

Factors Affecting the Applicability of Cost-Effectiveness Studies of Treatment

Many of the treatments for breast, colorectal, and lung cancer that have been shown to be efficacious in controlled clinical trials have been estimated to have cost-effectiveness ratios in the range of a few thousand U.S. dollars to a few tens of thousands

Source: Ferlay and others 2001.

Figure 29.3 Age-Specific Incidence of Cervical and Breast Cancer, Developed and Developing Countries, 2000

of U.S. dollars per YLS. This range is considered quite favorable in developed countries but might be viewed as less favorable in low- and middle-income countries that face stringent constraints on health care resources. Disease incidence and time horizon do not loom as major considerations in the case of the cost-effectiveness of cancer treatment, because the cost of treatment applies only to those individuals already diagnosed with cancer and considered eligible for a specific treatment, not to a broader population considered to be at risk for developing cancer.

Thus, in low-income, low-cost countries with high mortality rates, because of the lack of primary treatment, the provision of basic cancer treatment may be a cost-effective first step toward cancer control, especially for highly treatable cancers with relatively low incidence in developing countries. For example, using a generalized cost-effectiveness approach, Ginsberg and others (2004) conclude that the provision of basic treatment for colorectal cancer in low-income African countries is likely to be a cost-effective first step toward cancer control.

Nevertheless, issues of economies of scale and scope may be associated with fixed investments in specialized medical equipment and skilled human capital. The centralization and regionalization of cancer treatment may be associated with a higher technical quality of care and might also be associated with the need to use these resources at economically efficient levels. Some cost elements, such as local labor and the availability of generic drugs since initial clinical trials were conducted, will clearly be lower in the contemporary setting of developing countries than in many of the cost-effectiveness studies reviewed earlier.

Finally, developments in cancer treatment, especially in relation to chemotherapy, are extremely dynamic. For example, the 1999 WHO list of essential drugs for cancer therapy (Sikora and others 1999; WHO 2003a), includes 5-fluorouracil as a priority one (essential) drug and irinotecan as a priority three (palliative benefit only) drug for the treatment of colorectal cancer. Just five years later, in many developed countries the following drugs, in addition to irinotecan, have been added to the basic regimen of 5-fluorouracil plus leucovorin for the treatment of colorectal cancer: oxaliplatin, bevacizumab, and cetuximab. Whereas 5-fluorouracil-based treatment of metastatic colorectal cancer increased median survival from 8 to 12 months, the newer drugs increase median survival to 21 months or more, at a significantly increased economic cost. In the United States, the drug cost of 5-fluorouracil-based therapy ranges from US\$63 to US\$263 for the initial eight weeks of therapy. Adding irinotecan or oxaliplatin increases the drug cost to about US\$10,000, and adding bevacizumab or cetuximab adds another US\$20,000 to US\$30,000 to the cost of initial treatment. If the latter drugs are used over the longer term as envisioned, the average cost of supplying the drugs to a

single patient could approach US\$300,000. Those estimates do not consider the additional costs of chemotherapy preparation, administration, and supervision and supportive care (Schrag 2004). The situation is similar for other common cancers. Clearly, low- and middle-income countries cannot afford to make the newest cancer drugs widely available to cancer patients; however, this example illustrates the need for periodic updating of available chemotherapy options along with evaluations of the incremental costs and benefits associated with them.

RESEARCH AGENDA

Knowledge about the feasibility, effectiveness, and cost-effectiveness of cancer control interventions by health services in developing countries is extremely limited, partly because of the relative paucity of active research in this area. Work in the area of descriptive epidemiology, especially work based on cancer registry data, dominates the research literature on cancer in developing countries. A second body of literature consists of comparative epidemiology and case-control studies designed to assess the importance of various risk factors for cancer.

Although information from such studies is an essential first step for characterizing the nature and extent of the cancer burden and for monitoring the ultimate effect of cancer control interventions, it does not provide a sufficient knowledge base for designing and implementing cancer control programs. For progress to be made for developing countries, much more work is needed in the following areas:

- *Clinical evaluation studies of cancer control interventions in developing countries.* Clinical evaluation studies of preventive, screening, and treatment interventions that are specifically tailored to the needs and conditions of developing countries would be useful, including controlled clinical trials where possible.
- *Health services research in developing countries.* Health services research designed to characterize the amount, distribution, and organizational structure of health sector resources in developing countries would be helpful, along with research to fill the gaps between current resource endowments and the amount of funding that would be needed to implement the minimally acceptable level of effective cancer control. In developing countries, shortages of the equipment and personnel needed to administer radiotherapy for cancer, for example, have been well documented (Levin, Meghizifene, and Tatsuzaki 2001). However, no systematic analyses are available outside developed countries (Owen, Coia, and Hanks 1997) that project radiotherapy resource needs in terms of clinically effective applications of

radiotherapy, both by cancer site and by the known effectiveness of radiotherapy for primary treatment, adjuvant therapy, and palliative care. Similarly, even though researchers have carried out patterns of care studies that characterize the dissemination of radiation, chemotherapy, and hormonal therapy in many developed countries, comparable information for developing countries is generally unavailable. Health services research studies could also contribute important information about the current structure and organization of primary, secondary, and tertiary care in specific developing countries, with the ultimate aim of modeling and implementing cancer control delivery systems that either are integrated with or supplement existing care delivery systems. Studies of this type are needed to ensure that there is a balance, for example, between resources devoted to screening and those devoted to diagnostic follow-up and treatment. The disappointing performance of cervical cancer screening programs in many developing countries has been due in part to the lack of effective diagnostic follow-up and treatment following screening.

- *Country-specific economic evaluation studies.* Country-specific studies need to be done that assess resource requirements, economic costs, effectiveness, and ultimately cost-effectiveness of cancer control interventions adapted or tailored to the needs and requirements of low- and middle-income settings. Heuristic extrapolation is a first analytical step in this direction, but such studies can indicate only whether more direct and realistic studies are needed.
- *Studies of innovative health care information and communications technology.* More research is needed to determine if technological advances, such as computerized image reading or long-distance consultation by oncology specialists, facilitated by telemedicine communications technology, might alter the cost-effectiveness equation by raising quality, by lowering costs, or both. For remote localities or small, low-income developing countries, training and employing local expertise or advanced equipment for every aspect of cancer control may not be necessary if advanced communication and information technology could be used to facilitate virtual collaboration.

CONCLUSIONS

Our ability to draw any conclusions about the cost-effectiveness of cancer control interventions for low- and middle-income developing countries is limited, because most cost-effectiveness studies in this area have been conducted in high-income, developed countries. Cancer control interventions that appear to be cost-effective in high-income countries may not be cost-effective in low-income countries, even when the lower cost of providing health services is taken into account.

A useful way to draw inferences about the relative cross-country affordability of interventions is to translate cost-effectiveness ratios into percentage of per capita gross national product (GNP) per YLS (WHO 2001a). Our preliminary analysis of breast cancer screening in India, for example, suggesting an absolute cost-effectiveness level for screening mammography of about US\$2,000 per YLS, compared with about US\$3,000 per YLS in the Netherlands. At about 10 percent per capita GNP per YLS, screening mammography might be considered to be extremely cost-effective for the Netherlands. In India, however, we found a CE estimate equal to 400 percent per capita GNP per YLS suggesting that national policy makers would be much less likely to consider screening mammography as a viable intervention given India's health care budget constraints. However, they might well consider a CBE breast cancer screening program, at about 200 percent per capita GNP per YLS in India, to be moderately affordable if the program were definitively established to be effective.

For middle-income developing countries that have cancer incidence rates similar to those in high-income developed countries, the results of cost-effectiveness analyses from the developed countries may be more relevant, although further analysis clearly is needed. The case study of cervical cancer control that was cited earlier suggests that for low-income countries tailored cancer control interventions may need to be developed that would be both cost-effective and affordable. However, that suggestion does not imply that low-tech approaches should be uncritically embraced and assumed to be cost-effective. Until recently, education campaigns to promote breast self-examination were widely advocated as the low-tech alternative to screening mammography for breast cancer control in low-income countries; however, the best current evidence now indicates that such campaigns have no effect on breast cancer mortality (Semiglazov and others 1999; Thomas and others 2002).

In cancer treatment interventions, the cost-effectiveness of initial surgical treatment for treatable cancers, such as breast, cervical, and colorectal cancer, may be in the relatively favorable range of a few to several thousand dollars per YLS, which indicates that such interventions are likely to be cost-effective for middle-income countries and are possibly cost-effective for low-income countries. Although cost-effectiveness ratios for some of the approaches to adjuvant therapy that use conventional radiation and drugs also fall within this relatively favorable range, others are in the range of tens of thousands of dollars for each YLS. Thus, these forms of treatment would likely be considered potentially cost-effective and affordable in middle-income countries but not in low-income countries; however, more detailed examinations of specific cost conditions and available resource endowments for the delivery of cancer treatment services are needed to confirm these preliminary impressions. As with the case of cervical cancer control,

treatment interventions that are tailored to the conditions of low-income countries might be shown to be efficacious and more economically attractive than treatment approaches that are transported directly from developed countries; however, research in this area is lacking.

Time Horizon and a Balanced Approach to Cancer Control Programs

The time horizon for cancer prevention and screening interventions is highly relevant to policy makers and health system planners, yet reports on the cost-effectiveness of such interventions often omit information about time horizons. For example, interventions that involve cancer control agents that prevent cancer cases that would have otherwise occurred many years after the preventive action, such as HPV vaccination, have a long time horizon. Similarly, the favorable cost-effectiveness of preventive screening for stomach cancer is not apparent until four decades following the initiation of the intervention. In the case of the 25-year program of CBE in India analyzed earlier, only about 10 percent of the benefits in terms of breast cancer deaths prevented would have been realized after 10 years of program operation. Decision makers must understand and take these time horizons into account when interpreting and acting on cost-effectiveness ratios; however, the long time horizon for cancer prevention and screening interventions is, in itself, not an argument against the application of such interventions. In some cases, countries that are more recent entrants into the field of cancer control may be able to benefit from the experience of developed countries and from the dynamic technical progress in this area to go directly to new innovations. For example, they might be able to implement HPV testing right away as the basis for cervical cancer screening, bypassing cervical cytology. Achieving the optimal temporal balance in comprehensive cancer control represents a daunting challenge to planning, evaluation, and implementation.

Start Small, Scale Up Smart

Because the current understanding of the effectiveness, optimal resource mix, and cost of many cancer control interventions is incomplete and uncertain, especially in relation to low- and middle-income countries, developing countries should start small. By starting small, they can gain knowledge from pilot programs that are well documented with regard to organizational and process factors; that are conducted in controlled settings, if possible; and that are monitored for efficiency, performance, and effectiveness. Thus, for example, new screening or treatment programs can be initiated in focused geographical areas or specific facilities with known and well-characterized target populations, and their performance and outcomes can be compared with matched control areas or facilities.

Developing countries should consider scaling up their regional or national programs only after the pilot programs have been shown to perform well.

Starting small also might entail applying an initial pilot program to a limited age range that is estimated to yield the most benefits per resource use or to a limited group of high-risk individuals defined by various risk characteristics, such as first-degree relatives of people with cancer. Indeed, various versions of this approach have characterized the dissemination of many cancer control interventions in developed countries. Organized breast cancer screening programs in some European countries, for example, were first implemented as pilot programs in specific regions and evaluated against control communities (Fracheboud and others 2001; Olsson and others 2000; van der Maas 2001), and regional and national programs were initially limited to the age groups, screening procedures, and screening frequencies estimated to be the most cost-effective. The programs were later extended, in terms of more intensive procedures, more frequent screening intervals, and wider age groups, after monitoring and analysis of initial program performance indicated that the incremental cost-effectiveness of these extensions would be favorable (Boer and others 1995; Shapiro and others 1998). The United Kingdom has taken a similar approach to colorectal cancer screening (Steele and others 2001).

ACKNOWLEDGMENTS

The authors would like to thank Rachel Ballard-Barbash, M.D.; Ted Trimble, M.D.; and Stephen Taplin, M.D., of the National Cancer Institute, and Deborah Schrag, M.D., of Memorial Sloan Kettering Cancer Institute for reading and commenting on early versions of this chapter. We thank Kerry Kemp and Penny Randall-Levy for editorial assistance. The exploratory analysis of breast cancer screening is the joint work of Quirine J. Lamberts, M.D., M.Sc.; Arno J. Der Kinderen, M.Sc.; Gerrit Draisma, Ph.D.; and Harry J. de Koning, M.D., of the Department of Public Health, Erasmus University Medical Center, Rotterdam. Steven Sweet, Jane Kim, and Jeremy Goldhaber-Fiebert of the Harvard Initiative for Global Health made invaluable contributions to the section on cervical cancer.

Chapter 30

Diabetes: The Pandemic and Potential Solutions

K. M. Venkat Narayan, Ping Zhang, Alka M. Kanaya, Desmond E. Williams, Michael M. Engelgau, Giuseppina Imperatore, and Ambady Ramachandran

NATURE AND DISTRIBUTION OF DIABETES

Diabetes is a metabolic disease characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both (American Diabetes Association 2004).

Classification of Diabetes

Diabetes takes three major forms. Type 1 diabetes results from destruction of the beta cells in the pancreas, leading to absolute insulin deficiency. It usually occurs in children and young adults and requires insulin treatment. Type 2 diabetes, which accounts for approximately 85 to 95 percent of all diagnosed cases, is usually characterized by insulin resistance in which target tissues do not use insulin properly. A third type of diabetes, gestational diabetes, is first recognized during pregnancy. Other rare types of diabetes include those caused by genetic conditions (for example, maturity-onset diabetes of youths), surgery, drug use, malnutrition, infections, and other illnesses.

The Burden of Diabetes

Diabetes affects persons of all ages and races. The disease reduces both a person's quality of life and life expectancy and imposes a large economic burden on the health care system and on families.

Secular Trend and Projections. In 2003, the worldwide prevalence of diabetes was estimated at 5.1 percent among

people age 20 to 79 (table 30.1). The prevalence of diabetes was higher in developed countries than in developing countries. In the developing world, the prevalence was highest in Europe and Central Asia and lowest in Sub-Saharan Africa. Some of these variations may reflect differences in the age structures and level of urbanization of the various populations. By 2025, the worldwide prevalence is projected to be 6.3 percent, a 24 percent increase compared with 2003. The largest increase in prevalence by 2025 is expected to be in East Asia and the Pacific, and the smallest in Sub-Saharan Africa. In terms of those affected, the biggest increase in the developing countries is projected to take place among adults of working age.

In 2003, 194 million people worldwide ages 20 to 79 had diabetes, and by 2025, this number is projected to increase to 333 million, a 72 percent increase (table 30.1). The developing world accounted for 141 million people with diabetes (72.5 percent of the world total) in 2003. During the same period, the number of people with diabetes is projected to double in three of the six developing regions: the Middle East and North Africa, South Asia, and Sub-Saharan Africa.

Diabetes-Related Mortality and Disability. The death rate of men with diabetes is 1.9 times the rate for men without diabetes, and the rate for women with diabetes is 2.6 times that for women without diabetes (W. L. Lee and others 2000). Premature mortality caused by diabetes results in an estimated 12 to 14 years of life lost (Manuel and Schultz 2004; Narayan and others 2003). Cardiovascular disease

Table 30.1 Estimated Numbers of People Age 20 to 79 with Diabetes, Mortality, DALYs, and Direct Medical Costs Attributable to Diabetes, by Regions

Region	Number of people (thousands)		Prevalence (percent)		Direct medical costs, 2003 (US\$ million)		Deaths, 2001 (thousands)	Disability-adjusted life years, 2001 (thousands)
	2003	2005	2003	2005	Low estimate	High estimate		
Developing countries	140,849	264,405	4.5	5.9	12,304	23,127	757	15,804
East Asia and the Pacific	31,363	60,762	2.6	3.9	1,368	2,656	234	4,930
Europe and Central Asia	25,764	33,141	7.6	9.0	2,884	5,336	51	1,375
Latin America and the Caribbean	19,026	36,064	6.0	7.8	4,592	8,676	163	2,775
Middle East and North Africa	10,792	23,391	6.4	7.9	2,347	4,340	31	843
South Asia	46,309	94,848	5.9	7.7	840	1,589	196	4,433
Sub-Saharan Africa	7,595	16,199	2.4	2.8	273	530	82	1,448
Developed countries	53,337	68,345	7.8	9.2	116,365	217,760	202	4,192
World	194,186	332,750	5.1	6.3	128,669	240,887	959	19,996

Source: Number of persons with diabetes, prevalence of diabetes, and direct medical costs of diabetes, International Diabetes Federation 2003b; all other information, WHO 2004.

(CVD) causes up to 65 percent of all deaths in developed countries of people with diabetes (Geiss, Herman, and Smith 1995).

The World Health Organization (WHO) estimates that, in 2001, 959,000 deaths worldwide were caused by diabetes, accounting for 1.6 percent of all deaths, and approximately 3 percent of all deaths caused by noncommunicable diseases. More recent estimates by WHO suggest that the actual number may be triple this estimate and that about two-thirds of these deaths occur in developing countries (WHO 2004). Within the developing regions, most deaths caused by diabetes occurred in East Asia and the Pacific and the fewest in Sub-Saharan Africa (table 30.1).

Diabetes-related complications include microvascular diseases (for example, retinopathy, blindness, nephropathy, and kidney failure) and macrovascular diseases (coronary heart disease, stroke, peripheral vascular disease, and lower-extremity amputation). Those complications result in disability. In the United States, a much higher proportion of people with diabetes than of people without diabetes have physical limitations: 66 percent compared with 29 percent (Ryerson and others 2003). Disabilities are even more pronounced among older people (Gregg and others 2000).

The World Health Organization estimated that, in 2001, diabetes resulted in 19,996,000 disability-adjusted life years (DALYs) worldwide. More than 80 percent of the DALYs resulting from diabetes were in developing countries (table 30.1). East Asia and the Pacific had the largest burden, and the Middle East and North Africa had the smallest burden. DALYs resulting from diabetes increased by 250 percent worldwide from 1990 to 2001 and by 266 percent for low- and middle-income countries (Mathers and others 2000).

Economic Burden of Diabetes

Diabetes imposes large economic burdens on national health care systems and affects both national economies and individuals and their families. Direct medical costs include resources used to treat the disease. Indirect costs include lost productivity caused by morbidity, disability, and premature mortality. Intangible costs refer to the reduced quality of life for people with diabetes brought about by stress, pain, and anxiety.

Direct Medical Costs. Good data on the direct medical costs of diabetes are not available for most developing countries. Extrapolation from developed countries suggests that, in 2003, the direct costs of diabetes worldwide for people age 20 to 79 totaled at least US\$129 billion and may have been as high as US\$241 billion (table 30.1). In the developing world, the costs were highest in Latin America and the Caribbean and lowest in Sub-Saharan Africa. The direct health care costs of diabetes range from 2.5 to 15.0 percent of annual health care budgets, depending on local prevalence and sophistication of the treatments available (International Diabetes Federation 2003b).

Indirect and Intangible Costs. In developing countries, the indirect costs of diabetes are at least as high, or even higher, than the direct medical costs (Barcelo and others 2003). Because the largest predicted rise in the number of people with diabetes in the next three decades will be among those in the economically productive ages of 20 to 64 (King, Aubert, and Herman 1998), the future indirect costs of diabetes will be even larger than they are now.

Diabetes lowers people's quality of life in many ways, including their physical and social functioning and their perceived physical and mental well-being. With a value of

1 representing the health-related quality of life without illness and 0 representing death, people with type 2 diabetes had a value of 0.77 in the population of the United Kingdom prospective diabetes study (Clarke, Gray, and Holman 2002).

Risk Factors for Diabetes

Risk factors for diabetes vary by disease type.

Type 1 Diabetes. Type 1 diabetes is most likely a polygenic disease, and a number of potential environmental risk factors have been implicated—including dietary factors; breastfeeding; initiation of bovine milk; infectious agents (for example, enterovirus, rotavirus, and rubella); chemicals; and toxins—but the results have been inconclusive (Akerblom and Knip 1998).

Type 2 Diabetes. The risk for type 2 diabetes is higher in monozygotic twins and people with a family history of diabetes (Rich 1990). This finding strongly suggests that genetic determinants play a role, but so far few genes have been associated with type 2 diabetes.

Environmental factors include prenatal factors, obesity, physical inactivity, and dietary and socioeconomic factors (Qiao and others 2004). Exposure to diabetes in utero increases the risk of developing type 2 diabetes in early adulthood (Dabelea and others 2000). Disproportionate growth and low birthweight increase the risk of developing diabetes and insulin resistance. In the postnatal environment, breastfeeding protects against the development of obesity, insulin resistance, and diabetes (Pettitt and others 1997; Young and others 2002).

The strongest and most consistent risk factors for diabetes and insulin resistance among different populations are obesity and weight gain (Haffner 1998): for each unit increase in body mass index, the risk of diabetes increases by 12 percent (Ford, Williamson, and Liu 1997). The distribution of fat around the trunk region, or central obesity, is also a strong risk factor for diabetes (Yajnik 2001). Diabetes risk may be reduced by increasing physical activity. Conversely, a sedentary lifestyle and physical inactivity are associated with increased risks of developing diabetes (Hu and others 2003). Some studies report a positive relationship between dietary fat and diabetes, but specific types of fats and carbohydrates may be more important than total fat or carbohydrate intake. Polyunsaturated fats and long-chain omega-3 fatty acids found in fish oils (Adler and others 1994) may reduce the risk of diabetes, and saturated fats and trans fatty acids may increase the risk of diabetes (Hu, van Dam, and Liu 2001). Sugar-sweetened beverages are associated with an increased risk of diabetes (Schulze and others 2004). High intakes of dietary fiber and of vegetables may reduce the risk of diabetes (Fung and others 2002; Stevens and others 2002).

Increased affluence and Westernization have been associated with an increase in the prevalence of diabetes in many

indigenous populations and in developing economies (Rowley and others 1997; Williams and others 2001). Conversely, in developed countries, those in lower socioeconomic groups have a higher risk of obesity and consequently of type 2 diabetes (Everson and others 2002). Surrogates for socioeconomic status, such as level of education attained and income (Paeratakul and others 2002; Robbins and others 2001) are inversely associated with diabetes in high-income countries.

INTERVENTIONS AND DELIVERY MODES

Interventions against diabetes include those for preventing the disease, those for detecting the disease in its asymptomatic stage, and those for managing the disease to reduce its complications.

Preventing Type 1 Diabetes

Not enough scientific evidence is available to indicate that type 1 diabetes can be prevented, although various interventions have been explored. Examples of tested interventions include eliminating or delaying exposure to bovine protein and using insulin or nicotinamide for people at high risk of developing the disease.

Preventing Type 2 Diabetes

Four major trials—in China, Finland, Sweden, and the United States—have demonstrated that intensive lifestyle interventions involving a combination of diet and physical activity can delay or prevent diabetes among people at high risk (Eriksson and Lindgarde 1991; Knowler and others 2002; Pan and others 1997; Tuomilehto and others 2001). In the largest randomized, controlled trial to date, the Diabetes Prevention Program (Knowler and others 2002), the goals of the intensive lifestyle intervention were weight loss of 7 percent of baseline bodyweight through a low-calorie diet and moderate physical activity for at least 150 minutes per week. After 2.8 years of follow-up, the average weight loss was 4.5 kilograms for those in the lifestyle intervention group and less than 0.3 kilograms for those in the placebo group. The lifestyle intervention reduced the incidence of diabetes by 58 percent.

Pharmacological studies of diabetes prevention have been reviewed in detail elsewhere (Kanaya and Narayan 2003). In summary, a variety of specific medications have been tested (for example, metformin, acarbose, orlistat, troglitazone, angiotensin-converting enzyme [ACE] inhibitors, statins, estrogens, and progestins) and have been found to lower diabetes incidence, but the expense, side effects, and cumulative years of drug intervention are practical concerns. Except for the Diabetes Prevention Program (Knowler and others 2002), no trial of medication intervention has directly compared the effectiveness of a drug to that of lifestyle modification.

Screening for People with Diabetes or Prediabetes

The benefits of early detection of type 2 diabetes through screening are not clearly documented, nor is the choice of the appropriate screening test established. Questionnaires used alone tend to work poorly; biochemical tests alone or in combination with assessment of risk factors are a better alternative (Engelgau, Narayan, and Herman 2000).

Managing Diabetes

High-quality evidence exists for the efficacy of several current treatments in reducing morbidity and mortality in people with diabetes. These interventions are summarized in table 30.2.

In addition, a review of previous studies (Norris, Engelgau, and Narayan 2001) found positive effects for short follow-up (less than six months) of self-management training

Table 30.2 Effectiveness and Cost-Effectiveness of Interventions for Preventing and Treating Diabetes in Developed Countries

Strategy	Benefit	Quality of evidence ^a	Cost-effectiveness ratio (US\$/QALY) ^b
<i>Preventing diabetes</i>			
• Lifestyle interventions for preventing type 2 diabetes	Reduction of 35–58 percent in incidence among people at high risk	I	1,100 (Diabetes Prevention Program Research Group forthcoming)
• Metformin for preventing type 2 diabetes	Reduction of 25–31 percent in incidence among people at high risk	I	31,200 (Diabetes Prevention Program Research Group forthcoming)
<i>Screening for diabetes</i>			
• Screening for type 2 diabetes in general population	Reduction of 25 percent in microvascular disease	III	73,500 (CDC Diabetes Cost-Effectiveness Study Group 1998)
<i>Treating diabetes and its complications</i>			
• Glycemic control in people with HbA1c greater than 9 percent	Reduction of 30 percent in microvascular disease per 1 percent drop in HbA1c	I	Cost saving (CDC Diabetes Cost-Effectiveness Study Group 1998)
• Glycemic control in people with HbA1c greater than 8 percent	Reduction of 30 percent in microvascular disease per 1 percent drop in HbA1c	I	34,400 (CDC Diabetes Cost-Effectiveness Study Group 1998; Klonoff and Schwartz 2000)
• Blood pressure control in people whose pressure is higher than 160/95 mmHg	Reduction of 35 percent in macrovascular and microvascular disease per 10 mmHg drop in blood pressure	I	Cost saving (CDC Diabetes Cost-Effectiveness Study Group 1998)
• Cholesterol control in people with total cholesterol greater than 200 milligrams/deciliter	Reduction of 25–55 percent in coronary heart diseases events; 43 percent fall in death rate	II-1	63,200 (CDC Diabetes Cost-Effectiveness Study Group 1998)
• Smoking cessation with recommended guidelines	16 percent quitting rate	I	12,500 (CDC Diabetes Cost-Effectiveness Study Group 1998)
• Annual screening for microalbuminuria	Reduction of 50 percent in nephropathy using ACE inhibitors for identified cases	III	47,400 (Klonoff and Schwartz 2000)
• Annual eye examinations	Reduction of 60 to 70 percent in serious vision loss	I	6,000 (Klonoff and Schwartz 2000; Vijan, Hofer, and Hayward 2000)
• Foot care in people with high risk of ulcers	Reduction of 50 to 60 percent in serious foot disease	I	Cost saving (Ragnarson and Apelqvist 2001)
• Aspirin use	Reduction of 28 percent in myocardial infarctions, reduction of 18 percent in cardiovascular disease	I	Not available
• ACE inhibitor use in all people with diabetes	Reduction of 42 percent in nephropathy; 22 percent drop in cardiovascular disease	I	8,800 (Golan, Birkmeyer, and Welch 1999)
• Influenza vaccinations among the elderly for type 2 diabetes	Reduction of 32 percent in hospitalizations; 64 percent drop in respiratory conditions and death	II-2	3,100 (Sorensen and others 2004)
• Preconception care for women of reproductive age	Reduction of 30 percent in hospital charges and 25 percent in hospital days	II-2	Cost saving (Klonoff and Schwartz 2000)

Source: Authors.

Note: mmHg = millimeters of mercury; QALY = quality-adjusted life year.

a. I indicates evidence from at least one randomized, controlled trial; II-1 indicates evidence from a well-designed, controlled trial without randomization; II-2 indicates evidence from cohort or case control studies; and III indicates opinions of respected authorities (U.S. Preventive Services Task Force 1996).

b. We adjusted cost-effectiveness ratios to 2002 U.S. dollars using the consumer price index for medical care. In cases in which multiple studies evaluated the cost-effectiveness of an intervention, we report the median cost-effectiveness ratio.

on knowledge, frequency, and accuracy of self-monitoring of blood glucose; self-reported dietary habits; and glycemic control. Effects on lipids, physical activity, weight, and blood pressure varied.

COST-EFFECTIVENESS OF INTERVENTIONS AND PRIORITIES

Most of the interventions to prevent and treat diabetes and its complications significantly affect the use of health services. The limitations of clinical trials include their failure in most cases to capture the entire intervention effect over a lifetime and to include all segments of a population to whom the intervention may apply. Evaluating the cost-effectiveness of interventions often requires the use of computer simulation models, but data availability, technical complexity, and resource needs present a significant barrier to constructing such models for developing countries. Furthermore, data on interventions are often available only from developed countries, and these data are often extrapolated to developing countries.

Estimating the Cost-Effectiveness of Interventions in Developing Countries

To assess the cost-effectiveness of interventions in developing countries, we updated the results from Klonoff and Schwartz's (2000) comprehensive review by including studies that were published up to 2003. Table 30.2 summarizes the cost-effectiveness of interventions for the developed countries, mainly in the United States. The results show that the cost-effectiveness of interventions varies greatly—from cost saving (an intervention is both more effective and less expensive than the comparator) to US\$73,500 per quality-adjusted life year (QALY) gained.

We estimated the cost-effectiveness ratio of diabetes interventions for the six developing regions shown in table 30.3. We assumed that the effectiveness of these interventions, as measured in QALYs, was the same as in developed countries but that the cost of interventions and other diabetes care differed between developed and developing countries and also among the six developing regions. Using this assumption, we estimated the cost-effectiveness ratio for a developing region as the cost-effectiveness ratio in the developed country, mainly represented by the United States, multiplied by the ratio of costs in the developing region to the cost in the developed countries, which we calculated as follows. These cost-effectiveness ratios are based on costs and benefits over a lifetime, except for preconception care for women of reproductive age.

We estimated that the cost of intervention and other diabetes care in the United States was 8.6 times the cost in Latin America and the Caribbean. This cost ratio was an average of four cost

ratios—each weighted by its share (Barcelo and others 2003)—for outpatient care, inpatient care, drugs and laboratory tests, and treatment for diabetic complications. The cost ratio for each cost component was calculated as the cost of medical services or drugs in the United States divided by the cost of the same services or drugs in Latin America and the Caribbean. U.S. data for medical services and drugs for routine diabetes care, plus treatment cost for diabetes complications, were obtained from a 1998 cost-effectiveness Markov model of the U.S. Centers for Disease Control and Prevention (CDC). Data for laboratory service were obtained from the 2001 Clinical Diagnostic Laboratory Fee Schedule from the U.S. Centers for Medicare Services (available from <http://www.cms.gov>). Data for Latin America and the Caribbean were obtained from three countries—Argentina (Gagliardino and others 1993), Brazil (Health Policy Division of the Brazilian Ministry of Health), and Mexico (Villarreal-Rios and others 2000).

We applied Mulligan and others' framework (2003) to estimate the costs of intervention and diabetes care in each developing region. Assuming that cost estimates are available for one of the regions, this framework allows the development of a relative cost index for health care services that can then be used to obtain cost estimates for the other five regions. Using costs estimated by Mulligan and others (2003), we first estimated three health service indexes, including hospital bed days, outpatient and inpatient services, and laboratory tests and procedures. We then combined the three indexes into one overall index for diabetes care in accordance with the share of each component in developing countries (Barcelo and others 2003). Finally, we estimated the costs of intervention and diabetes care in the other five developing regions by multiplying the cost of care in the Latin America region by the overall regional relative cost index.

Ranking Implementation Priorities

We assessed the implementation priority and feasibility of interventions, as explained in table 30.3.

Level 1 Interventions. All three interventions in this category are cost saving and are also feasible in terms of all four aspects considered. The barrier to implementing these interventions may be a short-term hike in intervention costs.

Glycemic control in a population with poor control (hemoglobin A1c greater than 9 percent or another measure of glucose control in situations where HbA1c tests may be unaffordable) is cost saving because the reduction in medical care costs associated with both short-term and long-term complications is greater than is the cost of intervention. Glycemic control for people with type 1 diabetes involves insulin use and, for people with type 2 diabetes, depending on the stage and severity of the disease, consists of diet and physical activity, oral

Table 30.3 Cost-Effectiveness of Interventions for Preventing and Treating Diabetes and Its Complications in Developing Regions

Intervention	Cost/QALY (2001 US\$)						Feasibility ^a	Implementing priority ^b
	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa		
<i>Level 1</i>								
Glycemic control in people with HbA1c higher than 9 percent	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	+++	1
Blood pressure control in people with pressure higher than 160/95 mmHg	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	+++	1
Foot care in people with a high risk of ulcers	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	+++	1
<i>Level 2</i>								
Preconception care for women of reproductive age	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	Cost saving	++	2
Lifestyle interventions for preventing type 2 diabetes	80	100	130	110	60	60	++	2
Influenza vaccinations among the elderly for type 2 diabetes	220	290	360	310	180	160	+++	2
Annual eye examination	420	560	700	590	350	320	++	2
Smoking cessation	870	1,170	1,450	1,230	730	660	++	2
ACE inhibitor use for people with diabetes	620	830	1,020	870	510	460	+++	2
<i>Level 3</i>								
Metformin intervention for preventing type 2 diabetes	2,180	2,930	3,630	3,080	1,820	1,640	++	3
Cholesterol control for people with total cholesterol higher than 200 milligrams/deciliter	4,420	5,940	7,350	6,240	3,680	3,330	+++	3
Intensive glycemic control for people with HbA1c higher than 8 percent	2,410	3,230	4,000	3,400	2,000	1,810	++	3
Screening for undiagnosed diabetes	5,140	6,910	8,550	7,260	4,280	3,870	++	3
Annual screening for microalbuminuria	3,310	4,450	5,510	4,680	2,760	2,500	++	3

Source: Authors.

a. Feasibility was assessed based on difficulty of reaching the intervention population (the capacity of the health care system to deliver an intervention to the targeted population), technical complexity (the level of medical technologies or expertise needed for implementing an intervention), capital intensity (the amount of capital required for an intervention), and cultural acceptability (appropriateness of an intervention in terms of social norms and/or religious beliefs). +++ indicates feasible for all four aspects, ++ indicates feasible for three of the four, + indicates feasible for two of the four, and + indicates feasible for one of the four.

b. Implementing priority was assessed by combining the cost-effectiveness of an intervention and its implementation feasibility; 1 represents the highest priority and 3 represents the lowest priority.

glucose-lowering agents, and insulin. Patient education is an essential component of these interventions to encourage patients to comply with medication regimes and to change to and maintain healthy lifestyles.

Glucose is generally poorly controlled in people with both type 1 and type 2 diabetes, mostly because of lack of access to insulin and other diabetes supplies in developing countries.

For example, the mean HbA1c level for people with diabetes in India was 8.9 percent in 1998 (Raheja and others 2001). A survey conducted by the International Diabetes Federation in 1997 (2003b) showed that no country in Africa had 100 percent accessibility to insulin. Ensuring adequate access to insulin should be an important priority for developing countries.

Blood pressure control for people with diabetes and hypertension reduces the incidence of both microvascular and macrovascular diseases. Major medication interventions include an ACE inhibitor, thiazide diuretics, or a beta blocker. Blood pressure control is cost saving mainly because of its large health benefits and relatively low intervention costs. Even in the United States, moderate blood pressure control costs less than US\$250 per patient per year. Because many blood pressure medications are generic drugs, the costs are much lower in developing countries. In addition, the prevalence of people with poor control of blood pressure may be high in developing countries. For example, in Latin America and the Caribbean, 60 percent of people with type 2 diabetes in 2000 had blood pressure higher than 140/90 mmHg (Gagliardino, de la Hera and Siri 2001).

Complications related to foot problems are common among diabetics in developing countries. For example, in India, 43 percent of diabetes patients had foot-related complications (Raheja and others 2001). Interventions for foot care are low tech and require little capital. Interventions for foot care in developing countries should include educational programs for patients and professionals (for example, on foot hygiene, treatment of calluses, awareness of functional infections, and care for skin injuries); access to appropriate footwear; and multidisciplinary clinics. All three interventions could be cost saving, mainly because the cost of the interventions is low and the interventions can reduce the risk of foot ulceration and amputation, which are costly. Applying these interventions for high-risk patients, such as those with at least one previous foot ulcer or amputation, would yield even larger savings (Klonoff and Schwartz 2000).

Level 2 Interventions. The six interventions in this category are either cost saving and not feasible in one or more aspects or cost less than US\$1,500 per QALY and are at least moderately feasible. Thus, interventions in this category represent good value for money but may present some difficulties in terms of feasibility.

Preconception care among women of reproductive age includes patient education and intensive glucose management. This intervention reduces short-term hospital costs for both mothers and infants and improves birth outcomes. However, the intervention may not be feasible in some developing countries because of the resources needed for the intervention and the difficulty of reaching the target population.

The lifestyle intervention for preventing type 2 diabetes costs US\$60 to US\$130 per QALY over a lifetime, depending on the region. The potential population eligible for a lifestyle intervention (those with impaired glucose tolerance or impaired fasting glucose) is large in developing countries. The International Diabetes Federation (2003b) estimates that the prevalence of impaired glucose tolerance was at least as high as

the prevalence of diabetes in all regions. The expertise required for the intervention, such as dietitians and exercise physiologists, and the capacity of health care systems to handle the large populations eligible for the intervention may present a barrier to implementing the intervention in many developing countries.

People with diabetes are at higher risk of complications from influenza and pneumococcal infections than those without diabetes. Influenza vaccinations are a relatively cost-effective intervention, mainly because of the low intervention cost. However, the level of adoption for the intervention would depend on a country's ability to deliver the intervention to the targeted population.

The detection of proliferative diabetic retinopathy and macular edema by dilated eye examination followed by appropriate laser photocoagulation therapy prevents blindness. Annual screening and treatment programs for diabetic retinopathy cost US\$700 or less per QALY gained in developing countries. The intervention is more cost-effective among older people, those who require insulin (Klonoff and Schwartz 2000), or those with poor glucose control (Vijan, Hofer, and Hayward 2000). In addition, screening less frequently, such as every two years, may be more cost-effective than screening every year (Vijan, Hofer, and Hayward 2000). Eye complications among people with diabetes are common in developing countries; for example, 39 percent of people with diabetes in India had eye-related complications (Rajala and others 1998). Although laser treatment is an effective intervention, such treatment may not be available in many developing countries or may be extremely costly.

ACE inhibitors can lower the blood pressure of those with hypertension and delay the onset or prevent further progression of renal disease for those with diabetes. Compared with screening for microalbuminuria and treating only those who have the condition, offering ACE inhibitors to all people with diabetes was more cost-effective at less than US\$1,020 per QALY gained. This intervention was more cost-effective among younger people and was sensitive to the cost of drug. Thus, lowering the cost of the medication is a key factor for the success of this intervention in developing countries.

Smoking cessation includes both counseling and using medication such as a nicotine patch. Smoking cessation appears to be the least cost-effective among the level 2 interventions. However, the benefits of smoking cessation may be underestimated because our calculations only took the reduced risk of CVD into account (Earnshaw and others 2002). Adding the health benefits derived from preventing cancer and pulmonary diseases would improve the cost-effectiveness of smoking cessation. Considering the high prevalence of smoking in developing countries, smoking cessation should be a high-priority intervention, but the availability of the nicotine patch may be a barrier to implementing this intervention in developing countries.

Level 3 Interventions. The five interventions included in this category cost at least US\$1,640 per QALY but could cost as much as US\$8,550 per QALY. Compared with the level 1 and 2 interventions, those in this category are also less feasible. In general, depending on cost-effectiveness and feasibility, these interventions may not always be justifiable for all people in developing countries, given the limited health care resources. However, these interventions may be reasonable for selected subpopulation groups, such as those who can afford them.

Metformin therapy for preventing type 2 diabetes among people at high risk, such as those with prediabetes, is feasible because the drug is affordable in many developing countries; however, the intervention may not be good value for money. Cholesterol control intervention for people with diabetes falls into the same category. The cost-effectiveness of both these interventions would improve if the costs of the drug could be lowered.

The aim of intensive glucose control is to lower the glucose level of a person with diabetes to a level close to that of a person without diabetes. Implementing this intervention is a lower priority, mainly because of its relatively low cost-effectiveness in the context of the limited health care resources in developing countries. Although the U.K. Prospective Diabetes Study clearly demonstrates that lowering glucose levels can prevent or delay long-term diabetes complications (UKPDS Group 1998), the marginal return on very intensive glucose control in developing countries was relatively small.

Screening for undiagnosed diabetes is a low-priority intervention mainly because of its relatively high cost per QALY. However, screening for undiagnosed diabetes can be a worthwhile intervention for subpopulation groups, such as those that have a high prevalence of undiagnosed diabetes. In the United States, for example, screening for undiagnosed diabetes among African Americans was estimated to be 10 times more cost-effective than screening among other population groups (CDC Diabetes Cost-Effectiveness Study Group 1998). In addition, screening for undiagnosed diabetes may be a worthwhile intervention for patients with risk factors for other chronic diseases, such as hypertension, high lipid profiles, and prediabetes.

Annual screening for microalbuminuria was a low-priority intervention because screening added costs with no significant benefits. Treating all persons with diabetes with ACE inhibitors was a better treatment option than screening for microalbuminuria and treating only those who have the condition.

Cost-Effectiveness of a Polypill to Prevent CVD

A meta-analysis estimated that a hypothetical polypill could reduce the risk of CVD by 80 percent among all people over 55 or people with diabetes of any age (Wald and Law 2003). This hypothetical pill is a combination of three half-dose

antihypertensive medications— aspirin, statin, and folic acid (see also chapter 33). Currently, neither is it available for use, nor have estimates of its benefits and adverse effects been confirmed in a formal, randomized, controlled trial. The idea is thus still theoretical. The cost-effectiveness of this hypothetical pill was, however, simulated using a computer model of people with newly diagnosed diabetes in the United States (Sorensen and others 2004), and the assessment found that a polypill intervention would cost US\$11,000 per QALY gained. The intervention would be cost saving if such a pill cost US\$1.28 or less per day. We estimated that the cost-effectiveness ratio of the polypill ranged from US\$560 to US\$1,280 per QALY gained for the six developing regions. This result was sensitive to changes in the cost of the intervention, but the intervention remained cost-effective within the most likely ranges of its cost (Sorensen and others 2004). A barrier to this intervention, in addition to the feasibility of producing such pill, is that its benefits and side effects would still have to be established in a randomized clinical trial.

Cost-Effectiveness of Diabetes Education

People with diabetes play a central role in managing their disease. Thus, diabetes education is an integral part of diabetes care. The goal of diabetes education is to support the efforts of people with diabetes to understand the nature of their illness and its treatment; to identify emergency health problems at early, reversible stages; to adhere to self-care practices; and to make necessary changes to their health habits (International Diabetes Federation 2003b). Health providers can deliver diabetes education programs in various settings. Evaluating the effectiveness of health education is challenging because of the difficulty of separating out its effect from that of other interventions. Nevertheless, a review of literature published in the United States suggests that self-management diabetes education may be cost-effective (Klonoff and Schwartz 2000).

Training in diabetes self-management reduces medical costs for diabetes care in developing countries in the short term. A multicenter intervention study in 10 Latin American countries demonstrated that an education program could reduce the cost of drugs by 62 percent (International Diabetes Federation 2003b), and another program in Argentina found a reduction in diabetes-related costs of 38 percent (Gagliardino and Etchegoyen 2001). Because the costs of education programs are generally low, the intervention may be cost-effective. Training patients to better manage their diabetes is also feasible because of its low technical complexity, low capital requirements, and cultural acceptability. Thus, diabetes education should be a high-priority intervention for all developing regions.

LESSONS AND EXPERIENCE

A number of lessons can be learned from the experiences in countries where the interventions described have been implemented.

Prevention

Data are sparse on community- or population-based strategies for preventing diabetes along with other chronic diseases such as CVD. Available studies on preventing type 2 diabetes have used clinic-based approaches targeted at high-risk groups, and researchers generally agree that type 2 diabetes can be prevented or its onset delayed. Putting these results into practice, however, is fraught with difficulties and unanswered questions, such as the following:

- Who would benefit from diabetes prevention?
- How can those who may benefit be identified?
- What are the costs and cost-effectiveness of diabetes prevention at a population level?
- How should results be extrapolated from developed countries to developing countries, whose priorities and approaches may be different?

Treatment

The quality of diabetes care generally remains suboptimal worldwide, regardless of a particular country's level of development, health care system, or population (Engelgau and others 2003; Garfield and others 2003). The Costs of Diabetes in Europe—Type 2 study, conducted in eight European countries, found suboptimal diabetes care in each country (Liebl, Mata, and Eschwege 2002). In the United States, population-based surveys in the 1990s among adults age 18 to 75 with diabetes found that only 63 percent of them had had a dilated eye examination and only 55 percent had had a foot examination within the past year, 18 percent had poor glycemic control, 42 percent had good cholesterol control, and 66 percent had a blood pressure within the normal range (Saaddine and others 2002).

The Diabcare-Asia project was conducted in the late 1990s. Results from India, Singapore, and Taiwan (China) found that in 1998, 32 to 50 percent of the diabetic population had poor glycemic control (equivalent to HbA1c > 8 percent), 43 to 67 percent had high cholesterol (greater than 5.2 millimoles per deciliter), and 47 to 54 percent had an abnormal level of triglyceride (greater than 1.7 millimoles per deciliter) (W. R. Lee and others 2001; Raheja and others 2001). Data from Latin America and the Caribbean showed that 41 percent of people with type 1 diabetes and 57 percent of those with type 2 diabetes had poor glucose control. Of those with type 2 diabetes, 56 percent

had hypertension, 53 percent had high cholesterol, and 45 percent had abnormal triglycerides (Gagliardino, de la Hera, and Siri 2001).

Quality of Diabetes Care

Small, single-site studies indicate that several interventions to improve quality of care at the patient, provider, or system levels are promising (Narayan and others 2004). A systematic review (Renders and others 2001) found that multifaceted professional interventions may enhance providers' performance in managing diabetes care; that organizational interventions involving regularly contacting and tracking patients by means of computerized tracking systems or through nurses can also improve diabetes management; that patient-oriented interventions can improve patients' outcomes; and that nurses can play an important role in patient-oriented interventions by educating patients and facilitating patients' adherence to treatment regimes. (See also chapter 70.)

Interventions that could modify providers' behavior include education as part of more complex interventions that also focus on systems and on the organization of practices—for example, feedback on performance, reminder systems, consensus development, and clinical practice guidelines. Potential systemic interventions include the use of continuous quality improvement techniques; feedback on performance; physician incentives for quality; nurses to provide diabetes care (which is typically provided by physicians); computerized reminder systems for providers, alone or in combination with a performance feedback program; patient-tracking or other reminder systems to improve regular follow-up; dedicated blocks of time set aside for diabetes patients in primary care practices; team care; electronic medical record systems; and other methods, such as telephone and mailing reminders, chart stickers, and flow sheets to prompt both providers and patients.

Interventions that empower patients can be successful components of diabetes programs. A systems-oriented approach using manual or computerized systems that remind patients to make follow-up appointments and that prompt staff members to generate reminder cards for patients can improve compliance with follow-up and enhance efficiency of office practices. In addition, comprehensive implementation of multiple risk-factor interventions in real-life settings has been shown to reduce vascular events by more than 50 percent among people with diabetes (Gaede and others 2003).

The Institute of Medicine Committee on Quality of Health Care in America (2001) argues strongly that newer systems of care and newer ways of thinking are needed to tackle complex diseases such as diabetes. Furthermore, the model of the process of change in a simple mechanical system is woefully inadequate for dealing with the complex, interactive, and interconnected

adaptive systems in which diabetes is prevented and treated. Applied research, designed to encompass the system as a whole and not simply its component parts, can enhance our understanding of complex health care dynamics for chronic diseases (Fraser and Greenhalgh 2001; Plsek and Greenhalgh 2001).

RESEARCH AND DEVELOPMENT AGENDA

The following subsections discuss the major issues for research and development.

Prevention

Well-designed community-based studies of primary prevention for type 2 diabetes are needed, especially as part of multifactorial interventions, in developing countries. Research is also needed into safer and cheaper drugs to prevent diabetes when lifestyle intervention either is not feasible or has failed. In addition, we need to know the long-term effects of diabetes prevention on CVD and other outcomes. More effective and cheaper ways to prevent the major complications of diabetes are also needed. Other areas also deserving of research include noninvasive methods for monitoring blood glucose and more effective and efficient ways of screening for prediabetes, diabetes, and early diabetes complications. Evidence of the benefits of diabetes education on outcomes is lacking, and organized research to assess effective components of diabetes education and their impact on control of risk factors and long-term outcomes should be a priority.

Epidemiological and Economics Research

Scant data are available on the future burden of diabetes and its complications in developing countries. Data on trends in and the effects of risk factors for diabetes in developing countries—obesity; birthweight; physical inactivity; television viewing; dietary factors; fast foods; socioeconomic factors; and effects of urbanization, industrialization, globalization, and stress—are also sparse. Low-cost ways to obtain such data in a standardized manner may be worth considering. More data are also needed on the costs of diabetes, the impact of the disease on quality of life, and the cost-effectiveness of various interventions in the context of developing countries (International Diabetes Federation 2003a).

Health Systems and Operational Research

Greater emphasis on translation research is needed. Well-designed and standardized studies of quality of care and outcomes will help (TRIAD Study Group 2002). Research aimed at understanding system-level complexity and finding ways to deliver chronic disease care that takes such complexity into account is also likely to yield profitable results (Institute of

Medicine Committee on Quality of Health Care in America 2001). Computer models suitable for assessing cost-effectiveness and for forecasting the burden in developing countries are needed. Operational research aimed at understanding the tradeoffs and the best mix of resource allocation for diabetes and chronic disease care in developing countries is also needed.

Basic Research

Further strategic unraveling of the genetic basis of type 2 diabetes and gene-environment interactions may help explain the diabetes epidemic and provide better understanding of the pathophysiology of the disease. It may also lead to better prevention and treatment strategies. Understanding the role of prenatal influences, especially in developing countries, may offer productive opportunities for interventions. Because of the increasing occurrence of type 2 diabetes in children, as well as the role of obesity in accelerating the onset of type 1 diabetes, further research into the typology and classification of diabetes is vital. The rapid industrialization and economic development being experienced by several developing countries may make research into the role of socioeconomic factors, urban stress, and lifestyle factors on the causation of diabetes productive.

CONCLUSIONS

A growing diabetes pandemic is unfolding with rapid increases in the prevalence of type 2 diabetes. The direct health care costs of diabetes worldwide amount to 2003 US\$129 billion per year. Estimates indicate that developing countries spend between 2.5 and 15.0 percent of their annual direct health budgets on diabetes care, and families with diabetic members spend 15 to 25 percent of their incomes on diabetes care.

A whole array of effective interventions to prevent diabetes and its complications is available, and we have attempted to assess their potential cost-effectiveness in developing regions. Using these estimations and a qualitative assessment of the feasibility of implementation, we have prioritized available interventions into the following three categories:

- level 1—cost saving and highly feasible
- level 2—cost saving or cost less than US\$1,500 per QALY but pose some feasibility challenges
- level 3—cost between US\$1,640 and US\$8,550 per QALY and pose significant feasibility challenges.

Table 30.4 presents a summary of all major diabetes interventions, major health effects of the interventions, and level of implementation priority.

In addition, we propose diabetes education as an essential intervention. However, more organized research into the precise components of diabetes education and its effect on

Table 30.4 Key Cost-Effective Interventions for Preventing and Treating Diabetes and Its Complications

Intervention	Description	Applicable population	Major effect
<i>Level 1^a</i>			
• Glycemic control in people with poor control	Insulin, oral glucose-lowering agents, diet and exercise	People with diabetes, all ages, HbA1c greater than 9 percent	Reduction in microvascular disease
• Blood pressure control	Blood pressure control medications	People with diabetes, hypertensive, all ages	Reduction in macrovascular disease, microvascular disease, and mortality
• Foot care	Patient and provider education, foot examination, foot hygiene, and appropriate footwear	People with diabetes, middle-aged or older	Reduction in serious foot diseases and amputations
<i>Level 2^b</i>			
• Preconception care for women of reproductive age	Patient self-management	Women with diabetes who plan to become pregnant	Reduction in HbA1c level and hospital expenses of the mother and baby
• Lifestyle intervention to prevent diabetes	Behavioral change, including diet and physical activity, to reduce bodyweight	People who are at high risk (for example, prediabetes for type 2 diabetes)	Reduction in type 2 diabetes incidence by 58 percent
• Influenza vaccination	Vaccination	Elderly people with diabetes	Reduction in hospitalizations, respiratory conditions, and mortality
• Detection and treatment of eye diseases	Eye examination to screen for and treat eye diseases	People with diabetes, middle-aged or older	Reduction in serious vision loss
• ACE inhibitors	Angiotensin-converting enzyme medication	People with diabetes	Reduction in nephropathy, cardiovascular disease, and death
• Smoking cessation	Physician counseling and nicotine replacement therapy	People with diabetes, all ages, smokers	Increase in quitting rate and reduction in cardiovascular disease
<i>Level 3^c</i>			
• Metformin therapy for preventing diabetes	Metformin medication	People who are at high risk (for example, prediabetes for type 2 diabetes)	Reduction in type 2 diabetes incidence by 33 percent
• Intensive glucose control	Insulin, oral glucose-lowering agents, or both	Diabetes, all ages, with HbA1c less than 9 percent	Reduction in microvascular disease
• Lipid control	Cholesterol-lowering medication	Diabetes, all ages, with high cholesterol	Reduction in cardiovascular disease events and mortality
• Screening for microalbuminuria	Screening for microalbuminuria and treating those who test positive	Diabetes, all ages	Reduction in kidney diseases
• Screening for undiagnosed diabetes	Screening for undiagnosed diabetes and treating those who test positive	People who are at high risk for type 2 diabetes	Reduction in microvascular disease
<i>Essential background intervention^d</i>			
Diabetes education	Patient self-management	Diabetes, all ages	Reduction in HbA1c level and better compliance with lifestyle changes
<i>Other promising intervention^e</i>			
Polypill	Hypothetical pill combining low doses of antihypertensive medication, aspirin, statin, and folate	Diabetes, all ages	Reduction in cardiovascular disease

Source: Authors.

a. Level 1 interventions are cost saving and highly feasible.

b. Level 2 interventions are cost saving or cost less than US\$1,500 per quality-adjusted life year but pose feasibility challenges.

c. Level 3 interventions cost between US\$1,640 and US\$8,550 per quality-adjusted life year and pose significant feasibility challenges.

d. Diabetes education is the backbone on which many diabetes interventions depend, but empirical data on the effectiveness of diabetes education on outcomes and on the precise components of diabetes education are still lacking.

e. An intervention that appears promising but needs further research to document its effectiveness and/or safety. The polypill is only a theoretical concept at this time and is not available for implementation.

long-term outcomes is needed. We also propose that further research be launched in relation to the novel and potentially promising polypill.

Finally, this chapter suggests a number of interventions at the level of the patient, provider, and system that could help address the overall suboptimal quality of diabetes care; notes the possible benefits of making important drugs available at cheaper costs in developing countries; and suggests some research priorities for developing regions.

Chapter 31

Mental Disorders

Steven Hyman, Dan Chisholm, Ronald Kessler, Vikram Patel,
and Harvey Whiteford

Mental disorders are diseases that affect cognition, emotion, and behavioral control and substantially interfere both with the ability of children to learn and with the ability of adults to function in their families, at work, and in the broader society. Mental disorders tend to begin early in life and often run a chronic recurrent course. They are common in all countries where their prevalence has been examined. Because of the combination of high prevalence, early onset, persistence, and impairment, mental disorders make a major contribution to total disease burden. Although most of the burden attributable to mental disorders is disability related, premature mortality, especially from suicide, is not insignificant. Table 31.1 summarizes discounted disability-adjusted life years (DALYs) for selected psychiatric conditions in 2001.

Mental disorders have complex etiologies that involve interactions among multiple genetic and nongenetic risk factors. Gender is related to risk in many cases: males have higher rates of attention deficit hyperactivity disorder, autism, and substance use disorders; females have higher rates of major depressive disorder, most anxiety disorders, and eating disorders. Biochemical and morphological abnormalities of the brain associated with schizophrenia, autism, mood, and anxiety disorders are being identified using approaches such as post-mortem analysis and noninvasive neuroimaging. Major worldwide efforts under way to identify risk-conferring genes for mental disorders are proving challenging, but initial results are promising. Identifying the gene or genes causing or creating vulnerability for a disorder should help us understand what goes wrong in the brain to produce mental illness and should have a clinical effect by contributing to improved diagnostics and therapeutics (Hyman 2000).

Twin studies make it clear that environmental risk factors also play an important role in mental disorders; concordance for disease among identical twins, although substantially higher than among nonidentical twins, is still well below 100 percent (Kendler and others 2003). However, as is the case for genetic factors, investigation of environmental risk factors has proved difficult. For schizophrenia, where nongenetic components of risk may include obstetrical complications and season of birth (Mortensen and others 1999), perhaps as a proxy for infections early in life, research has been hampered by the modest proven effect of the nongenetic risk factors identified to date. For depression, anxiety, and substance use disorders, where environmental risk factors are more robust, adverse circumstances associated with risk, such as early childhood abuse, violence, poverty, and stress (Patel and Kleinman 2003) correlate with multiple disorders and could be affected by selection bias as well as by bias associated with self-reporting. Generalizable, prospective cross-cultural studies are needed to delineate nongenetic risk factors more clearly. Posttraumatic stress disorder (PTSD) is the mental disorder for which clear environmental triggers are best documented. Even here, though, enormous interindividual variability occurs in the threshold of stress severity associated with PTSD as well as in the evidence from twin studies of genetic influences on stress reactivity in triggering PTSD.

The last half of the 20th century saw enormous progress in the development of treatments for mental disorders. Beginning in the early 1950s, effective psychotropic drugs were discovered that treated the symptoms of schizophrenia, bipolar disorder, major depression, anxiety disorders, obsessive-compulsive disorder, attention deficit hyperactivity disorder, and others. The safety and efficacy of antipsychotic, mood-stabilizing,

Table 31.1 Disease Burden of Selected Major Psychiatric Disorders, by World Bank Region

antidepressant, anxiolytic, and stimulant drugs have been established through a large number of randomized clinical trials. Psychosocial treatments have been developed and tested using modern methodologies. Brief, symptom-focused psychotherapies such as cognitive-behavioral therapies have been shown to be efficacious for panic disorder, phobias, obsessive-compulsive disorder, and major depression.

There is, however, an important caveat about the current knowledge base for treatment. As is the case for almost all of medicine, randomized clinical trials have been performed largely with highly selected populations in specialized research settings in industrial countries. A need exists to subject existing treatments to effectiveness trials in more representative populations and diverse settings, especially in developing countries. That limitation notwithstanding, a substantial body of knowl-

edge exists to guide treatment. It is particularly unfortunate, therefore, that timely diagnoses and the application of research-based treatments significantly lag behind the state of knowledge in industrial and developing countries alike. As a result, substantial opportunities exist to decrease the enormous burden attributable to mental disorders worldwide by closing the gap between *what we know* and *what we do*.

Mental disorders are stigmatized in many countries and cultures (Weiss and others 2001). Stigma has been facilitated by the slow emergence of convincing scientific explanations for the etiologies of mental disorders and by the mistaken belief that symptoms are caused by a lack of will power or reflect some moral taint. Recent scientific findings combined with educational efforts in some countries have begun to reduce the stigma (Rahman and others 1998), but shame and fear associated with

mental illness remain substantial obstacles to help seeking, to diagnosis, and to treatment worldwide. The stigmatization of mental illness has resulted in disparities, compared with other illnesses, in the availability of care, in research, and in abuses of the human rights of people with these disorders.

This chapter focuses on the attributable and avoidable burden of four leading contributors to mental ill health globally: schizophrenia and related nonaffective psychoses, bipolar affective disorder (manic-depressive illness), major depressive disorder, and panic disorder. The choice of these disorders is determined not only by their contribution to disease burden, but also by the availability of data for the cost-effectiveness analyses. Even where such data are available, they are often from industrial countries and extrapolation has been necessary. The exclusion of other mental disorders, such as childhood disorders, from analysis is not because the authors consider these disorders unimportant but because of the paucity of data. Also, this chapter does not specifically deal with the important issue of suicide. A background paper on suicide in developing countries has been developed as part of the Disease Control Priorities Project (DCPP) and is available (Vijayakumar, Nagaraj, and John 2004). The economic analysis presented in this chapter uses the cost-effectiveness analysis methodology specifically developed for the DCPP. The authors recognize that mental disorders impose costs and burdens on families as well as individuals that are not captured by the DALY. Treatment will alleviate some of this burden in addition to alleviating symptoms and disability.

A description of the major clinical features, natural course, epidemiology, burden, and treatment effectiveness for each group of disorders is given in the next section. For diagnostic criteria, readers are referred to *The ICD-10 Classification of Mental and Behavioral Disorders* (ICD-10) (WHO 1992) or *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IVTR) (American Psychiatric Association 2000). A discussion follows of population-level costs and cost-effectiveness of interventions capable of reducing the current burden associated with four disorders in different developing regions of the world (tables 31.2–31.6), before moving to a discussion of key issues and implications for mental health policy and improvement of services in developing regions of the world.

SCHIZOPHRENIA AND NONAFFECTIVE PSYCHOSES

Schizophrenia is a chronic disorder punctuated by episodes of florid psychotic symptoms, such as hallucinations and delusions. Hallucinations are sensory perceptions that occur in the absence of appropriate stimuli. Hallucinations may occur in any sensory modality but in schizophrenia are most commonly auditory—for example, hearing voices or noises. Delusions are

fixed false beliefs that are not explained by the person's culture and that the patient holds despite all reasonable evidence to the contrary.

Patients also exhibit *negative symptoms*—that is, deficits in normal capacities, such as marked social deficits, impoverishment of thought and speech, blunting of emotional responses, and lack of motivation. Additionally, patients typically have cognitive symptoms, such as disorganized or illogical thinking and an inability to hold goal information in mind to make decisions or plan actions.

Natural History and Course

Schizophrenia, as defined in current diagnostic manuals, is almost certainly heterogeneous, but still does not comprise all nonaffective psychoses (NAPs). In addition to schizophrenia, NAPs include schizophreniform disorder, characterized by schizophrenia-like symptoms of inadequate duration to qualify as schizophrenia. Because they cannot be readily disentangled in community epidemiological surveys, schizophrenia and other NAPs are considered together. Because of the data available, however, the cost-effectiveness analyses reported below are restricted to schizophrenia. Despite likely etiological heterogeneity, schizophrenia exhibits consistency in its symptom pattern across those countries and cultures studied (Jablensky and others 1992).

Incidence studies show that onset of schizophrenia and other NAPs is typically in middle to late adolescence for males and late adolescence to early adulthood for females, although later onsets are observed. Childhood-onset cases are quite rare but particularly severe (Nicolson and Rapoport 1999). Often, schizophrenia is first diagnosed with the occurrence of an acute episode of florid psychotic symptoms. The first psychotic episode is often preceded by prodromal symptoms such as social withdrawal, irritability or dysphoria, increasing academic or work-related difficulties, and increasing eccentricity. However, such symptoms are not specific; studies of whether early diagnosis and intervention can improve outcomes are under way (McGorry and others 2002).

The course of schizophrenia is typically one of acute exacerbations of severe psychotic symptoms, followed by full or partial remission. Psychotic episodes may be followed by a full remission after the first and occasionally other early episodes, but over time, residual symptoms and disability typically continue between relapses (Robinson and others 1999). The time between relapses is markedly extended by maintenance treatment with antipsychotic drugs, generally at lower doses than are needed to treat acute episodes. Cognitive and occupational functioning tends to decline over the first years of the illness and then to plateau at a level that is generally well below what would have been expected for the individual. Residual impairment, though, has substantial cross-cultural variation for reasons that are not well understood. Schizophrenia has consistently been found in epidemiological surveys to be highly

comorbid, usually with anxiety disorders, mood disorders, and substance use disorders (Kendler and others 1996).

Epidemiology and Burden

A great many studies of NAP incidence have been carried out in clinical samples. In a review of these studies, Jablensky (2000) found incidence estimates to be in the range of 0.002 to 0.011 percent per year for schizophrenia and 0.016 to 0.042 percent per year for overall NAP. Those annual estimates can be multiplied by the number of birth cohorts at risk to yield an estimate of lifetime risk in any one cohort. Assuming conservatively that the main age range of risk is between ages 15 and 55, researchers estimate lifetime risk is in the range of 0.08 to 0.44 percent for schizophrenia and in the range of 0.64 to 1.68 percent for NAPs. Lifetime prevalence estimates from community epidemiological surveys of NAPs are quite consistent with those from clinical studies, in the range of 0.3 to 1.6 percent (see, for example, Hwu, Yeh, and Cheng 1989; Kendler and others 1996).

Although schizophrenia is a relatively uncommon disorder, aggregate estimates of disease burden are high—around 2,000 DALYs lost per 1 million total population (table 31.1)—because the condition is associated with early onset, long duration, and severe disability.

Interventions

A substantial body of evidence exists on the efficacy of various treatments for schizophrenia and NAP and on the effectiveness of various models of health care delivery for persons with these disorders. This evidence comes primarily from industrial countries. The efficacy data show conclusively that antipsychotic drugs reduce severity of the episodes, hasten resolution of florid symptoms, and reduce duration of hospitalization. Maintenance treatment with antipsychotic drugs prolongs the period between relapses (Joy, Adams, and Lawrie 2001).

A second generation of antipsychotic medications (also called *atypical*) is replacing older *neuroleptic* antipsychotic drugs throughout the industrial world. In some clinical trials, second-generation drugs show small advantages in efficacy over first-generation drugs, but their widespread adoption results from marked improvement in tolerability. Their relative lack of side effects compared with first-generation drugs has led to improved quality of life and improved treatment adherence. Second-generation drugs are not without side effects, however; for example, some are associated with substantial weight gain and increased risk of diabetes. One drug, clozapine, has greater efficacy than other antipsychotic drugs, but because of a 1 percent risk of agranulocytosis, its use requires weekly blood counts and is cumbersome and expensive.

Psychosocial interventions also play an important role in managing schizophrenia (Bustillo and others 2001). Cognitive-

behavioral approaches to managing specific symptoms and improving medication adherence, group therapy, and family interventions all have demonstrated efficacy in improving clinical outcomes. Community-based models of mental health care delivery with case management and assertive outreach programs have been shown in health systems of industrial countries to be effective ways of managing schizophrenia in the community, for example, by reducing the need for hospital admissions. However, the applicability of these models to developing countries, as is discussed later, is hard to estimate because of differences in health system characteristics. Long-term remission rates for schizophrenia in developing countries appear to be significantly higher than those reported in industrial countries (Harrison and others 2001), likely resulting from such factors as strong family social support.

Despite their clear usefulness, current treatments do not prevent schizophrenia, and no clear evidence demonstrates that they induce full recovery or prevent premature mortality. Instead, treatment reduces time in episode of florid psychosis and increases time between episodes; thus treatment effects can be understood in terms of improvements in disability. Reported treatment effect sizes from meta-analyses in the literature, converted into improvements in the average level of disability (Andrews and others 2003; Sanderson and others 2004), show improvements (compared with no treatment) of 18 to 19 percent (antipsychotic drugs alone) and 30 to 31 percent (antipsychotic drugs with adjunctive psychosocial treatment). Placed on a disability scale of 0 to 1, where 0 equals no disability, an “average” case of schizophrenia moves from a disability level of 0.63 (untreated weight from the Global Burden of Disease study, Murray and Lopez 1996) to 0.43 to 0.54 (treated).

MOOD DISORDERS

The cardinal features of mood disorders are pervasive abnormalities in the predominant emotional state of the person, such as depressed, elated, or irritable. In mood disorders, these core emotional symptoms are accompanied by abnormalities in physiology, such as changes in patterns of sleep, appetite, and energy, and by changes in cognition and behavior. In developing countries, concurrent somatic symptoms are also commonly reported and may be the chief complaint. A generally accepted subclassification of mood disorders distinguishes unipolar depressive disorders from bipolar disorder (defined by the occurrence of mania). This distinction is based on symptoms, course of illness, patterns of familial transmission, and treatment response.

Bipolar Disorder

Bipolar disorder is characterized by episodes of mania and depression, often followed by relative periods of healthy mood

(euthymia). Mixed states with symptoms of both mania and depression also occur. Mania is typically characterized by euphoria or irritability, a marked increase in energy, and a decreased need for sleep. Individuals with mania often exhibit intrusive, impulsive, and disinhibited behaviors. They may be excessively involved in goal-directed behaviors characterized by poor judgment; for example, a person might spend all funds to which he or she has access and more. Self-esteem is typically inflated, frequently reaching delusional proportions. Speech is often rapid and difficult to interrupt. Individuals with mania also may exhibit cognitive symptoms; patients cannot stick to a topic and may jump rapidly from idea to idea, making comprehension of their train of thought difficult. Psychotic symptoms are common during manic episodes. The depressive episodes of people with bipolar disorder are symptomatically indistinguishable from those who have unipolar depressions alone. Unlike anxiety and unipolar mood disorders, which are more common in women, bipolar disorder has an equal gender ratio of lifetime prevalence, although the ratio of depressive-to-manic episodes is higher among bipolar women than men.

Natural History and Course. Retrospective reports from community epidemiological surveys consistently show that bipolar disorder has an early age of onset (in the late teens through mid-20s). Onset in childhood is increasingly recognized, although it remains controversial. Late onset is less common. The vast majority of patients with bipolar disorder have recurrent episodes of illness, both mania and depression. Classic descriptions of bipolar disorder suggest recovery to baseline functioning between episodes, but many patients have residual symptoms that may cause significant impairment (Angst and Sellaro 2000). These states of mania, depression, and lesser (or absent) symptoms are used in the intervention analysis below.

The rate of cycling between mania and depression varies widely among individuals. One common pattern of illness is for episodes initially to be separated by a relatively long period, perhaps a year, and then to become more frequent with age. A minority of patients with four or more cycles per year, termed *rapid cyclers*, tend to be more disabled and less responsive to existing treatments. Once cycles are established, most acute episodes start without an identifiable precipitant; the best documented exception is that manic episodes may be initiated by sleep deprivation, making a regular daily sleep schedule and avoidance of shift work important in management (Frank, Swartz, and Kupfer 2000).

Bipolar disorder has consistently been found in epidemiological surveys to be highly comorbid with other psychiatric disorders, especially anxiety and substance use disorders (ten Have and others 2002). The extent of comorbidity is much greater than for unipolar depressive disorders or anxiety disorders. Some individuals with classic symptoms of bipolar

disorder also exhibit chronic psychotic symptoms superimposed on their mood syndrome. These individuals are said to have schizoaffective disorder. Their prognosis tends to be less favorable than for the usual bipolar patient, although somewhat better than for individuals with schizophrenia. Schizoaffective disorder may also be diagnosed when chronic psychotic symptoms are superimposed on unipolar depression. Individuals with this combination of symptoms have outcomes similar to patients with schizophrenia (Tsuang and Coryell 1993).

Epidemiology and Burden. Lifetime and 12-month prevalence estimates of bipolar disorder have been reported from a number of community psychiatric epidemiological surveys. Lifetime prevalence estimates are in the range 0.1 to 2.0 percent (Vega and others 1998; Vicente and others 2002), with a weighted mean across surveys of 0.7 percent. Prevalence estimates for past-year episodes have a similarly wide range (0.1 to 1.3 percent) (Vega and others 1998) and a weighted mean of 0.5 percent. It is important to note that good evidence exists suggesting that bipolar disorder has a wide subthreshold spectrum that includes people who are often seriously impaired even though they do not meet full DSM or ICD criteria for the disorder (Perugi and Akiskal 2002). This spectrum might include as much as 5 percent of the general population. The ratio of recent-to-lifetime prevalence of bipolar disorder in community surveys is quite high (0.71), indicating that bipolar disorder is persistent.

Epidemiological data show that bipolar disorder is associated with substantial impairments in both productive and social roles (Das Gupta and Guest 2002). Epidemiological evidence documents consistent delays in patients initially seeking professional treatment (Olfson and others 1998), especially among early-onset cases, as well as substantial undertreatment of current cases. Each of these characteristics—chronic, recurrent course; significant impairments to functioning; modest treatment rates—contributes to estimates of aggregate disease burden that approach those for schizophrenia (1,200 to 1,800 DALYs lost per 1 million population, making up more than 5 percent of the burden attributable to neuropsychiatric disorders as a whole—see table 31.1).

Interventions. Analyses of the primary treatment approaches for bipolar disorder are based on the three health states that characterize the disorder—mania, depression, and euthymia. Robust evidence from controlled trials shows that antipsychotic drugs and some benzodiazepines produce a relatively rapid reduction in symptoms of a manic phase. Mood-stabilizing drugs act more slowly, but they reduce the severity and duration of acute manic episodes. Maintenance treatment with two mood-stabilizing drugs—lithium and valproic acid (administered as sodium valproate)—has been shown to have

significant, albeit partial, efficacy in reducing rates of both manic and depressive relapses. The drawback of lithium is that toxic levels are not much greater than therapeutic levels; thus, serum-level monitoring is required.

For the cost-effectiveness analyses, lithium and valproic acid, which have empirical data supporting their efficacy in treating and preventing manic and depressive episodes, were considered. Because evidence suggests that psychosocial approaches enhance compliance with medication (Huxley, Parikh, and Baldessarini 2000), adjuvant strategies also were assessed. The primary treatment effect was a change in the population-level disability associated with bipolar disorder (a weighted average of time spent in a manic, depressed, or euthymic phase of illness). Both an acute treatment effect—calculated as the product of initial response and reduced episode duration—and a prophylactic treatment effect were ascribed to lithium and valproic acid, resulting in an estimated improvement of close to 50 percent over the untreated composite disability weight of 0.445 (Chisholm and others forthcoming). This estimate then was adjusted for expected nonadherence to treatment in real-world clinical settings—slightly lower for lithium than for valproic acid (Bowden and others 2000). A secondary effect of treatment—reduction of the case fatality rate by two-thirds—was also ascribed to lithium, though, because of an absence of current evidence, not to valproic acid (Goodwin and others 2003). This reduction was derived through a change in the standardized mortality ratio from 2.5 to 1.5, estimated on the basis of natural history studies reported for the prelithium era (for example, Astrup, Fossum, and Holmboe 1959; Helgason 1964) to the postlithium era (for example, Goodwin and others 2003).

Major Depressive Disorder

The core symptom of major depression is a disturbance of mood; sadness is most typical, but anger, irritability, and loss of interest in usual pursuits may predominate. Often the affected person is unable to experience pleasure (anhedonia) and may feel hopeless. In many countries of the developing world, patients will not complain of such emotional symptoms, but rather of physical symptoms, such as fatigue or multiple aches and pains.

Typical physiological symptoms that occur across cultures include sleep disturbance (most often insomnia with early morning awakening, but occasionally excessive sleeping); appetite disturbance (usually loss of appetite and weight loss, but occasionally excessive eating); and decreased energy. Behaviorally, some individuals with depression exhibit slowed motor movements (psychomotor retardation), whereas others may be agitated. Cognitive symptoms may include thoughts of worthlessness and guilt, suicidal thoughts, difficulty concen-

trating, slow thinking, and poor memory. Psychotic symptoms occur in a minority of cases.

Natural History and Course. Major depression is an episodic disorder that generally begins early in life (median age of onset in the mid to late 20s in community epidemiological surveys), although new onsets can be observed across the lifespan. Childhood onset is being increasingly recognized, although not all childhood precursors of adult depression take the form of a clear depressive disorder. Most individuals suffering from a depressive episode will have a recurrence (Mueller and others 1999), with recurrence risk greater among those with early-onset disease. Many individuals do not recover completely from their acute episodes and have chronic milder depression punctuated by acute exacerbations (Judd and others 1998). The current term for chronic, milder depression lasting more than two years is *dysthymia*. Although the symptoms of minor depression are, by definition, less severe than those of a major depressive episode, chronicity ultimately makes even this lesser form of the illness very disabling in many cases (Judd, Schettler, and Akiskal 2002). Depression has consistently been found in epidemiological surveys to be highly comorbid with other mental disorders, with roughly half the people who have a history of depression also having a lifetime anxiety disorder. Comorbidities of depression and anxiety disorders are generally strongest with generalized anxiety disorder and panic disorder (Kessler and others 1996).

Epidemiology and Burden. Prevalence of nonbipolar depression has been estimated in a number of large-scale community epidemiological surveys. Lifetime prevalence estimates of having either major depressive disorder or dysthymia in these surveys are in the range 4.2 to 17.0 percent (Andrade and others 2003; Bijl and others 1998), with a weighted mean of 12.1 percent. Six- to 12-month prevalence estimates have a similarly wide range (1.9 to 10.9 percent) (Andrade and others 2003; Robins and Regier 1991), with a weighted mean of 5.8 percent. These wide differences in prevalence likely represent the difficulties inherent in self-reporting of conditions that are invariably stigmatized across cultures. Prevalence estimates are consistently highest in North America and lowest in Asia (with prevalence estimates of major depressive disorders generally a good deal higher than those of dysthymia).

Epidemiological data document consistent delays in patients initially seeking professional treatment for depression, especially among early-onset cases (Olfson and others 1998), as well as substantial undertreatment. For example, World Mental Health surveys in six Western European countries found that only 36.6 percent of people with active nonbipolar depression in the 12 months before the survey received any professional treatment for this disorder during the subsequent year

(ESEMED/MHEDEA 2000 Investigators 2004). The situation is even worse in developing countries, where the vast majority of people with depression who seek help do so in general health care settings and complain of nonspecific physical symptoms. Such individuals receive a correct diagnosis in less than one-quarter of cases and typically are treated with medicines of doubtful efficacy (Linden and others 1999).

Depression is consistently found in community surveys to be associated with substantial impairments in both productive and social roles (Wang, Simon, and Kessler 2003). As with bipolar depression, but exacerbated by its high incidence, the recurrent nature and disabling consequences of (unipolar) depression mean that overall disease burden estimates are high in all regions of the world (5,000 to 10,000 DALYs per 1 million population, as much as 5 percent of the total burden of disease from all causes; table 31.1). Depression is, in fact, ranked as the fourth leading cause of disease burden globally and represents the single largest contributor to nonfatal burden (Ustun and others 2004).

Interventions. Efficacy has been demonstrated for several classes of antidepressant drugs and for two psychosocial treatments for depression (Paykel and Priest 1992). The older tricyclic antidepressants (TCAs) and newer drugs, including the selective serotonin reuptake inhibitors (SSRIs), have similar efficacy. The newer drugs have milder side-effect profiles and are consequently more likely to be tolerated at therapeutic doses (Pereira and Patel 1999). SSRIs have not been widely used in developing countries because of their higher cost, although as the patent protection expires, this situation is likely to change (Patel 1996). Of the psychosocial treatments with demonstrated efficacy, the most widely accepted are cognitive-behavioral approaches. Alone or in combination, drug and psychosocial treatments speed recovery from acute episodes. Maintenance treatment with drugs decreases relapse risk (Geddes and others 2003). Some evidence suggests that a course of psychotherapy may also delay relapses. Although most of the clinical trials have been carried out in industrial countries, at least three high-quality trials have demonstrated the efficacy of antidepressants, group therapy, or both in developing countries (Araya and others 2003; Bolton and others 2003; Patel and others 2003).

For the cost-effectiveness analyses, depression was modeled as an episodic disorder with a high rate of remission and subsequent recurrence, and with excess mortality from suicide (Chisholm and others 2004). None of the selected depression interventions was accorded a reduction in case fatality, however, owing to the lack of robust clinical evidence that antidepressants or psychotherapy in themselves alter the relative risk of death by suicide (Storosum and others 2001). The main modeled impact of intervention targeted toward episodic treatment of a new

depressive episode was a reduction in the duration of time depressed, equivalent to an increase in the remission rate (25 to 40 percent improvement over no treatment; Malt and others 1999; Solomon and others 1997). In addition, all interventions were attributed a modest improvement in the level of disability for an unremitted depressive episode (10 to 15 percent), resulting from increased proportions of cases moving from more to less severe health states. For the estimated 56 percent of prevalent cases eligible for maintenance treatment (at least two lifetime episodes), an additional effect of efficacious maintenance treatment was incorporated into the analysis by reducing the incidence of recurrent episodes by 50 percent (Geddes and others 2003). Estimates of intervention effectiveness include the positive change that would occur naturally and also incorporate any placebo effect, which, in the treatment of depression, is not inconsiderable (Andrews 2001).

ANXIETY DISORDERS

Anxiety disorders are a group of disorders that have as their central feature the inability to regulate fear or worry. Although anxiety in itself is likely to feature in the clinical presentation of most patients, somatic complaints such as chest pain, palpitations, respiratory difficulty, headaches, and the like are also common, and these symptoms may be more common in developing countries. A number of different types of anxiety disorder exist, some of which are now briefly described.

The central feature of *panic disorder* is an unexpected panic attack, which is a discrete period of intense fear accompanied by physiologic symptoms such as a racing heart, shortness of breath, sweating, or dizziness. The person may have an intense fear of losing control or of dying. Panic disorder is diagnosed when panic attacks are recurrent and give rise to anticipatory anxiety about additional attacks. People with panic disorder may progressively restrict their lives to avoid situations in which panic attacks occur or situations from which it might be difficult to escape should a panic attack occur. They commonly avoid crowds, traveling, bridges, and elevators, and ultimately some individuals may stop leaving home altogether. Pervasive phobic avoidance is described as agoraphobia.

Generalized anxiety disorder is characterized by chronic unrealistic and excessive worry. These symptoms are accompanied by specific anxiety-related symptoms such as sympathetic nervous system arousal, excessive vigilance, and motor tension. *Posttraumatic stress disorder* follows serious trauma. It is characterized by emotional numbness, punctuated by intrusive reliving of the traumatic episode, generally initiated by environmental cues that act as reminders of the trauma; by disturbed sleep; and by hyperarousal, such as exaggerated startle responses.

Social anxiety disorder (social phobia) is characterized by a persistent fear of social situations or performance situations that expose a person to potential scrutiny by others. The affected person has intense fear that he or she will act in a way that will be humiliating. Separating social anxiety disorder from extremes of normal temperament, such as shyness, is difficult. Nonetheless, social anxiety disorder can be quite disabling. *Simple phobias* are extreme fear in the presence of discrete stimuli or cues, such as fear of heights.

The core features of *obsessive-compulsive disorder* are obsessions (intrusive, unwanted thoughts) and compulsions (performance of highly ritualized behaviors intended to neutralize the negative thoughts and emotions resulting from the obsessions). One symptom pattern might be repetitive hand washing beyond the point of skin damage to neutralize fears of contamination.

Natural History and Course

The anxiety disorders differ in their age of onset, course of illness, and symptom triggers. One of these disorders, PTSD, is dependent for its etiology on one or more powerfully negative life events. Although the anxiety disorders are discussed as a group, panic disorder is chosen because of the available data for the purposes of the cost-effectiveness analysis.

Prevalence estimates of anxiety disorders based on community epidemiological surveys vary widely, from a low of 2.2 percent (Andrade and others 2003) to a high of 28.5 percent (Kessler and others 1994), with a weighted mean across surveys of 15.6 percent. Prevalence estimates for anxiety disorders in the past 6 to 12 months have a similarly wide range (1.2 to 19.3 percent) (Andrade and others 2003; Kessler and others 1994), with a weighted mean of 9.4 percent. Despite wide variation in overall prevalence, several clear relative prevalence patterns can be seen across surveys. Specific phobia is generally the most prevalent lifetime anxiety disorder, with social phobia generally the second most prevalent lifetime anxiety disorder. Panic disorder and obsessive-compulsive disorder are generally the least prevalent.

These surveys also provide evidence about the persistence of anxiety disorders, indirectly defined as the ratio of 6-month or 12-month to lifetime prevalence. This ratio averages approximately 60 percent for overall anxiety disorders, indicating a high rate of persistence across the life course. The highest persistence is generally found for social phobia, and the lowest for agoraphobia. These estimates of high persistence are consistent with results obtained from longitudinal studies of patients (Yonkers and others 2003).

Anxiety disorders have consistently been found in epidemiological surveys to be highly comorbid both among themselves and with mood disorders (for example, de Graaf and others 2003). The vast majority of people with a history of one anxiety

disorder typically also have a second anxiety disorder, while more than half the people with a history of either anxiety or mood disorder typically have both types of disorder. Retrospective reports from community surveys consistently show that anxiety disorders have early average ages of onset. An impressive cross-national consistency can be seen in these patterns, with an estimated median age of onset of anxiety at approximately 15.

Epidemiological surveys have also looked at the treatment of anxiety disorders. As with depression, consistent evidence in these surveys suggests that delays in initially seeking professional treatment for an anxiety disorder are widespread after first onset (Olfson and others 1998). This finding is especially true among early-onset cases. Epidemiological data also show that only a minority of current cases receive any formal treatment in Western countries, whereas treatment of anxiety disorders is virtually nonexistent in many developing countries. The most recently published surveys, the World Mental Health surveys in six Western European countries, found that only 26.3 percent of people with an active anxiety disorder in the 12 months before the survey received any professional treatment (ESEMeD/MHEDEA 2000 Investigators 2004).

Anxiety disorders have consistently been found to be associated with substantial impairments in both productive roles (for example, work absenteeism, work performance, unemployment, and underemployment) and social roles (social isolation, interpersonal tensions, and marital disruption, among others) (see, for example, Kessler and Frank 1997). As noted earlier, for the purposes of this chapter, one of the anxiety disorders—panic disorder—has been chosen to describe interventions and undertake cost-effectiveness analysis. Panic disorder is as disabling as obsessive-compulsive disorder and PTSD, accounts for about one-third of all seriously impairing anxiety disorders, is one of the most common anxiety disorders presenting for treatment, and imposes an estimated burden of 600 to 800 DALYs per 1 million population.

Good evidence exists that both drug and psychosocial treatments are effective for managing anxiety disorders. Antidepressant drugs (both older TCAs and SSRIs) have been shown to be effective for the treatment of several anxiety disorders, including panic disorder, reducing the duration and intensity of the disorder. Although high-potency benzodiazepines are efficacious for panic disorder, these drugs carry a risk of dependence and are not considered the first line of treatment. Psychosocial treatments, especially cognitive-behavioral therapy, are also effective in diminishing both panic attacks and phobic avoidance.

Interventions for Panic Disorder

Although evidence-based interventions for panic disorder have yet to be evaluated or made widely available in developing

countries, the potential population-level impact of a number of interventions—including older and newer antidepressants, anxiolytic drugs (benzodiazepines), and psychosocial treatments—was examined. Interventions reduce the severity of panic attacks and improve the probability of making a full recovery. Effect sizes for symptom improvement were drawn from a meta-analysis of the long-term effects of intervention of panic disorder (Bakker and others 1998) and converted into an equivalent change in disability weight (Sanderson and others 2004). Concerning remission, a number of controlled and naturalistic studies (for example, Faravelli, Paterniti, and Scarpato 1995; Yonkers and others 2003) reveal a consistent remission rate of 12 to 13 percent for pharmacological and combination strategies—except for benzodiazepine use, for which the evidence is that longer-term recovery is actually worse than placebo (Katschnig and others 1995)—which represents a 62 percent improvement in efficacy over the untreated remission rate (7.4 percent).

COST-EFFECTIVENESS METHODS AND RESULTS

This section estimates the burden attributed to schizophrenia, bipolar disorder, depression, and panic disorder that could be averted (through scaling up) by proven, efficacious treatments. It is followed by calculations of the expected cost and cost-effectiveness of such treatments. Analysis is conducted at the level of six low- and middle-income geographical World Bank regions.

Estimation of Population-Level Effectiveness of Treatments

In modeling the impact of mental health interventions, we used a state-transition model (Lauer and others 2003) that traces the development of a population, taking into account births, deaths, and the disease in question. In addition to population size and structure, the model makes use of a number of epidemiological parameters (incidence and prevalence, remission, and cause-specific and residual rates of mortality) and assigns age- and gender-specific disability weights to both the disease in question and the general population. The output of the model is an estimate of the total healthy life years experienced by the population over a lifetime period (100 years). The model was run for a number of possible scenarios, including no treatment at all (natural history), current treatment coverage, and scaled-up coverage of current as well as potential new interventions. For the treatment scenarios, an implementation period of 10 years was used (thereafter, epidemiological rates and health state valuations return to natural history levels). The model derived the number of additional healthy years gained (equivalent to DALYs averted) each year in the population compared with the outcome for no treatment at all. DALYs averted in future years were discounted at a rate of 3 percent

(reflecting a societal preference for health benefits to be realized sooner), but no age-weighting was used.

Estimation of the baseline epidemiological situation that would prevail without treatment used incidence and prevalence estimates from the Global Burden of Disease 2000 study of the World Health Organization (WHO) (see online Global Burden of Disease documentation for the four disorders at <http://www.who.int/evidence/bod>). Current pharmacological or psychosocial treatments do not exert a primary preventive effect on the onset of the four conditions (although some evidence exists that treating depression in parents may reduce risk for offspring), indicating that currently observed incidence rates coincide with those that would pertain under no treatment. Prevention of recurrences of acute episodes (secondary prevention) has been demonstrated for maintenance treatments for major depression and bipolar disorder. Maintenance treatment with antipsychotic drugs decreases the risk of recurrent acute episodes of schizophrenia. For each condition, a range of treatment strategies was considered and assessed, including older (and widely available) psychotherapeutic drugs, newer pharmacotherapies, psychosocial treatments, and combination treatments (see table 31.2 for a list of interventions included).

Estimation of Population-Level Treatment Costs

Cost estimation followed the principles and procedures described in chapter 7 for carrying out economic analyses of disease control priorities in developing countries. For depression and panic disorder, treatment was assumed to occur in a primary care setting, whereas for schizophrenia and bipolar disorder, which often produce highly disruptive behaviors, both hospital- and community-based outpatient service models were derived and compared. Both program- and patient-level costs were identified and estimated. Program-level costs included the infrastructure and administrative support for implementing mental health treatments, as well as training inputs (for example, two to three days per trainee were estimated for training primary care doctors and case managers in psychotropic medication management). Patient-level resource inputs included medication regimens (for example, fluoxetine, 20 milligrams daily), laboratory tests (for example, lithium blood levels), primary care visits (including any contacts with a case manager), and hospital outpatient and inpatient care. Estimated patient-level resource inputs for each of the four disorders were informed by empirical economic evaluative studies (for example, Patel and others 2003; Srinivasa Murthy and others 2005) as well as a multinational Delphi consensus study of resource use for psychiatric disorders in seven developing countries (Ferri and others 2004). Region-specific unit costs or prices were applied to all resource inputs (see Mulligan and others 2003) to give an annual cost for each case as well as for all cases at the specified level of treatment

Table 31.2 Interventions for Reducing the Burden of Major Psychiatric Disorders in Developing Countries

Disorder	Intervention	Example
<i>Schizophrenia</i> Treatment setting: hospital outpatient Treatment coverage (target): 80 percent	Older (neuroleptic) antipsychotic drug	Haloperidol
	Newer (atypical) antipsychotic drug	Risperidone
	Older antipsychotic drug and psychosocial treatment	Haloperidol plus family psychoeducation
	Newer antipsychotic drug and psychosocial treatment	Risperidone plus family psychoeducation
<i>Bipolar affective disorder</i> Treatment setting: hospital outpatient Treatment coverage (target): 50 percent	Older mood-stabilizing drug	Lithium carbonate
	Newer mood-stabilizing drug	Sodium valproate
	Older mood-stabilizing drug and psychosocial treatment	Lithium plus family psychoeducation
	Newer mood-stabilizing drug and psychosocial treatment	Valproate plus family psychoeducation
<i>Depression</i> Treatment setting: primary health care Treatment coverage (target): 50 percent	Episodic treatment	
	Older TCA	Imipramine or amitriptyline
	Newer antidepressant drug (SSRI; generic)	Fluoxetine
	Psychosocial treatment	Group psychotherapy
	Older antidepressant drug and psychosocial treatment	Amitriptyline plus group psychotherapy
	Newer antidepressant drug and psychosocial treatment	Fluoxetine plus group psychotherapy
	Maintenance treatment	
	Older antidepressant drug and psychosocial treatment Newer antidepressant drug and psychosocial treatment	Imipramine plus group psychotherapy Fluoxetine plus group psychotherapy
<i>Panic disorder</i> Treatment setting: primary health care Treatment coverage (target): 50 percent	Benzodiazepines	Alprazolam
	Older TCA	Amitriptyline
	Newer antidepressant drug (SSRI; generic)	Fluoxetine
	Psychosocial treatment	Cognitive therapy
	Older antidepressant drug and psychosocial treatment	Amitriptyline plus cognitive therapy
	Newer antidepressant drug and psychosocial treatment	Fluoxetine plus cognitive therapy

coverage. Costs incurred over the 10-year implementation period were discounted at 3 percent and expressed in U.S. dollars (rather than international dollars, which attempt to adjust for differences in purchasing power between countries).

Coverage

In each World Bank region, treatment costs and effects were ascribed to the population in need, both at current levels of intervention coverage and at a scaled-up, target level of coverage (80 percent for schizophrenia, 50 percent for the other conditions). Target coverage levels were predicated on the basis of what could feasibly be achieved given existing rates of treatment (Ferri and others 2004; Kohn and others 2004), as well as on prerequisites for increased coverage, such as recognition of common mental disorders in primary care. Estimation of current regional levels of effective coverage is hampered by lack of data; nevertheless, an attempt was made to approximate the expected proportion of the diseased population receiving

evidence-based pharmacological and psychosocial treatments (Ferri and others 2004; Kohn and others 2004), plus those in contact with traditional healers (the effectiveness of which was conservatively approximated by ascribing a placebo effect size for each disorder).

Results

Tables 31.3 through 31.6 provide estimates of the population-level effects (measured in DALYs averted), costs, and cost-effectiveness of each intervention by world region for the four types of psychiatric disorder considered in this chapter. A number of key findings emerge from this analysis.

Treatment Effectiveness. Results for schizophrenia and bipolar disorder are similar (albeit at differing coverage levels), ranging from less than 100 DALYs averted per 1 million population under the current situation in Sub-Saharan Africa and South Asia to 350 to 400 DALYs averted per 1 million population for

combination drug and psychosocial interventions in Europe and Central Asia and East Asia and the Pacific. Second-generation (atypical) antipsychotic drugs were considered slightly more effective than first-generation drugs (on the basis of a modest intrinsic efficacy difference and differences in

tolerability and adherence); lithium was considered modestly more effective as a mood-stabilizing drug than valproate (on the basis of its additional positive effect on suicide rates). Adjuvant psychosocial treatment in combination with pharmacotherapy significantly added to expected population-level health gain.

With the exception of Europe and Central Asia, less than 10 percent of the disease burden currently is being averted, whereas the implementation of combined interventions at a scaled-up level of coverage is expected to avert 14 to 22 percent of the burden of schizophrenia (coverage level, 80 percent) and 17 to 29 percent of the burden of bipolar disorder (coverage level, 50 percent).

For primary care treatment of common mental disorders, including depression and panic disorder, current levels of effective coverage avert only 3 to 8 percent of the existing disease burden, whereas scaling up of the most effective interventions to a coverage level of 50 percent could be expected to avert more than 20 percent of the burden of depression and up to one-third of the burden of panic disorder. Considered at a population level, episodic treatments for depressive episodes did not differ substantially within regions (averting 10 to 15 percent of current burden); more substantial health gain is expected by providing maintenance treatment to individuals with recurrent depression (approximately 1,200 to 1,900 DALYs averted per 1 million population; 18 to 23 percent of burden). Such an approach has been found to reduce the risk of relapse by half. Although the evidence to date from developing regions is meager, our results suggest that SSRIs such as fluoxetine, alone or in combination with psychosocial treatment, are the most effective treatments for panic disorder, with health gains considerably better than those estimated for benzodiazepine anxiolytic drugs such as alprazolam.

Treatment Costs. Community-based service models for schizophrenia and bipolar disorder were found to be appreciably less costly than hospital-based service models (for example, interventions for bipolar disorder were 25 to 40 percent less costly). The total cost per capita of community-based outpatient treatment with first-generation antipsychotic or mood-stabilizing drugs, including all patient-level resource needs as well as infrastructural support, ranged from US\$0.40 to US\$0.50 in Sub-Saharan Africa and South Asia to US\$1.20 to US\$1.90 in Latin America and the Caribbean and in Europe and Central Asia (equivalent patient costs per year, US\$170 to US\$300 and US\$300 to US\$800, respectively). The cost per capita for interventions using second-generation (atypical) antipsychotic drugs still under patent is much higher (US\$2.50 to US\$5.00). By contrast, some of the newer antidepressant drugs (SSRIs) are now off patent, and their use in treating depression and panic disorder was accordingly costed at their generic, nonbranded price. The patient-level cost of treating a 6-month episode of depression ranged from as little as US\$30 (older antidepressants in Sub-Saharan Africa or South Asia) to US\$150 (newer antidepressants in combination with brief psychotherapy in Latin America and the Caribbean). Total annual costs for all incidents of depressive episodes receiving treatment, including training and other program-level costs, were as much as US\$2 to US\$5 per capita for a maintenance treatment

program using newer antidepressants, three times more costly than episodic treatment with newer antidepressant drugs only. Patient-level resource inputs for panic disorder interventions cost US\$50 to US\$200 per case per year, and overall costs including program costs of training and administration amounted to US\$0.10 to US\$0.30 per capita.

Cost-Effectiveness. Compared with both the current situation and the epidemiological situation of no treatment (natural history), the most cost-effective strategy for averting the burden of psychosis and severe affective disorders in developing countries is expected to be a combined intervention of first-generation antipsychotic or mood-stabilizing drugs with adjuvant psychosocial treatment delivered through a community-based outpatient service model, with a cost-effectiveness ratio of below US\$2,000 in Sub-Saharan Africa and South Asia, rising to US\$5,000 in Latin America and the Caribbean (equivalent to more than 500 DALYs averted per US\$1 million expenditure in Sub-Saharan Africa and South Asia and 200 DALYs averted in Latin America and the Caribbean). Currently, the high acquisition price of second-generation antipsychotic drugs makes their use in developing regions questionable on efficiency grounds, although this situation can be expected to change as these drugs come off patent. By contrast, evidence indicates that the relatively modest additional cost of adjuvant psychosocial treatment reaps significant health gains, thereby making such a combined strategy for schizophrenia and bipolar disorder treatment more cost-effective than pharmacotherapy alone.

For more common mental disorders treated in primary care settings (depressive and anxiety disorders), the single most cost-effective strategy is the scaled-up use of older antidepressants (because of their lower cost but similar efficacy compared with newer antidepressants). However, as the price margin between older and generic newer antidepressants continues to diminish, generic SSRIs—which have milder side effects and are more likely to be taken at a therapeutic dose (Pereira and Patel 1999)—can be expected to be at least as cost-effective and, therefore, the pharmacological treatment of choice in the future. Because depression is often a recurring condition, proactive care management, including long-term maintenance treatment with antidepressant drugs, represents a cost-effective way of significantly reducing the enormous burden of depression that exists in developing regions now (400 to 1,300 DALYs averted per US\$1 million expenditure).

POLICY AND SERVICE IMPLICATIONS

Many attempts have been made during the past 50 years to have mental health care placed higher on national and international agendas. In 1974, a WHO Expert Committee on the

Organization of Mental Health Services in Developing Countries (WHO 1975) made the following recommendations:

- Develop a national mental health policy and create a unit within the Health Ministry to implement it.
- Budget for workforce development, essential drug procurement, infrastructure development, data collection, and research.
- Decentralize service provision and integrate mental health into primary health care.
- Train and supervise primary health care providers in mental health using specialist mental health staff.

Thirty years later, international agencies, nongovernmental organizations, and professional bodies continue to make those exact recommendations. One reason for the lack of action in mental health has been the paucity of information on the cost-effectiveness of mental health interventions. Advocacy without the necessary science can readily be ignored in countries with massive health problems and meager resources. This chapter aims to address this deficiency.

Symptoms of mental disorders are often attributed to other illnesses, and mental disorders are often not considered health problems (Jacob 2001). Many nonscientific explanations for mental illness exist, and stigma exists to varying degrees everywhere (Weiss and others 2001) with widespread delays or failure to seek appropriate care (James and others 2002).

When care is sought, a hierarchy of interventions comes into play, ranging from self-help, informal community support, traditional healers, primary health care, specialist community mental health care, and psychiatric units in general hospitals to specialist long-stay mental hospitals. The mix of interventions depends on the availability of resources within a country or region (Saxena and Maulik 2003). The more resource-constrained the country or region is, the greater is the reliance on self-help, informal community support (especially family-based), and primary health care.

Traditional healers are often the first source individuals with mental illness and their families turn to for professional assistance (see, for example, Abiodun 1995). A recent review of common mental disorders among primary health clinics and traditional healers in urban Tanzania showed that the prevalence of common mental disorders among those attending traditional healers was double that of patients at primary health care centers (Ngoma, Prince, and Mann 2003). Traditional healers are a heterogeneous group and include faith healers, spiritual healers, religious healers, and practitioners of indigenous or alternative systems of medicine. In some countries, they are part of the informal health sector, but in other countries, traditional healers charge for their services and should be considered part of the private health care sector. Often, traditional healers have high acceptability and are accessible; at times, traditional healers

work closely (and apparently effectively) with conventional mental health services (Thara, Padmavati, and Srinivasan 2004). Alternatively, animosity and competition can exist, and recent examples of human rights violations by traditional healers demonstrate the heterogeneity of this group of providers.

The formal diagnosis and treatment of mental disorders occur in both primary and specialist health services. Examples in nearly a dozen countries now show it is feasible and practicable to treat common mental disorders in primary health care settings (for example, Chisholm and others 2000; De Jong 1996; Mohit and others 1999). The challenge is to enhance systems of care by taking effective local models and disseminating them throughout a country.

Concern has been expressed that the more sophisticated psychotherapies used in mental health care are beyond the human resources of developing countries. However, basic psychological therapies can be effective, though there is some evidence, at least for depression, that the newer drug therapies are more cost-effective than psychological therapies (Patel and others 2003). Psychoeducational family intervention has been shown to be suitable for rehabilitation in schizophrenia in rural China (Ran and others 2003) and to be cost-effective compared with other standard treatment (Xiong and others 1994). Evidence also shows that nurses can replace physicians as primary health care providers in certain circumstances without loss of effectiveness (Climent and others 1978). Primary care practitioners need support to develop skills and experience in diagnosing and treating mental disorders: they need a sustainable supply of medicines, access to supervision, and incentives to see patients with mental illness (Abas and others 2003). Community approaches using low-cost, locally available resources may improve treatment adherence and clinical outcomes even in rural and underresourced settings (Chatterjee and others 2003; Srinivasa Murthy and others 2005).

In most countries, acute inpatient beds are being moved from mental hospitals into general or district hospitals. Although this policy potentially improves accessibility and increases the links with, and support provided to, primary mental health care, concerns can be raised as to whether general hospitals can adapt to provide adequate services to people with severe mental disorders. However, such services have been effectively established in a number of countries (see, for example, Alem and others 1999; Kilonzo and Simmons 1998), showing this form of service delivery to be feasible when it is clinically indicated.

Nongovernmental organizations are important providers of mental health care. An estimated 93 percent of African and 80 percent of Southeast Asian countries have nongovernmental organizations in the mental health sector. They provide diverse services—including advocacy, informal support, housing, suicide prevention, substance misuse counseling, dementia support, rehabilitation, research, and other programs—that

complement, or in some cases substitute for, public and private clinical services (Levkoff, Macarthur, and Bucknall 1995; Patel and Thara 2003).

Services for children and adolescents, the majority of the population in many developing countries, are even more deficient than those for adults. Priority needs to be given to these services (Rahman and others 2000). At the other end of the life spectrum, many developing countries are facing aging populations with grossly underdeveloped aged care services (Levkoff, Macarthur, and Bucknall 1995). The high level of civil conflict and natural disasters requires attention to postconflict and posttrauma mental health conditions. The prevalence of these disorders is demonstrated by a recent study (Livanou, Basoglu, and Kalendar 2002) showing that, of 1,000 survivors of the August 1999 earthquake in Turkey, the incidence of PTSD was 63 percent and of depression was 42 percent.

Specialist mental health providers, especially mental hospitals, tend to focus the services they provide on the lower-prevalence, higher-disability disorders, such as schizophrenia and bipolar disorder. Modern treatments, if available and used, allow most patients to be treated effectively out of hospital. Specifically, the use of antipsychotic and mood-stabilizing drugs and the development of strategies for community-based treatment have led to the closing of large numbers of psychiatric inpatient beds in many countries and their replacement with community services and general hospital psychiatric units (for example, Larrobla and Botega 2001).

However, in some countries, the majority of psychotic patients remain in long-term inpatient facilities that engage in custodial care, which is often of poor quality; moreover, basic rights are often violated at such facilities (van Voren and Whiteford 2000). Even if the quality of care is reasonable, accessibility is a problem: these hospitals are often situated in urban areas, but populations are largely rural and have limited transportation (Saraceno and others 1995). Furthermore, the concentration of resources in these facilities can leave little for other service components (Gallegos and Montero 1999). For example, in Indonesia, 97 percent of the mental health budget is spent on public mental hospitals (Trisnantoro 2002). For many developing countries, the debate about the role of, or problems with, mental hospitals is subsumed within a gross deficiency of psychiatric beds of any kind.

The priority for virtually all countries is generating sufficient resources for primary mental health care and deciding how to expand and best use scarce specialist resources. The quality of care is often very poor, and huge variations exist in resource availability between countries (Saxena and Maulik 2003; WHO 2001). Very few countries have what could be considered an optimal mix of these services, and there are no universally accepted planning parameters. However, conceptual models for developing national mental health policy and guidelines for service planning exist that can be useful in

developing countries (Tansella and Thornicroft 1998; Townsend and others 2004; WHO 2003).

CONCLUSION: PUBLIC SUPPORT FOR A COST-EFFECTIVE INTERVENTION PACKAGE

In developing countries, much of the mental health care spending is reported to be out of pocket. Individuals purchase modern and traditional treatments if they can afford to do so. Although a large private health sector exists in low-income countries (Mills and others 2002), the quality and cost vary. Although unregulated markets fail in health, they fail even more in mental health. It is unlikely that a country will be able to rely on an unregulated private sector to deliver services that will reduce the burden of mental disorders.

In addition to being a large and growing component of disease burden, mental disorders meet virtually all the criteria by which we determine the need for government involvement in health care (Beeharry and others 2002). They affect the poor, cause externalities, and inflict catastrophic costs; moreover, private demand is inadequate. Indeed, the authors recognize that the main measure of outcome used in this and other chapters—the disability-adjusted life year—is limited to capturing change in service user-level symptoms, disability, recovery, and case-fatality. The DALY does *not* capture the positive change that treatment may have on a number of other significant consequences of mental disorders, including family burden (in particular, productive time and household resources given up in the care of the sick family member) and lost productivity, at the level of both the individual and the household (treatment accelerates return to paid work or usual household activities) and, by implication, at the level of society in general. The evidence base for these productivity increases, although modest in volume, constitutes an important additional argument alongside “cost per DALY” considerations for investing in mental health.

The total budgetary requirements and health consequences of a cost-effective package of mental health care can begin to be mapped out by selecting one intervention for each of the four disorders considered in this chapter. Although the data available for this exercise have limitations and will need to be refined with further research, table 31.7 summarizes the estimated costs and effects of a package consisting of (a) outpatient-based treatment of schizophrenia and bipolar disorder with first-generation antipsychotic or mood-stabilizing drugs and adjuvant psychosocial treatment, (b) proactive care of depression in primary care with generic SSRIs (including maintenance treatment of recurrent episodes), and (c) treatment of panic disorder in primary care with generic SSRIs. The estimated benefit of such a package would be an annual reduction of 2,000 to 3,000 DALYs per 1 million population, at a cost of US\$3 million to US\$9 million (that is, US\$3 to US\$4 per capita in Sub-Saharan

Table 31.7 Costs and Effects of a Specified Mental Health Care Package

	World Bank region					
	Sub-Saharan Africa	Latin America and the Caribbean	Middle East and North Africa	Europe and Central Asia	South Asia	East Asia and the Pacific
<i>Total effect (DALYs averted per year per 1 million population)</i>						
Schizophrenia: older antipsychotic drug plus psychosocial treatment	254	373	364	353	300	392
Bipolar disorder: older mood-stabilizing drug plus psychosocial treatment	312	365	322	413	346	422
Depression: proactive care with newer antidepressant drug (SSRI; generic)	1,174	1,953	1,806	1,789	1,937	1,747
Panic disorder: newer antidepressant drug (SSRI; generic)	245	307	287	307	284	330
Total effect of interventions	1,985	2,998	2,779	2,862	2,867	2,891
<i>Total cost (US\$ million per year per 1 million population)</i>						
Schizophrenia: older antipsychotic drug plus psychosocial treatment	0.47	1.81	1.61	1.32	0.52	0.75
Bipolar disorder: older mood-stabilizing drug plus psychosocial treatment	0.48	1.80	1.23	1.39	0.62	0.95
Depression: proactive care with newer antidepressant drug (SSRI; generic)	1.80	4.80	3.99	3.56	2.81	2.59
Panic disorder: newer antidepressant drug (SSRI; generic)	0.15	0.27	0.21	0.23	0.16	0.20
Total cost of interventions	2.9	8.7	7.0	6.5	4.1	4.5
<i>Cost-effectiveness (DALYs averted per US\$1 million expenditure)</i>						
Schizophrenia: older antipsychotic drug plus psychosocial treatment	544	206	226	267	574	522
Bipolar disorder: older mood-stabilizing drug plus psychosocial treatment	647	203	262	298	560	446
Depression: proactive care with newer antidepressant drug (SSRI; generic)	652	407	452	502	690	675
Panic disorder: newer antidepressant drug (SSRI; generic)	1,588	1,155	1,339	1,350	1,765	1,649

Source: Authors' own estimates.

Africa and South Asia, and US\$7 to US\$9 per capita in Latin America and the Caribbean). Accordingly, for every US\$1 million invested in such a mental health care package, 350 to 700 healthy years of life would be gained over what would occur without intervention.

At a country level, data such as those presented in this chapter can be used to estimate the proportion of burden currently averted, the proportion that can be averted with current knowledge and optimal coverage, and the burden not able to be averted with current knowledge. Such modeling has been done for some countries (for example, Andrews and others 2004).

Although much remains to be learned about the etiology and treatment of mental disorders, the potential clearly exists for a considerable reduction in the burden caused by them. For these gains to be made, the challenge is to overcome the

cultural, financial, and structural barriers that prevent people from seeking and receiving treatment. We need to close the gap between what we know and what we do in treating mental disorders. We can alleviate the substantial burden of these disorders and reverse or limit many of the devastating social and economic impacts.

Chapter 32

Neurological Disorders

Vijay Chandra, Rajesh Pandav, Ramanan Laxminarayan, Caroline Tanner, Bala Manyam, Sadanand Rajkumar, Donald Silberberg, Carol Brayne, Jeffrey Chow, Susan Herman, Fleur Hourihan, Scott Kasner, Luis Morillo, Adesola Ogunniyi, William Theodore, and Zhen-Xin Zhang

Historically, policy makers and researchers have used mortality statistics as the principal measure of the seriousness of diseases, based on which countries and organizations have launched disease control programs. Mortality statistics alone, however, underestimate the suffering caused by diseases that may be non-fatal but cause substantial disability. Many neurological and psychiatric conditions belong in this category. The absence of some neurological disorders from lists of leading causes of death has contributed to their long-term neglect. When the relative seriousness of diseases is assessed by time lived with disability rather than by mortality, several neurological disorders appear as leading causes of suffering worldwide.

World Health Organization data suggest that neurological and psychiatric disorders are an important and growing cause of morbidity. The magnitude and burden of mental, neurological, and behavioral disorders is huge, affecting more than 450 million people globally. According to the Global Burden of Disease Report, 33 percent of years lived with disability and 13 percent of disability-adjusted life years (DALYs) are due to neurological and psychiatric disorders, which account for four out of the six leading causes of years lived with disability (Mathers and others 2003).

Unfortunately, the burden of these disorders in developing countries remains largely unrecognized. Moreover, the burden imposed by such chronic neurological conditions in general can be expected to be particularly devastating in poor populations. Primary manifestations of the impact on the poor—including the loss of gainful employment, with the attendant

loss of family income; the requirement for caregiving, with further potential loss of wages; the cost of medications; and the need for other medical services—can be expected to be particularly devastating among those with limited resources. In addition to health costs, those suffering from these conditions are also frequently victims of human rights violations, stigmatization, and discrimination. Stigmatization and discrimination further limit patients' access to treatment. These disorders, therefore, require special attention in developing countries.

This chapter addresses Alzheimer's disease (AD) and other dementias, epilepsy, Parkinson's disease (PD), and acute ischemic stroke. These conditions are current or emerging public health problems in developing countries, as assessed by high prevalence, large numbers of people who are untreated, and availability of inexpensive but effective interventions that could be applied on a large scale through primary care. Unfortunately, reliable population-based data from developing countries on the epidemiology of these and other neurological disorders are extremely limited. Some other important neurological conditions that cause high morbidity, such as headache, are not covered because of difficulties in recommending evidence-based interventions in developing countries.

ALZHEIMER'S DISEASE AND OTHER DEMENTIAS

Dementia is a deterioration of intellectual function and other cognitive skills that is of sufficient severity to interfere with

social or occupational functioning. Of the many diseases that lead to dementia, AD is the most common cause worldwide among people age 65 and older, followed by vascular dementia, mixed dementia consisting of AD plus vascular dementia, and dementia caused by general medical conditions. Although distinguishing AD from other causes of dementia is important, particularly for treatment with acetylcholinesterase inhibitors, the burden from all causes of dementia is similar. Although the discussion in this chapter deals mostly with AD, the role of treatable dementias in developing countries is important as it can reduce the burden of caring in families.

Prevalence and Incidence Rate

More than 100 prevalence studies of AD and other dementias have been reported throughout the world. The prevalence of dementia has generally been found to double with every five-year increase in age, from 3 percent at age 70 to 20 to 30 percent at age 85 (Henderson and Jorm 2000). Studies in developing countries have shown a prevalence of dementia ranging from 0.84 to 3.50 percent (Chandra and others 1998; Hendrie and others 1995; Rajkumar, Kumar, and Thara 1997). Several studies have reported the incidence rate of AD and other dementias in Europe and the United States (Jorm and Jolley 1998). Compared with incidence rates in developed countries, very low age-specific incidence rates of AD and other dementias have been reported from developing countries (Chandra and others 2001; Hendrie and others 2001).

A comparison of data from developed and developing countries raises several important questions. The reported differences in the prevalence of AD and other dementias across countries could be due partly to methodological differences or could be due to genuine differences caused by variations in diet, education, life expectancy, sociocultural factors, and other risk factors. The low incidence reported from Ballabgarh, India, and Ibadan, Nigeria, raises the possibility of environmental factors or gene-environment interactions in the causation of AD. At the same time, multi-infarct dementia is more common than primary degenerative dementia in China (Li and others 1991), which also suggests variation in risk factors across countries.

Risk and Protective Factors and Survivorship

Three separate genes (APP, PS1, and PS2) are linked to early-onset, familial AD. Another gene (APO E4) is a risk factor for late-onset, nonfamilial cases (Henderson and Jorm 2000). Other genes have been implicated but not confirmed in large studies. Other risk factors reported in the literature include increasing age, positive family history of dementia, female gender (but this factor is controversial), lower level of education, several medical conditions, and exposure to such environmental factors as organic solvents and aluminum (Henderson and Jorm 2000).

Protective factors reported in the literature include a higher level of education, a specific gene (APO E2), the intake of anti-oxidants, and the use of some anti-inflammatory medications (Henderson and Jorm 2000). The use of estrogen supplements for women was believed to be a protective factor for AD (Henderson 1997), but a recent study of women taking a combination of estrogen and progesterone showed that these women had twice the risk of developing dementia than women taking a placebo (Shumaker and others 2003).

Studies from developed countries have reported median survival after the onset of dementia symptoms ranging from 5.0 years to 9.3 years (Walsh, Welch, and Larson 1990). In developing countries, the reported median survival was 3.3 years for all demented subjects and 2.7 years for those with AD (Chandra and others 1998).

Burden of Disease

Burden of disease estimates of AD and other dementias include vascular dementia, unspecified dementias, and other unclassified degenerative diseases of the nervous system. Mathers and others (2003) estimate DALYs for all dementias as 17,108,000, with the burden being almost twice as much for females (11,016,000) as for males (6,092,000). Because dementia is a disease of older ages, the burden from dementia is generally greater in high-income countries, where life expectancy is higher, diagnosis is better, and better treatment leads to increased longevity. Note, however, the relatively high burden in East Asia and the Pacific and South Asia relative to their level of economic development (table 32.1).

The bulk of care for those with dementia in developing countries is provided by the family at home, where the main caregivers are spouses (36 percent) and children (42 percent) (Prince 2000). Women in both developed and developing countries are usually the main caregivers (Prince 2000). Studies in developed countries indicate that caregivers' psychological well-being is a key factor in patients' admission to nursing or residential care (Levin, Moriarty, and Gorbach 1994).

In estimating the overall costs of care for dementia, one must emphasize the value of reducing the burden on caregivers. Caregiving can result in social isolation, psychological stress, and high rates of depression (Buck and others 1997). However, the methodology for estimating the costs of informal care needs to be standardized.

Interventions

As of now, there is no cure for AD, but some measures can provide symptomatic relief to patients and caregivers.

Population-Based Interventions. No firm evidence indicates that any form of population-based intervention can prevent AD or that the progression of cognitive decline in old age can

Table 32.1 Disability-Adjusted Life Years by Cause and Region, 2001
(thousands)

Condition	Global total			East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa	High-income countries
	Both sexes	Males	Females							
AD and other dementias	17,108	6,092	11,016	4,110	1,612	1,215	292	1,955	450	7,468

Source: Mathers and others 2006.

be halted or reduced. However, growing inferential evidence suggests that reducing the risk of brain trauma in earlier life, for example, by mandating seat belt and crash helmet use, may help prevent dementia in later life (Gentleman, Graham and Roberts 1993).

Personal Interventions. There is a reduction in brain levels of the neurotransmitter acetylcholine in patients suffering from AD. Drugs that inhibit acetylcholinesterase, the enzyme responsible for metabolizing acetylcholine, cause an increase in brain acetylcholine. Evidence from randomized trials has confirmed that, for patients with mild to moderate AD, cognitive performance benefits, at least in the short term, from the use of acetylcholinesterase inhibitors (Foster and others 1996). Despite this benefit to patients, the practical benefits of treatment with acetylcholinesterase inhibitors are mainly attributable to the lowered caregiver burden. The benefits of using acetylcholinesterase inhibitors for other dementias have yet to be proven.

The behavioral and psychological symptoms of dementia are a major source of stress to family members providing care to patients. Training family caregivers in behavioral management techniques, including problem solving, memory training, and reality orientation, has been shown to reduce the level of agitation and anxiety in people with dementia (Brodsky and Gresham 1989; Haupt, Karger, and Janner 2000). Use of low doses of antipsychotic medications, which calm the patient and reduce symptoms such as aggression and wandering, have been shown to reduce caregiver stress, but these improvements have not been quantified (Melzer and others 2004).

Interventions that have specifically targeted stress and depression among caregivers and have shown positive results include caregiver training, counseling and support for caregivers, and cognitive and behavioral family interventions (Marriott and others 2000). Limitations to the implementation of such strategies include the need for training by specialists, which makes these strategies less suitable for developing countries. The challenge for developing countries is to develop

culturally appropriate interventions that can be delivered within existing resources, such as supporting families in their role as caregivers.

Treating underlying disease and risk factors for cardiovascular disease can help prevent future cerebrovascular disease that could lead to multi-infarct dementia. Other conditions, such as hypothyroidism or vitamin B₁₂ deficiency, which could lead to or aggravate dementia, are easily treatable, and the costs of treatment are much lower than the costs of dementia care.

In Western countries, the model of care for patients with moderate to severe dementia is based on skilled, long-term care in institutions. However, such long-term care institutions do not exist in developing countries, and if they were set up, they would be extremely expensive and beyond the reach of most patients and their families. Thus, the model of care in developing countries should be based on home care, along with providing training and support for family caregivers.

Interventions that should not be pursued include the use of multiple medications, which can be detrimental in older age groups, particularly unproven medications such as cerebral activators and neurotropic agents. In addition, in many developing countries, dementia is still equated with “madness,” and patients are sometimes taken to traditional healers. Community education has a role to play in eliminating such practices.

EPILEPSY

Epilepsy is a common brain disorder characterized by two or more unprovoked seizures. Seizures are discrete events caused by transient, hypersynchronous, abnormal neuronal activity. Seizures may occur in close temporal association with a variety of acute medical and neurological diseases, such as acute stroke, sepsis, or alcohol withdrawal. However, the vast majority of seizures have no immediate identifiable cause.

Epilepsy can be broadly divided into three categories: idiopathic epilepsy (for example primary generalized childhood-onset absence epilepsy), which is thought to have a

genetic basis; secondary or symptomatic epilepsy, which is caused by a known central nervous system injury or disorder, such as infection, stroke, traumatic brain injury, or cerebral dysgenesis; and cryptogenic epilepsy, for which there is no clear evidence of an etiological factor. Idiopathic and cryptogenic cases represent approximately 70 percent of epilepsy cases; the remaining 30 percent are symptomatic (secondary).

Prevalence, Incidence Rate, Remission, and Mortality

The generally accepted estimate of the prevalence of active epilepsy globally is in the range of 5 to 8 per 1,000 population, but investigators from African and Latin American countries report at least double the prevalence reported elsewhere (Leonardi and Ustun 2002).

The incidence rate of epilepsy in developed countries is approximately 43 per 100,000 (Kotsopoulos and others 2002). In developing countries, the incidence rate of epilepsy is higher, with a median of 69 per 100,000 (Kotsopoulos and others 2002).

Based on follow-up of patients under treatment by general practitioners in the United Kingdom, Cockerell and others (1997) report that after nine years 86 percent of epilepsy patients had achieved a remission of three years, and 68 percent had achieved a remission of five years. Thus, data from developed countries suggest a good outcome of seizure control in most patients with treatment. In developing countries, although many people with new onset seizures do not receive treatment, some proportion of patients go into spontaneous remission even without treatment (Mani and others 1993). However, the actual remission rate in developing countries is yet to be documented in population-based studies.

The risk of premature death in people with epilepsy is two to three times higher than for the general population. In addition to sudden unexplained death, which occurs in up to 1 in 100 patients with severe refractory epilepsy, additional mortality results from accidents and suicide. However, the exact cause of the increased risk is not known in most cases.

Risk Factors

A reported risk factor for idiopathic (presumed genetic) epilepsy is family history of epilepsy. Reported risk factors for symptomatic epilepsy include prenatal or perinatal causes (obstetric complications, prematurity, low birthweight, neonatal asphyxia). Recent data suggest that the effect of obstetric complications or neonatal asphyxia may have been overemphasized. Prematurity, low birthweight, and neonatal seizures may be independent risk factors as well as markers of underlying disease. Other causes include traumatic brain injuries, central nervous system infections, cerebrovascular disease, brain tumors, and neurodegenerative diseases. Developmental

disabilities are not a risk factor for epilepsy in themselves, but they may be associated with seizure disorder (Casetta and others 2002; Leone and others 2002).

Treatment Gap

Epilepsy affects about 50 million people worldwide, of whom approximately 80 percent live in developing countries (WHO 2000). The difference between the number of people with active epilepsy and the number who are being appropriately treated in a given population at a given point in time is known as the *treatment gap*. Meinardi and others (2001) estimate that 90 percent of people with epilepsy in developing countries are inadequately treated. Possible reasons for the high treatment gap include fear of stigmatization, cultural beliefs, lack of knowledge about the medical nature of epilepsy, illiteracy, economic issues, distance to health facilities, inadequate supply of antiepileptic drugs (AEDs), and lack of prioritization by health authorities (Wang and others 2003). Even in the developed world, patients who live in isolated rural regions or inner-city slums and those who are isolated from the majority because of cultural factors may suffer a treatment gap.

Faith Healers

Many people with epilepsy seek treatment from faith healers, to whom they pay large sums in cash or in kind for treatment with no beneficial medical effects. Karaagac and others (1999) find that in Silivri, Turkey, 65 percent of 49 people with epilepsy had visited religious figures at the onset or during the course of the disease. A study from rural India revealed that 44 percent of children with epilepsy had sought help from traditional practitioners, whereas approximately 33 percent had received help from both qualified and traditional practitioners (Pal and others 2002). Native Americans still seek traditional healing ceremonies for epilepsy instead of—or in addition to—Western medicine.

Patient Compliance

In a study in rural Thailand, only 57 percent of people with epilepsy were 100 percent compliant with treatment, possibly because of misunderstanding of the instructions (48 percent), forgetfulness (16 percent), and economic limitations (13 percent) (Asawavichienjinda, Sitthi-Amorn, and Tanyanont 2003). To improve compliance in a rural African community, medical personnel visited the community every 6 months and provided a long-term supply of medications; this effort led to a substantial increase in compliance at 20 months (Kaiser and others 1998). In India, Desai and others (1998) demonstrate the dependency of compliance on access to free treatment. Inadequate communication between doctors and patients influences compliance negatively (Gopinath and others 2000).

Burden of Disease

The burden of disease (BOD) estimates for epilepsy include epilepsy and status epilepticus. Mathers and others (2003) estimate the DALYs for epilepsy as 6,223,000, with slightly higher rates for males (3,301,000) than for females (2,922,000). Many risk factors for epilepsy are linked with a lower level of economic development; thus, the burden is highest in South Asia followed by Sub-Saharan Africa (table 32.1). A notable observation is the reportedly low burden in the Middle East and North Africa, despite parts of that region being relatively underdeveloped. Epilepsy imposes a large economic burden on patients and their families. It also imposes a hidden burden associated with stigmatization and discrimination against patients and even their families in the community, workplace, school, and home. Social isolation, emotional distress, dependence on family, poor employment opportunities, and personal injury add to the suffering of people with epilepsy.

Interventions

Currently, there are no preventive measures for idiopathic or cryptogenic epilepsy; however, much can be done to prevent secondary seizures.

Population-Based Interventions. Public health policies, such as better perinatal care by well-trained birth attendants (particularly in rural areas) and strategies to control severe head injuries (for example, by means of laws requiring motorcyclists to wear helmets and prohibiting drunk driving), can modify risk factors for epilepsy and thereby reduce the incidence and prevalence of epilepsy. Policies to control neurocysticercosis (for instance, building latrines in rural areas) can serve to prevent such infections. Mass deworming for neurocysticercosis has not been shown to be effective in the long term (Pal, Carpio, and Sander 2000) but was effective in a campaign in Ecuador (M. Cruz, personal communication, 2004).

Estimates indicate that 70 to 80 percent of people in developing countries live in rural and remote areas and have no easy access to skilled medical care. Strategies that involve training community-based health care providers who practice in these communities to identify and manage patients with epilepsy should be considered.

Policies are needed to ensure the continuous availability of cheap and efficacious medications, such as phenobarbital, to all epilepsy patients. Campaigns to educate communities about the medical nature of epilepsy and to dispel myths and misconceptions about epilepsy could reduce stigma against epilepsy and thereby encourage patients to seek medical treatment.

Personal Interventions. Researchers, primarily in high-income countries, have tested (a) the efficacy of both older

AEDs (such as phenobarbital, phenytoin, carbamazepine, and valproic acid) and newer AEDs (such as lamotrigine, oxcarbazepine, and topiramate) in controlling seizure frequency and (b) the safety of these AEDs when prescribed alone or in combination. Some, but not all, of the new AEDs may be better tolerated in monotherapy and have fewer long-term adverse effects than older AEDs. However, no study has shown any difference in efficacy between the older and newer medications (Aldenkamp, De Krom, and Reijs 2003). Newer medications are more expensive and, for people in most developing countries, are practically impossible to access. In some low-income countries, however, even older AEDs are not available, and when they are, their supply is irregular.

Newer AEDs are generally recommended as add-on or adjunctive drugs for better seizure control in patients with refractory epilepsy already on AEDs. The first AED will render approximately 50 percent of patients seizure free. Approximately 20 to 40 percent of patients who do not respond to the first AED will respond to the introduction of a second AED, with a greater than 50 percent decrease in seizure frequency (Schapel and others 1993).

The Global Campaign against Epilepsy, which is jointly sponsored by the World Health Organization, International League against Epilepsy, and International Bureau for Epilepsy, advocates using phenobarbital to close the high treatment gap in low-income countries. As a first step, all patients with epilepsy should be given phenobarbital, so that the majority of patients responsive to phenobarbital will be appropriately treated. In resource-poor countries, phenobarbital can be provided for as little as US\$5 to US\$10 per year. Phenobarbital has extremely low abuse potential. Its side effects—predominantly sedation, possible mild cognitive impairment, and depression—have limited its use in industrial countries. In developing countries, however, side effects are less important than uncontrolled seizures, and they can be diminished by using the lowest possible effective doses. Thus, phenobarbital is the drug of choice for large-scale, community-based programs, particularly in rural and remote areas of developing countries.

In recent years, some centers in both developed and developing countries have been performing surgery on cases of *refractory epilepsy*, that is, on patients who do not respond to any AEDs. Before centers can undertake such surgery, however, they must have the requisite expertise, facilities, and equipment, including a skilled neurosurgeon. Proper selection of patients—for example, those with mesial temporal pathology on MRI—is extremely important. A meta-analysis of studies of people who underwent epilepsy surgery in developed countries shows that 58 percent are seizure free and 10 to 15 percent have reduced seizure frequency (Engel and others 2003). After surgery, even if patients are seizure free, medication should be continued for one to two years (Engel and others 2003).

PARKINSON'S DISEASE

PD is characterized by bradykinesia, resting tremor, cogwheel rigidity, postural reflex impairment, progressive course, and good response to dopaminergic therapy. Other distinct forms of parkinsonism include relatively rare genetic forms and the less common neurodegenerations with multiple system involvement or significant striatal lesions (for example, progressive supranuclear palsy or multiple system atrophy). Parkinsonism secondary to external causes, such as manganese poisoning or carbon monoxide poisoning, although now rare, is referred to as secondary parkinsonism. Because the burden of these diseases to the patient is similar to or greater than that for PD and there is no evidence for addressing these disorders separately, they will not be distinguished here.

Prevalence, Incidence Rate, and Mortality

Prevalence estimates vary widely across populations (Tanner and Goldman 1996; Zhang and Roman 1993). Recent reports, contrary to previous reports, suggest that the prevalence in developing and developed countries may be similar (Marras and Tanner 2002). Few incidence studies have been performed, and none in developing countries. Van Den Eeden and others (2003) report the incidence rate of PD in the United States as approximately 13 per 100,000 person-years. Men are affected more commonly than women (Tanner and Goldman 1996). Lower PD incidence in African Americans—and by extension Africans—has been suggested but is controversial (Van Den Eeden and others 2003). Most mortality estimates available for developed countries show about a twofold overall increased mortality, independent of age, in those with PD (Berger and others 2000).

Causes and Risk Factors

The cause of PD is unknown. A specific environmental risk factor has not been identified. Pure genetic forms account for 10 to 15 percent of cases or fewer. Increasing age and male gender are risk factors worldwide (Marras and Tanner 2002). Exposure to toxins, head trauma, frequent infections, diets high in animal fat, and midlife adiposity have been reported to increase PD risk, but none do so consistently (Tanner and Goldman 1996). The most consistent association is an inverse association with cigarette smoking and caffeine consumption, suggesting a protective effect (Ascherio and others 2001).

Burden of Disease

The BOD estimates for PD include Parkinson's disease and secondary parkinsonism. Mathers and others (2003) estimate the DALYs for PD as 2,325,000, with the burden being slightly

higher in females (1,202,000) than males (1,124,000). Though male gender is a risk factor for PD, the higher burden in females may reflect their longer life span. As PD is a disease of older ages, the burden from PD is generally higher in high-income countries, where life expectancy is higher, diagnosis is better, and better treatment leads to increased longevity. However, the burden is high in East Asia and the Pacific and South Asia relative to that in other regions (table 32.1).

The economic burden of PD includes direct costs, such as for medication, physicians, hospitals, and chronic care facilities. Estimated indirect costs resulting from the loss of labor of both patients and caregivers typically exceed direct costs. The quality of life of both patients and caregivers is adversely affected.

Interventions

Treatment of PD is based on symptomatic relief, except for preventing secondary parkinsonism caused by neurotoxins.

Population-Based Interventions. No determinants of PD amenable to population-based interventions have been identified.

Personal Interventions. Specific curative or neuroprotective treatments for PD have not been established. Interventions are primarily directed at palliation of symptoms and include pharmaceuticals, surgery, physical therapy, and—in some countries—traditional medicines.

Levo-dopa (l-dopa), l-dopa/decarboxylase inhibitor is the most widely used therapy for PD. It provides partial relief of all PD symptoms. Despite its benefits, chronic side effects after long-term use can cause significant morbidity.

Researchers in developing countries have studied the use of traditional medicines for PD. Clinical trials have shown that the seeds of *Mucuna pruriens*, which contain l-dopa, are a safe and effective treatment for PD (Parkinson's Disease Group 1995), and in animal studies, they are two to three times more effective than synthetic l-dopa dose per dose (Hussain and Manyam 1997). This substance is available in ayurvedic formulations in India at a much lower cost than that of synthetic antiparkinsonian drugs. Another traditional medicine is derived from *Banisteriopsis caapi*, which tribal societies of the Amazonian jungle use to make a potent hallucinogenic brew. It reportedly showed dramatic positive effects on rigidity and akinesia in 15 patients with postencephalitic parkinsonism (Lewin and Schuster 1929). A third traditional option is tai chi, a basic exercise in traditional Chinese medicine that may help with some of the motor deficits of PD.

Surgical treatment for PD by deep brain stimulation is generally recommended to address the loss of efficacy of dopaminergic drugs. For most patients, it is not effective independent of drugs. Although a few will have dramatic improvement and

may be able to reduce or stop drugs, this effect is generally temporary. Criteria for selection of patients for deep brain stimulation include those with advanced disease who are responsive to l-dopa, not demented, and in good general health. Additional considerations are the high cost of the equipment, the need for trained personnel to program the device, and—in most cases—the need for several visits to a medical center to program the stimulator correctly, with periodic returns to adjust the settings.

STROKE

Stroke, also known as *cerebrovascular accident* or *brain attack*, is a syndrome caused by an interruption in the flow of blood to part of the brain caused either by occlusion of a blood vessel (*ischemic stroke*) or rupture of a blood vessel (*hemorrhagic stroke*). The interruption in blood flow deprives the brain of nutrients and oxygen, resulting in injury to cells in the affected vascular territory of the brain. The occlusion of a blood vessel can sometimes be temporary and present as a reversible neurological deficit, which is termed a *transient ischemic attack*. Even though stroke is a clinical diagnosis, brain imaging is required to distinguish ischemic stroke from hemorrhagic stroke. When imaging is unavailable, clinical scores can be useful to identify patients with intracerebral hemorrhage (Allen 1983; Pongvarin, Viriyavejakul, and Komontri 1991).

Frequency of Types of Strokes, Prevalence, Incidence Rate, Mortality, and Disability after Stroke

In most parts of the world, about 70 percent of strokes are due to ischemia, 27 percent are due to hemorrhage, and 3 percent are of unknown cause (Gunatilake, Jayasekera, and Premawardene 2001). Approximately 25 percent of all ischemic strokes are due to cardioembolic causes, with the proportion being higher among younger individuals. In some parts of the world—for instance, China and Japan—hemorrhagic strokes account for a greater proportion of all strokes, ranging from 17.1 to 39.4 percent in China (Zhang and others 2003) to 38.7 percent in Japan (Fukiyama and others 2000).

Comparable data do not exist for all parts of the world. Most morbidity data from Southeast Asian countries, for example, are hospital based and are, thus, likely to be underestimates, because many stroke patients die before they are brought to the hospital. Mortality data are also likely to be underestimates, because verifying the cause of death is usually difficult.

In India, the prevalence of stroke has been estimated at 203 per 100,000 population older than 20 (Anand and others 2001). The male-to-female ratio was one to seven. In Taiwan, China, the crude point prevalence was 592 per 100,000 (Huang, Chiang, and Lee 1997).

He and others (1995) report the age-adjusted stroke incidence of 117 per 100,000 population in China. The annual incidence of stroke in China is reported to have increased in both men and women, with an average annual percentage change of 4.5 and 4.2 percent, respectively (Wang, Zhao, and Wu 2001). In Japan, the age-adjusted annual incidence of stroke was 105 per 100,000 (Fukiyama and others 2000). Wide variation within these countries and a high risk of death after the first stroke in the first year in Japan have been reported. Investigators believe that those observations are due to variations in the prevalence of hypertension and the consequent larger proportion of hemorrhagic stroke (Kiyohara and others 2003).

Walker and others (2000) report the yearly age-adjusted mortality rate per 100,000 for age group 15 to 64 ranged from 35 to 65 in men and 27 to 88 in women in Tanzania. When compared with the rates in England and Wales—11 for men and 9 for women—these rates are extremely high. The authors postulate that the high rates in Tanzania are due to untreated hypertension. Many developed countries have experienced a steep decline in stroke mortality in recent decades, but the rate of decline has fallen substantially in recent years (Liu, Ikeda, and Yamori 2001; Sarti and others 2000). Mortality from stroke has increased in some Eastern European countries (Sarti and others 2000).

Approximately 15 percent of patients die shortly after a stroke. Of the remaining 85 percent, approximately 10 percent recover almost completely, and 25 percent recover with minor impairments (National Stroke Association 2002). Thus, approximately 40 percent experience moderate to severe impairments that require special rehabilitative care. About 10 percent will require care in a nursing home or other long-term facility.

Risk Factors

Risk factors for stroke in general are similar to those for cardiovascular disease. Moreover, risk factors for first stroke and recurrence of stroke are also similar if they remain uncontrolled after the first attack (see chapter 33).

Increasing age, particularly after 55, is one of the most important risk factors for stroke (Thorvaldsen and others 1995). Although stroke is more prevalent among men, stroke-related fatality rates are higher among women (Goldstein and others 2001). Hypertension is the most important modifiable determinant of both first and recurrent stroke (Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998). The association between blood pressure and stroke in East Asian populations seems stronger than in Western populations (Eastern Stroke and Coronary Heart Disease Collaborative Research Group 1998). Other risk factors include smoking, environmental exposure to tobacco smoke, dyslipidemia, atrial fibrillation, diabetes and impaired glucose

tolerance, generalized and abdominal obesity, physical inactivity, excess alcohol consumption, increased homocysteine levels, drug abuse, hemostatic factors, and existing cerebrovascular disease (Goldstein and others 2001).

In developing countries, rheumatic heart disease leading to embolic stroke is also a major cause. This risk factor is declining in importance with the control of rheumatic fever. Dehydration in postpartum women can lead to a stroke, particularly in remote areas where deliveries are conducted at home.

Burden of Disease

The BOD estimates for stroke include subarachnoid hemorrhage, intracerebral hemorrhage, cerebral infarction, and sequelae of cerebrovascular disease. Mathers and others (2003) estimate the DALYs for cerebrovascular disease as 72,024,000, with the burden being almost similar for females (36,542,000) and males (35,482,000). The burden is highest in East Asia and the Pacific, followed by South Asia and by Europe and Central Asia (table 32.1). The burden in Sub-Saharan Africa is higher than in the Middle East and North Africa, which may suggest an etiology for stroke other than atherosclerotic disease.

Health experts anticipate that the number of stroke cases will increase, particularly in developing countries, because of aging populations and increased exposure to major risk factors. Corresponding to this increase in the number of stroke cases will be an increase in the number of people with disabilities surviving after stroke.

Interventions

Several intervention strategies are available for stroke, but only a few can be applied in developing countries.

Population-Based Interventions. Public health policies to address risk factors for stroke include tobacco and alcohol control, laws to provide labels showing the fat content of foods, and public education about the harm caused by high-fat foods. Public health programs to control rheumatic fever will reduce rheumatic heart disease and the subsequent risk of embolic strokes. Better training of birth attendants will reduce the risk of peripartum hemorrhage, which leads to puerperal strokes.

Personal Interventions. Modification of adverse lifestyle and major risk factors such as hypertension, diabetes, high lipid levels, smoking, and alcohol abuse is beneficial both for primary prevention and recurrence of stroke. Some evidence indicates that the decline in the incidence of stroke observed in many countries is due to better management of hypertension (MacWalter and Shirley 2002). Special consideration should be given to the profile of risk factors in developing countries,

which include not only recognized risk factors in developed countries but also locally relevant risk factors, such as rheumatic heart disease and puerperal stroke.

Treatment strategies for acute ischemic stroke include the following:

- *General management.* Overall medical care of patients with an acute stroke is important. Attention to complications such as bronchoaspiration, fluid and electrolyte imbalance, and control of blood sugar, as well as prevention of deep vein thrombosis, is crucial. Experience in developed countries suggests that specialized stroke units provide the best care for acute stroke patients (Smaha 2004), but in developing countries, particularly in rural areas, where hospital beds are scarce and most patients are attended by general physicians, such units are impractical.
- *Platelet antiaggregants.* Aspirin can prevent early stroke recurrence if given during the acute phase of stroke (within 48 hours) (Chinese Acute Stroke Trial Collaborative Group 1997; International Stroke Trial Collaborative Group 1997). The adverse effects of aspirin (cerebral hemorrhage and gastrointestinal complications) appear to be dose related, and most agree that using a low dose of aspirin is prudent (Antithrombotic Trialists' Collaboration 2002). Since aspirin can aggravate a hemorrhagic stroke, simple guidelines for the use of platelet antiaggregants should be developed and could be based on scales such as the Siriraj score to rule out hemorrhage (Poungvarin, Viriyavejakul, and Komontri 1991).
- *Thrombolytic therapy.* Tissue plasminogen activator and recombinant tissue plasminogen activator (rt-PA) can be used to halt a stroke by dissolving the blood clot that is blocking blood flow to the brain (National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group 1995). Thrombolytic therapy can increase bleeding and must be used only after careful patient screening, with a CT scan of the brain within three hours of stroke symptom onset, to exclude an intracranial bleed. It also requires appropriately trained physicians to administer the medication. These prerequisites for the administration of thrombolytic agents restrict its use to selected centers in developing countries.

Strategies for prevention of recurrence of stroke apply equally to individuals who have experienced a transient ischemic attack and to those who have experienced a complete stroke. These strategies include the following:

- *Platelet antiaggregants.* Aspirin therapy is effective in preventing recurrence of stroke, with low daily doses being at least as effective as higher daily doses (Antithrombotic Trialists' Collaboration 2002). When compared with aspirin,

clopidogrel has a slight benefit among those who have had a previous stroke, myocardial infarction, or symptomatic peripheral arterial disease. Clopidogrel is an effective and safe alternative for patients who do not tolerate aspirin. Although clopidogrel may be slightly more effective than aspirin, it is also more expensive. Antiplatelet combination therapy using agents with different mechanisms of action, such as the combination of extended release dipyridamole and aspirin, has been shown to reduce the risk of stroke over aspirin alone (Sacco, Sivenius, and Diener 2005). In contrast, combination therapy with aspirin and clopidogrel offers no advantage over aspirin alone and also increases the risk of hemorrhage (Diener and others 2004).

- *Anticoagulant therapy.* Anticoagulation with warfarin should be considered in stroke patients with atrial fibrillation, because of its clear efficacy in preventing embolic strokes, provided that patients are appropriately monitored (European Atrial Fibrillation Trial Study Group 1993; Mohr and others 2001). Anticoagulant therapy also reduces the risk of embolic stroke in patients with rheumatic heart disease. However, anticoagulation can be hazardous in developing countries because of the lack of monitoring facilities.
- *Surgical treatment.* In patients with symptomatic carotid disease with stenosis of 70 percent and in asymptomatic patients with high-grade stenosis, carotid endarterectomy has been shown to be more beneficial than medical care alone (Asymptomatic Carotid Atherosclerosis Study 1995; Asymptomatic Carotid Surgery Trial Collaborative Group 2004; North American Symptomatic Carotid Endarterectomy Trial Collaborators 1991). However, inappropriate selection of patients or high intraoperative complications could obviate such benefits. Carotid angioplasty has been suggested as an alternative to carotid endarterectomy in management of severe internal carotid artery disease, but its advantages and disadvantages have yet to be clearly established (Naylor, London, and Bell 1997). Carotid endarterectomy for stroke prevention is available at only a few centers in developing countries, which makes its widespread use impractical.

The goal of rehabilitation after a stroke is to enable individuals who have experienced a stroke to reach the highest feasible level of independence as soon as possible. Successful rehabilitation depends on the extent of brain damage, skill of the rehabilitation team, length of time before rehabilitation is started, and support provided by caregivers. Because each stroke patient has specific rehabilitation needs, customizing the rehabilitation program is important. Rehabilitation therapies include several complementary approaches:

- physical therapy, which helps stroke patients relearn simple motor activities, such as walking

- occupational therapy, which helps patients relearn everyday activities, such as eating and drinking
- speech therapy, which helps patients relearn language and speaking skills
- counseling, which can help alleviate some of the mental and emotional problems that result from stroke.

Comprehensive rehabilitation in a multidisciplinary stroke unit reduces deaths, disability, and the need for long-term institutional care (Smaha 2004), but such facilities are extremely limited in developing countries. Home-based rehabilitation services can prevent long-term deterioration in activities of daily living, although the absolute impact is relatively modest (Outpatient Service Trialists 2002). However, in developing countries, the vast majority of patients will be treated either at home by a general physician or in a small community hospital where no skilled rehabilitation therapist is available.

COST-EFFECTIVENESS OF INTERVENTIONS IN DEVELOPING COUNTRIES

We determined incremental cost-effectiveness ratios (ICERs) for selected interventions for each condition by calculating total DALYs lost by a population because of the condition with and without treatment and then dividing the difference by the treatment cost. The disability weights used are presented in table 32.2. All analyses in this section followed the volume editors' standardized guidelines for economic analysis, region-specific age structures, and underlying mortality rates. We converted nontradable inputs into U.S. dollars at the market exchange rate. We assumed that the costs of tradable inputs were internationally consistent, as were costs associated with surgical treatments. Table 32.3 presents the costs of drugs and medical services. No fixed costs were assumed; therefore, our results are not linked with the extent of treatment coverage.

Table 32.2 Disability Weights Used in ICER Analysis

Weight	AD and other dementias	Epilepsy	PD	Acute stroke	Recurrent stroke
Untreated	0.627	0.15	0.392 ^a	0.278 ^b	0.556
Treated	0.627 ^c	0	0.316	0.235 ^b	n.a. ^d

Source: Mathers and others 2006.

n.a. = not applicable.

a. Treatment for PD is assumed to be effective for a maximum of 10 years. We also assume that a patient reverts to the untreated disability weight after 10 years.

b. Disability is assumed to last a maximum of 10 years; then we assume the patient recovers fully.

c. The patient is assumed to experience no benefit from treatment. Benefits are in the form of reduced caregiver hours.

d. Treatment does not change the disability weight following a recurrent stroke; only the likelihood of experiencing a second stroke is reduced.

Table 32.3 Input Requirements for Interventions by Condition

Condition	Visits to primary health care doctor in outpatient department		Primary health care worker visits to patient in home or in outpatient department		Specialist care in outpatient department		Inpatient care		Annual drug costs (US\$)

Source: Authors.

n.a. = not applicable.

a. Percentage of patients receiving the specified treatment.

b. Non-drug treatment costs for lamotrigine are not included in the cost-effectiveness analyses because they are accounted for in the phenobarbital treatment costs. Lamotrigine is taken in addition to phenobarbital.

c. Epilepsy surgery also requires screening at a cost of US\$600 per screened patient. Because only half of screened patients are eligible for surgery, the cost amounts to US\$1,200 per treated patient.

d. This treatment requires testing for eligible patients. The costs of screening ineligible patients include all the same hospital and doctor costs as treatment, as well as 80 percent of the drug cost to account for the diagnostic CT.

AD and Other Dementias

We analyzed the use of acetylcholinesterase inhibitors in the treatment of AD on the basis of the following assumptions: first, only patients who were older than 60 at the time of onset were considered; second, the treatment has no long-term benefits—that is, it does not reduce patient disability and has no effect on mortality.

We computed the benefits of reduced caregiver hours on the basis of reports that the improvement in cognitive function in AD patients associated with treatment using acetylcholinesterase inhibitors was a 1.2 point change in the global assessment scale for cognitive function, as measured by the Mini Mental State Examination. A 1 point improvement in the score was associated with a 0.56 hour per day reduction in caregiver hours, or roughly 205 hours per year (Marin and others 2003).

The cost of using acetylcholinesterase inhibitors per hour of caregiver time saved averaged US\$13 across low- and middle-income countries (LMICs) and was at least US\$11 in specific regions (the regions are the same as those in table 32.1). This amount is substantially more than the wage rate in these regions, which would generally not exceed US\$1 to US\$1.50 per hour, even for hired caregivers specifically trained to care for AD patients. We, therefore, conclude that the use of acetylcholinesterase inhibitors in developing countries is not efficient from an economic perspective. Calculating the cost per DALY averted for acetylcholinesterase inhibitors would not be meaningful, because we assume no benefit to the patient. Finally, the use of acetylcholinesterase inhibitors is uncommon in developing countries; therefore, reducing its use is not an important concern.

Epilepsy

We analyzed the cost-effectiveness of phenobarbital in the treatment of epilepsy, and the results are shown in table 32.4. We assumed that phenobarbital was provided to all patients. The cost of using phenobarbital per DALY gained in LMICs was US\$89. Table 32.4 shows that the benefits of phenobarbital are large relative to its cost.

We did not look at other AEDs, such as phenytoin or carbamazepine, because the costs of those medications are much greater than that of phenobarbital, but their effectiveness is essentially the same (Aldenkamp, De Krom, and Reijs 2003). Although their use may be justified for specific medical reasons, phenobarbital is much more cost-effective.

We analyzed treatment options for patients who are refractory to treatment with phenobarbital. We assumed that such cases were treated either with a combination of phenobarbital and lamotrigine or with a combination of phenobarbital and surgery. We used the cost for epilepsy surgery of US\$2,600, in accordance with a study from Colombia, and applied it to all regions (Malmgren and others 1996; Tureczek, Fandino-

Franky, and Wieser 2000). We assumed that roughly half of surgery recipients experience no more seizures and that the remaining half continue to take phenobarbital despite undergoing surgery. Our evaluation of the surgical option included the costs of diagnostic services and the costs associated with screening patients who ultimately may not be eligible for surgery. For patients in LMICs who are refractory to phenobarbital, the ICER of the add-on drug lamotrigine was US\$3,000, and the ICER of the surgical option plus phenobarbital was US\$3,100. The difference between phenobarbital and the other two options was significant in all regions.

Among refractory epilepsy patients eligible for surgery and according to postoperative outcome studies conducted in developed countries, surgery may be of comparable cost-effectiveness to treatment with a combination of phenobarbital and lamotrigine. Because effectiveness data for developing countries are not available, this calculation is based on cost estimates from a study in Colombia and estimates of the effectiveness of surgery from developed countries. If the surgical outcome in developing countries were worse than in developed countries, the cost-effectiveness of surgery would be lower. Furthermore, we note a number of limitations to the use of surgery in refractory epilepsy, particularly in developing countries, along with the lack of long-term follow-up data on the outcome of surgery. We stress that the primary treatment of epilepsy is with phenobarbital, and effective treatment of epilepsy lies in more efficient use of this highly cost-effective medication to close the treatment gap.

Parkinson's Disease

We evaluated three interventions for PD: a combination of l-dopa and carbidopa, traditional medicines such as the ayurvedic treatment used in India, and deep brain stimulation. We assumed that treatment for all three modalities was effective for 10 years from the onset of treatment. The ICERs in LMICs for these three modalities were US\$1500, US\$750 and US\$31,000, respectively (table 32.4). On the basis of the cost of medication and evidence from clinical trials of effectiveness (Parkinson's Disease Group 1995) and from animal studies (Hussain and Manyam 1997), we found that ayurvedic treatment was the most cost-effective option. The relatively favorable ICER for ayurvedic treatment is due to the extremely low medication cost of this intervention. The relatively high ICER for deep brain stimulation was largely attributable to the extremely high cost of surgery. Table 32.4 shows DALYs gained for US\$1 million of health expenditure.

Stroke

We evaluated two sets of interventions for stroke: treatment of acute stroke and prevention of secondary stroke. We assumed

Table 32.4 Results from Cost-Effectiveness Analysis of Interventions for Alzheimer’s Disease, Epilepsy, Parkinson’s Disease, and Stroke, by World Bank Region

Condition	Low- and middle-income countries	East Asia and the Pacific	Europe and Central Asia	Latin America and the Caribbean	Middle East and North Africa	South Asia	Sub-Saharan Africa

that stroke sufferers have fully recovered 10 years after their last stroke.

We evaluated aspirin, heparin, and rt-PA for the treatment of acute stroke. The International Stroke Trial Collaborative Group (1997) reports that, within 14 days of the onset of stroke, mortality with heparin treatment is less than with a placebo; however, after six months, mortality is actually greater for patients treated with heparin than with a placebo—that is, there is a negative cost per DALY gained if this effect is incorporated. The estimates presented here are based on the change in the short-term mortality risk. For LMICs, the cost per DALY averted using aspirin was US\$150 (table 32.4). The equivalent costs of interventions using rt-PA and heparin were US\$1,300 and US\$2,700, respectively. The costs of heparin are higher than the costs of rt-PA, despite the expensive equipment required for rt-PA, because of the lower effectiveness of heparin.

Table 32.4 presents DALYs averted for US\$1 million of health expenditure for the three treatments. The cost per DALY gained using aspirin is a conservative estimate, because the use of aspirin has additional benefits in terms of preventing a recurrence of stroke.

Table 32.4 shows the costs of preventing a second stroke within two years of the first stroke. For LMICs, aspirin was the least expensive option at US\$3.80 per single percentage point decrease in the risk of a second stroke within two years of the first. This rate translates to roughly US\$70 per DALY gained (table 32.4). Combining dipyridamole with aspirin, because of higher cost, was slightly more expensive at roughly US\$5.20 per single percentage point decrease in recurrent stroke risk for a single individual, or about US\$93 per DALY. In contrast, carotid endarterectomy was US\$87 for an equivalent decrease in individual recurrence risk or almost US\$1,500 per DALY. The aspirin monotherapy option for preventing a recurrence of stroke was the most cost-effective approach only in South Asia and Sub-Saharan Africa, largely because of the relatively low costs of nontradable inputs, such as hospital and doctors' fees, in those regions. Low input costs of nontradables increase the relative importance of drug costs in determining the most cost-effective intervention; therefore, the cheaper drug, aspirin, was most cost-effective. Table 32.4 shows that, though US\$1 million would be most effectively spent on aspirin alone in South Asia and Sub-Saharan Africa, investment in aspirin and dipyridamole treatment would result in a greater DALY gain in the other regions.

RECOMMENDATIONS

The use of acetylcholinesterase inhibitors for treating patients with AD, as assessed by the number of caregiver hours saved, suggests that this intervention is not cost-effective. This finding, combined with the limited efficacy of acetylcholinesterase

inhibitors, suggests that they should not be widely used in developing countries. Instead, giving low doses of antipsychotic medication to patients with any form of dementia who also have behavioral problems may be a better option for reducing caregiver stress, although this possibility has not been systematically evaluated.

Phenobarbital is by far the most cost-effective intervention for managing epilepsy and should be recommended for widespread use in public health campaigns against epilepsy in LMICs. For those patients who do not respond to phenobarbital, the addition of lamotrigine is advisable rather than surgery, because of the resource-intensive evaluation and infrastructure required for epilepsy surgery.

Indigenous systems of medicine, such as the ayurvedic medicines used in India, are much more cost-effective than Western medications or surgical procedures for managing patients with PD. Other countries may wish to test and standardize such medications for their own use.

Aspirin is by far the most cost-effective intervention both for treating acute stroke and for preventing a recurrence of stroke. It is easily available in developing countries, even in rural areas.

RESEARCH AND DEVELOPMENT AGENDA

The populations of most developing countries are aging rapidly. Many neurological disorders frequently occur in the elderly, posing an emerging public health problem. As a result, developing countries should begin or expand their research and development agendas to address issues related to the prevention, identification, and management of neurological disorders. In the short term, they should focus on early identification, optimum treatment, and amelioration of distress and handicaps and on reduction of the social and economic burden on patients and their families. In the long term, they should develop and implement strategies for primary prevention of neurological disorders. Specific areas for research and development include the following:

- *Conducting population-based epidemiological studies in developing countries.* Population-based data from developing countries are insufficient, which limits evidence-based planning. In addition, such data may also suggest important hypotheses for research if they identify genuine differences across regions (for example, the reported difference in the incidence of AD in developed and developing countries). In addition, the identification of risk or protective factors would be useful in the primary prevention of such diseases.
- *Enhancing existing health care delivery systems.* In most developing countries, approximately 70 to 80 percent of patients live in rural areas, where medical care is frequently provided by nonphysician health care providers or, at best,

by a general physician. Limitations in the availability of health care have resulted in a huge treatment gap for many neurological disorders. For such situations, a simple model for the management of neurological disorders by existing community-based health care providers, trained to provide such services, would be helpful. Research is needed on optimum referral systems for more difficult cases that local communities will accept and can afford. Strategies for home-based care of patients need to be systematically evaluated.

- *Developing cheaper and more efficacious medicines.* Many currently available medications have significant side effects and are too expensive for many patients in developing countries. Newer medications need to be developed with lower costs, fewer side effects, better efficacy, and less frequent dose schedules.
- *Promoting the use of indigenous systems of medicine.* Many people in developing countries use local indigenous medicines. More research needs to be done on the pharmacological properties of those medications (see chapter 69).
- *Launching stigma removal campaigns.* The stigmatization of patients with neurological disorders and of their families is still prevalent, particularly in rural and remote areas, and it often prevents patients from seeking and obtaining appropriate medical care. Effective strategies to address this issue need to be developed and implemented on a large scale.

MISSED OPPORTUNITIES

Many research studies have reported that the incidence of AD is lower in developing countries than in Western countries. Migration studies, such as those looking at the migration of Africans to the United States, have shown a change in the risk for AD within one or two generations. This finding suggests that developing countries may have some protective factors that rapidly change on migration to developed countries. Despite this information being available for more than 25 years, no systematic efforts have been made to identify these protective factors. Given the rapid adaptation of Western lifestyles in developing countries, identifying these factors is important before the opportunity is permanently lost.

The successful use of phenobarbital for treating epilepsy was first described in 1912. Not only is it effective for many types of epilepsy, but it is also inexpensive. Nevertheless, despite its availability for more than 90 years and its modest cost, the treatment gap for epilepsy still exceeds 90 percent in many developing countries.

Indigenous systems of medicine, such as for the treatment of PD, have been used for centuries in developing countries. However, their utility has not been fully exploited.

Despite evidence of the benefit of control of hypertension in the primary prevention of stroke, most efforts in developing

countries are directed at treatment of stroke. This approach not only is more expensive but also is less beneficial to the patient.

ACKNOWLEDGMENTS

The lead author would like to acknowledge with gratitude the support provided by the regional director and director of program management of the South-East Asia Regional Office of the World Health Organization. Special mention must be made of Dr. Daniel Chisholm, who provided input into the cost-effectiveness analysis, particularly that dealing with epilepsy, and of Dr. Donald Silberberg, who served as the senior adviser to the chapter. The authors wish to thank the many reviewers for their valuable suggestions, which have been incorporated into the chapter.

Chapter 33

Cardiovascular Disease

Thomas A. Gaziano, K. Srinath Reddy, Fred Paccaud, Sue Horton, and Vivek Chaturvedi

Cardiovascular disease (CVD) is the number one cause of death worldwide (Mathers and others 2006; Murray and Lopez 1996; WHO 2002b). CVD covers a wide array of disorders, including diseases of the cardiac muscle and of the vascular system supplying the heart, brain, and other vital organs. This chapter reviews the epidemiological transition that has made CVD the world's leading cause of death, assesses the status of the transition by region, and indicates regional differences in the burden of CVD. It also reviews the cost-effectiveness of various interventions directed at the most relevant causes of CVD morbidity and mortality.

EPIDEMIOLOGY OF CVD

At the beginning of the 20th century, CVD was responsible for less than 10 percent of all deaths worldwide, but by 2001 that figure was 30 percent. About 80 percent of the global burden of CVD death occurs in low- and middle-income countries. Murray and Lopez (1996) predicted that CVD will be the leading cause of death and disability worldwide by 2020 mainly because it will increase in low- and middle-income countries. By 2001, CVD had become the leading cause of death in the developing world, as it has been in the developed world since the mid 1900s (Mathers and others 2006; WHO 2002a). Nearly 50 percent of all deaths in high-income countries and about 28 percent of deaths in low- and middle-income countries are the result of CVD (Mathers and others 2006). Other causes of death, such as injuries, respiratory infections, nutritional deficiencies, and HIV/AIDS, collectively still play a predominant role in certain regions, but even in those areas CVD is now a significant cause of mortality.

Predominant Cardiovascular Diseases

This chapter focuses on the most common causes of CVD morbidity and mortality:

- ischemic heart disease (IHD)
- stroke
- congestive heart failure (CHF).

These diseases account for at least 80 percent of the burden of CVD in all income regions, which share many of the same common risk factors; accordingly, similar interventions are appropriate. A fourth manifestation, rheumatic heart disease (RHD), which accounts for 3 percent of all disability-adjusted life years (DALYs) lost as a result of CVD, does not contribute significantly to the overall global burden of CVD. The burden of RHD will likely continue to diminish, but it is still an important inflammatory cause of heart disease in developing countries and accordingly is addressed in this chapter. We do not address many other forms of CVD because of the scope of this volume; the regional rather than global nature of some inflammatory diseases, such as Chagas disease; or the congenital abnormalities or genetically based cardiomyopathies for which prevention and treatment options remain limited.

Ischemic Heart Disease. IHD is the single largest cause of death in the developed countries and is one of the main contributors to the disease burden in developing countries. The two leading manifestations of IHD are angina and acute myocardial infarction. In 2001, IHD was responsible for 7.3 million deaths and 58 million DALYs lost worldwide (WHO 2002b). Seventy-five percent of global deaths and 82 percent of the total DALYs resulting from IHD occurred in the low- and middle-income countries.

Glossary

ACE inhibitors (angiotensin-converting enzyme inhibitors): a group of antihypertensive drugs that exert their influence through the renin-angiotensin-aldosterone system.

Antiplatelets: drugs that interfere with the blood's ability to clot.

Atherosclerosis: a chronic disease characterized by thickening and hardening of the arterial walls.

Atrial fibrillation: an abnormal rhythm of the heart that can result in an increased risk of stroke because of the formation of emboli (blood clots) in the heart.

Beta-blockers: a group of drugs that decrease the heart rate and force of contractions and lower blood pressure.

Cardiogenic shock: poor tissue perfusion resulting from failure of the heart to pump an adequate amount of blood.

Cardiomyopathy: a disorder of the muscle limiting the heart's function.

Chagas disease: a tropical American disease caused by a parasitic infection. Chronic symptoms include cardiac problems, such as an enlarged heart, altered heart rate or rhythm, heart failure, or cardiac arrest.

Dyslipidemia: a condition marked by abnormal concentrations of lipids or lipoproteins in the blood.

Embolus: a blood clot that moves through the bloodstream until it lodges in a narrowed vessel and blocks circulation.

Endocarditis: inflammation of the lining of the heart and its valves.

Hypertension: abnormally high arterial blood pressure.

Reperfusion: restoration of the flow of blood to a previously ischemic tissue or organ.

Statins: a group of drugs that inhibit the synthesis of cholesterol and promote the production of low-density lipoprotein (LDL)-binding receptors in the liver, resulting in a decrease in the level of LDL and a smaller increase in the level of high-density lipoprotein (HDL).

Thrombolysis: the breaking up of a blood clot.

Thrombus: a blood clot that forms inside a blood vessel or cavity of the heart.

Transient ischemic attack: transient reduced blood flow to the brain that produces strokelike symptoms but no lasting damage.

Angina is the characteristic pain of IHD. It is caused by atherosclerosis leading to stenosis (partial occlusion) of one or more coronary arteries. Patients with chronic stable angina have an average annual mortality of 2 percent or less. Acute myocardial infarction (AMI) is the total occlusion of a major coronary artery with a complete lack of oxygen and nutrients leading to cardiac muscle necrosis. AMI is usually diagnosed by changes in the electrocardiogram; by elevated serum enzymes, such as creatine phosphokinase and troponin T or I; and by pain similar to that of angina. Thirty-day mortality after an AMI is high: even with best medical therapy it remains at about 33 percent, with half the deaths occurring before the individual reaches the hospital. Even in a hospital with a coronary care unit where advanced care options are available, mortality is still 7 percent. In a hospital without such facilities or therapies, the mortality rate is closer to 30 percent. Even though mortality among patients who have recovered from an AMI has declined in recent decades, approximately 4 percent of patients who survive initial hospitalization die in the first year following the event (Antman and others 2004).

Stroke. Stroke is caused by a disruption in the flow of blood to part of the brain either because of the occlusion of a blood vessel (ischemic stroke) or the rupture of a blood vessel (hemorrhagic stroke). Many of the same risk factors for IHD apply to stroke; in addition, atrial fibrillation is an important risk factor for stroke. The annual risk of stroke in patients with non-valvular atrial fibrillation is 3 to 5 percent, with 50 percent of thromboembolic stroke being attributable to atrial fibrillation (Wolf, Abbott, and Kannel 1991). Chapter 32 discusses the diagnosis and management of the clinical syndromes in greater detail.

Congestive Heart Failure. CHF is the end stage of many heart diseases. It is characterized by abnormalities in myocardial function and neurohormonal regulation resulting in fatigue, fluid retention, and reduced longevity. CHF is caused by pathological processes that affect the heart; IHD and hypertension-related heart disease are the most common etiologies. The risk of developing CHF is two times more in hypertensive men and three times more in hypertensive women compared with those who are normotensive. CHF is five times more common in those who

have had an AMI than in those who have not. The prognosis for those with established CHF is generally poor and worse than for those with most malignancies (McMurray and Stewart 2000) or AIDS, with a one-year mortality rate as high as 40 percent and a five-year mortality between 26 and 75 percent.

The worldwide burden of CHF is substantial and continues to rise. Throughout the developed world the prevalence is about 2 to 3 percent, with an annual incidence rate of 0.1 to 0.2 percent (McMurray and Stewart 2000). However, the incidence and prevalence of CHF rise dramatically with age. Prevalence is 27 per 1,000 population for those older than 65, compared with 0.7 per 1,000 for those younger than 50 (McKelvie 2003). CHF occurs more frequently in men, and incidence and mortality differ substantially according to gender and socioeconomic status. CHF causes 53,000 deaths in the United States each year and contributes to another 213,000, and the death rate attributed to CHF rose by 155 percent from 1979 to 2001 in the United States (American Heart Association 2002). CHF is the first-listed diagnosis in 1 million hospitalizations.

Rheumatic Heart Disease. RHD is the consequence of an acute rheumatic fever (ARF)—that is, a poorly adapted autoimmune response to group A β -hemolytic streptococci. It affects the connective tissue, mainly the joints and the heart valves. The most serious complications are valvular stenosis, regurgitation following the valvulitis, or both (Ephrem, Abegaz, and Muhe 1990). RHD is also a predisposing factor for infective endocarditis, a disease of younger adults, predominantly males (Koegelenberg and others 2003).

According to 2001 estimates, RHD accounts for 338,000 deaths per year worldwide, two-thirds of them in Southeast Asia and the Western Pacific (WHO 2002b). About 12 million people in developing countries, most of them children, suffer from RHD (WHO 1995). Steer and others' (2002) review of developing countries suggests that RHD prevalence in children is between 0.7 and 14 per 1,000, with the highest rates in Asia. RHD and ARF are the most common causes of cardiac disease among children in developing countries (Ephrem, Abegaz, and Muhe 1990; Schneider and Bezabih 2001; Steer and others 2002) and account for almost 10 percent of sudden cardiac deaths (Kaplan 1985).

Until the 1950s, ARF accounted for a substantial portion of cardiovascular problems among schoolchildren in developed countries, and even though it is now far less common, outbreaks still occur (Carapetis, Currie, and Kaplan 1999), suggesting that neither antibiotics nor other public health measures have been totally effective in controlling ARF.

The Epidemiological Transition

Over the past two centuries, the industrial and technological revolutions have resulted in a dramatic shift in the causes of

illness and death. Before 1900, infectious diseases and malnutrition were the most common causes of death; however, primarily because of improved nutrition and public health measures, they have gradually been supplanted in most high-income countries by CVD and cancer. As improvements continue to spread to developing countries, CVD mortality rates are increasing.

Known as the epidemiological transition, this shift is highly correlated with changes in personal and collective wealth (the economic transition), social structure (the social transition), and demographics (the demographic transition). Omran (1971) provides an excellent model of the epidemiological transition that divides it into three basic ages: pestilence and famine, receding pandemics, and degenerative and human-created diseases (table 33.1). Olshansky and Ault (1986) add a fourth stage: delayed degenerative diseases.

The consistent pattern for most high-income countries going through the epidemiological transition has been initially high rates of stroke, mostly hemorrhagic. Only in the third phase, with the presence of increased resources, but coupled with increased diabetes and smoking rates and adverse lipid profiles, do rates of IHD climb. This phase is also accompanied by better control of severe hypertension, reducing the rates of hemorrhagic stroke, which is then replaced by ischemic stroke. Most regions appear to be following this pattern and have a predominance of IHD. The two exceptions are East Asia and the Pacific and Sub-Saharan Africa. The pattern in East Asia and the Pacific is dominated by China and appears to be a result of China's stage in the transition but may also be following a pattern similar to Japan's—that is, dominated by more strokes and fewer IHD deaths—whereas Sub-Saharan Africa is in an earlier phase of the epidemiological transition.

Even though countries tend to enter these stages at different times, the progression from one stage to the next tends to proceed in a predictable manner. The six World Bank regions are at various phases of the epidemiological transition (table 33.1), and where development has occurred, it has often been at a more compressed rate than in the high-income countries. Although rates of IHD and stroke fell 2 to 3 percent per year in the high-income countries during the 1970s and 1980s, the rate of decline has since slowed. Overweight and obesity are escalating at an alarming pace, while rates of type 2 diabetes, hypertension, and lipid abnormalities associated with obesity are on the rise. This trend is not unique to the developed countries, however. According to the World Health Organization, worldwide more than 1 billion adults are overweight and 300 million are clinically obese. Even more disturbing are increases in childhood obesity that have led to large increases in diabetes and hypertension. If these trends continue, age-adjusted CVD mortality rates could increase in the high-income countries in the coming years. These trends are discussed in greater detail in chapter 45.

Table 33.1 Stages of the Epidemiological Transition and Its Global Status, by Region

Stage	Description	Life expectancy (years)	Dominant form of CVD	Percentage of deaths attributable to CVD	Percentage of the world's population in this stage	Regions affected
Pestilence and famine	Predominance of malnutrition and infectious diseases	35	RHD, cardiomyopathy caused by infection and malnutrition	5–10	11	Sub-Saharan Africa, parts of all regions excluding high-income regions
Receding pandemics	Improved nutrition and public health leads to increase in chronic diseases, hypertension	50	Rheumatic valvular disease, IHD, hemorrhagic stroke	15–35	38	South Asia, southern East Asia and the Pacific, parts of Latin America and the Caribbean
Degenerative and human-created diseases	Increased fat and caloric intake, widespread tobacco use, chronic disease deaths exceed mortality from infections and malnutrition	60	IHD, stroke (ischemic and hemorrhagic)	>50	35	Europe and Central Asia, northern East Asia and the Pacific, Latin America and the Caribbean, Middle East and North Africa, and urban parts of most low-income regions (especially India)
Delayed degenerative diseases	CVD and cancer are leading causes of morbidity and mortality, prevention and treatment avoids death and delays onset, age-adjusted CVD declines	>70	IHD, stroke (ischemic and hemorrhagic), CHF	<50	15	High-income countries, parts of Latin America and the Caribbean

Risk Factors

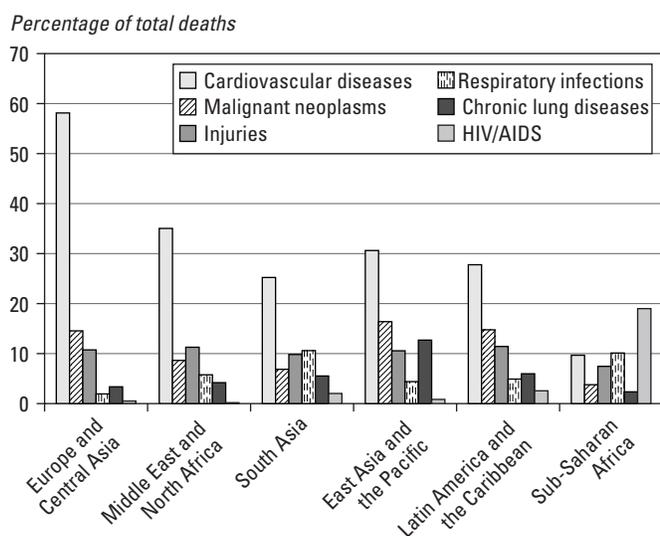

The risk of developing CVD depends to a large extent on the presence of several risk factors. The major risk factors for CVD include tobacco use, high blood pressure, high blood glucose, lipid abnormalities, obesity, and physical inactivity. The global variations in CVD rates are related to temporal and regional variations in these known risk factors. Discussions of the strength of the associations of the various factors with CVD are found elsewhere (chapters 30, 44, and 45). Although some risk factors, such as age, ethnicity, and gender, obviously cannot be modified, most of the risk is attributable to lifestyle and behavioral patterns, which can be changed.

BURDEN OF DISEASE

CVD is the leading cause of death in all World Bank regions with the exception of Sub-Saharan Africa (figure 33.1), where HIV/AIDS has emerged as the leading cause of mortality (Mathers and others 2006). Between 1990 and 2020, IHD is anticipated to increase by 120 percent for women and 137 percent for men in developing countries, compared with age-related increases of 30 to 60 percent in developed countries (Leeder and others 2004). Even though 80 percent of CVD deaths occur in low- and middle-income countries, the death rates for most regions are still below the rate for high-income countries, which is 320 per 100,000 population annually. The marked exception is Europe and Central Asia, which has a rate of 690 CVD deaths per 100,000 population.

Regional Burdens

The majority of the burden occurs in East Asia and the Pacific, Europe and Central Asia, and South Asia because a large pro-

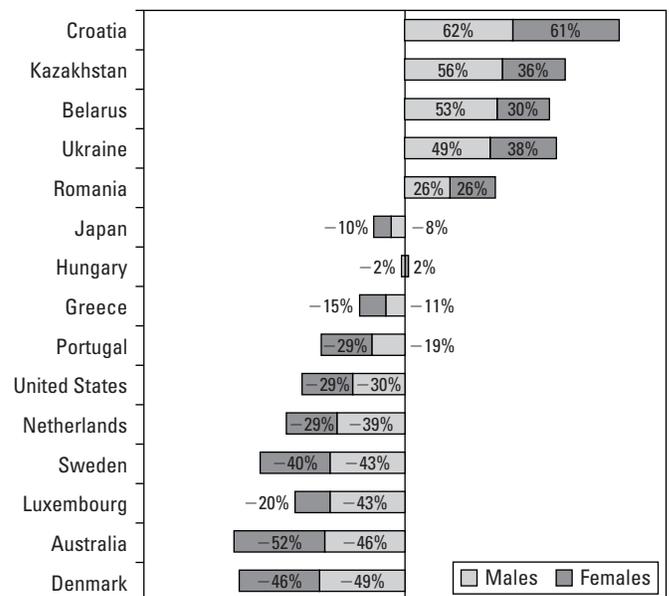

Source: Mathers and others 2006.

Figure 33.1 Major Causes of Death in Persons of All Ages in Low- and Middle-Income Regions

portion of the world's population lives in East Asia and the Pacific and South Asia and the incidence of IHD is high in Europe and Central Asia.

East Asia and the Pacific. The status and character of the epidemiological transition across the region reflects the diversity of economic circumstances in East Asia and the Pacific. Since the 1950s, life expectancy in China has nearly doubled from 37 years to 71 years (WHO 2003b). Approximately 60 percent of the population still lives outside urban centers, and as is the case in most developing countries, rates of IHD, stroke, and hypertension are higher in urban centers. China appears to be straddling the second and third stages of a Japanese-style epidemiological transition, with CVD rates higher than 35 percent, though dominated by stroke, not IHD. However, in urban China, the death rate from IHD rose by 53 percent from 1988 to 1996.

Europe and Central Asia. The emerging market economies, which consist of the former socialist states of Europe, are largely in the third phase of the epidemiological transition. As a group, they have the highest rates of CVD mortality in the world, similar to those seen in the United States in the 1960s when CVD was at its peak. Belarus, Croatia, Kazakhstan, Romania, and Ukraine have seen significant increases in IHD death rates (figure 33.2). In the Russian Federation, life expectancy for men has dropped precipitously since 1986 from 71.6 years to about 59 years in 2004, in large part because of CVD. In the Czech Republic, Hungary, Poland, and Slovenia, age-adjusted CVD rates have been declining. Nevertheless, CVD rates generally remain higher than in Western Europe.

Source: Mackay and Mensah 2004.

Figure 33.2 Percentage Change in Ischemic Heart Disease Death Rates in People Age 35 to 74, 1988–98, Selected Countries

Latin America and the Caribbean. In 2001, CVD accounted for about 31 percent of all deaths in Latin America and the Caribbean, but that figure is expected to rise to 38 percent by 2020 (Murray and Lopez 1996). In recent decades, average life expectancy in Latin America and the Caribbean has risen from 51 to 71 years, and the quality of nutrition has improved steadily. At the same time, the region has seen a switch from vegetables as a source of protein to animal protein and an increase in fat intake as a percentage of energy. As a whole, the region seems to be in the third phase, but in South America, some areas are still in the first phase of the transition.

Middle East and North Africa. Increasing economic wealth in the Middle East and North Africa has been characteristically accompanied by urbanization. The rate of CVD has been increasing rapidly and is now the leading cause of death, accounting for 25 to 45 percent of total deaths. Over the past few decades, daily per capita fat consumption has increased in most countries in the region, ranging from a 13.6 percent increase in Sudan to a 143.3 percent increase in Saudi Arabia (Musaiger 2002). IHD is the predominant cause of CVD, with about three IHD deaths for every stroke death. RHD remains a major cause of morbidity and mortality, but the number of hospitalizations for RHD is declining rapidly.

South Asia. Some regions of India appear to be in the first phase of the transition, whereas others are in the second or even the third phase. Nonetheless, India is experiencing an alarming increase in heart disease, which seems to be linked to changes in lifestyle and diet, rapid urbanization, and possibly an underlying genetic component. Diabetes is also a major health issue. India has 31.6 million diabetics, and the number is expected to reach 57.2 million by 2025 (Ghaffar, Reddy, and Singhi 2004). The World Health Organization estimates that, by 2010, 60 percent of the world's cardiac patients will be in India. About 50 percent of CVD-related deaths occur among people younger than 70, compared with about 22 percent in the West. Between 2000 and 2030, about 35 percent of all CVD deaths in India will occur among those age 35 to 64, compared with only 12 percent in the United States and 22 percent in China (Leeder and others 2004).

Sub-Saharan Africa. In Sub-Saharan Africa, deaths attributable to CVD are projected to more than double in between the years 1990 and 2020. Although HIV/AIDS is the leading overall cause of death in this region, CVD is the second-leading killer and is the first among those over the age of 30. Stroke is the dominant form, in keeping with patterns characteristic of earlier phases of the epidemiological transition. With increasing urbanization, levels of average daily physical activity are falling and smoking rates are increasing. Hypertension has emerged as a major public health concern, and hypertensive

disease accounts for the dominance of stroke (Bertrand 1999). RHD and cardiomyopathies, the latter caused mostly by malnutrition, various viral illnesses, and parasitic organisms, are also important causes of CVD mortality and morbidity.

Social and Economic Impact

Leeder and others' (2004) report highlights the economic impact of cardiovascular diseases in developing economies, which arises largely because working-age adults account for a high proportion of the CVD burden. Conservative estimates in Brazil, China, India, Mexico, and South Africa indicate that each year at least 21 million years of future productive life are lost because of CVD. In South Africa, for example, costs for the direct treatment of CVD were equivalent to 2 to 3 percent of gross domestic product, or roughly 25 percent of all health care expenditures (Pestana and others 1996).

Current expenditures in developed countries are indicators of possible future expenditure in developing countries. For example, Hodgson and others (2001) estimated that in 2003 the direct and indirect costs of CVD in the United States would amount to US\$350 billion. They also estimated that in 1998 Americans spent US\$109 billion on hypertension, equivalent to about 13 percent of the health care budget. Studies are limited but suggest that obesity-related diseases are responsible for 2 to 8 percent of all health care expenditures in developed countries.

COST-EFFECTIVENESS OF INTERVENTIONS

CVD remains one of the most studied and written about subjects in medicine. As a result, many interventions exist with strong evidence for significant reductions in morbidity and mortality associated with CVD.

Intervention Effectiveness by Disease

This chapter addresses those interventions believed to have the largest effect because they result in large reductions in CVD events, are inexpensive, or the prevalence or incidence of the diseases to which they are directed is significant. The omission of an intervention does not imply that it is not cost-effective but rather that either it had an effect on a smaller percentage of people or the chapter was unable to encompass all such interventions.

Acute Myocardial Infarction. Treatment of AMI involves medical therapies that reduce myocardial oxygen demand and fatal arrhythmias (beta-blockers), that restore blood flow by inhibiting platelet aggregation (aspirin), or that dissolve the thrombus occluding the arterial lumen (thrombolytics) or an invasive intervention with cardiac catheterization and angioplasty.

Beta-blockers are used both during and after an AMI. Benefits persist for at least 6 years and up to 15 years after the first AMI. The second Thrombolysis in Myocardial Infarction trial showed significant benefits when beta-blockers were used within two hours of symptoms (Roberts and others 1991).

Aspirin, an antiplatelet agent, and thrombolytic agents, the standard treatments for reopening the artery in AMI, have demonstrated an additive effect in reducing mortality (GISSI 1986), with a benefit irrespective of age, sex, blood pressure, heart rate, or previous history of AMI or diabetes (Fibrinolytic Therapy Trialists' Collaborative Group 1994). The benefits are greater the closer the thrombolytics are given to the time of onset, and the risk of bleeding is greater the later they are given. The risk of adverse events following administration of thrombolytics is low during the first 24 hours; trials with thrombolytics show that the benefits are greatest when they are administered less than 12 hours after an AMI and preferably less than 6 hours (Antman and others 2004).

The invasive alternative to immediate medical reperfusion of an occluded coronary artery is angioplasty or percutaneous coronary intervention. Its superiority over thrombolysis in developed countries remains a matter of debate. Issues that remain important in relation to the choice of strategy are overall severity or location of the AMI and the time from symptom onset to initiation of treatment. In patients presenting late or with a high risk of mortality, such as those in cardiogenic shock, percutaneous coronary intervention may be beneficial (Hochman and others 1999). However, as with thrombolytic agents, the benefits of percutaneous coronary intervention diminish significantly with time between the onset of symptoms and the opening of the artery (De Luca and others 2004; D. O. Williams 2004).

The invasive strategy requires a facility and individual physicians who conduct enough of the procedures annually to remain proficient. In the absence of these conditions, the American Heart Association recommends that treatment focus on thrombolytics (Antman and others 2004). Given either a lack of facilities and operators for percutaneous interventions or long distances to such facilities in many developing countries, we did not evaluate this procedure.

Long-Term Management of Existing Vascular Disease. The management of individuals with chronic vascular disease consists of invasive techniques, pharmacotherapy, lifestyle and behavioral changes, and rehabilitative measures. It also involves addressing such issues as adherence to treatment, regular follow-ups to determine compliance and assess risk, and treatment of comorbidities that are likely to have an impact on the progression of vascular disease (for instance, renal disease).

Invasive Interventions The three most common procedures are coronary artery bypass graft (CABG), percutaneous trans-

luminal coronary angioplasty (PTCA), and PTCA with stents. CABG is the placement of grafts, usually from the saphenous vein or internal mammary artery, to bypass stenosed coronary arteries while maintaining cerebral and peripheral circulation by cardiopulmonary bypass. CABG is a major operative procedure requiring appropriate surgical and anesthetic environments and has a perioperative mortality of 1 to 3 percent, with later complication rates of 15 to 20 percent.

Almost 1 million CABGs per year are performed worldwide, with about 519,000 interventions in the United States alone in 2000 (American Heart Association 2002). The main indication for CABG is for those with left main coronary artery stenosis or those with involvement of multiple coronary arteries with reduced left ventricular function, particularly among diabetics. The prevalence estimates of those with left main coronary artery stenosis or involvement of three coronary arteries has varied over time, but current estimates range from 7 to 20 percent of survivors of myocardial infarction (Kuntz and others 1996; Rogers and others 1991; Topol, Holmes, and Rogers 1991). For these cases, investigators have shown that CABG is more beneficial than medical treatment, both in terms of symptoms and of mortality (Eagle and others 1999).

Both developed and developing countries are increasingly using PTCA (Denbow and others 1997). The main indications for its use are low-risk patients with single- or double-vessel disease and poor response to medical treatment. The success rate of PTCA is more than 95 percent; however, because it has no mortality benefit when compared with medical therapy or CABG, we did not evaluate new analyses of the cost-effectiveness of this intervention, but instead provided information from experience in developed countries. The addition of stents to PTCA has led to a decrease in restenosis rates and readmissions to hospitals but shows no change in mortality compared with medical therapy.

Pharmacological Interventions The pharmacological interventions either prevent thrombosis, as does aspirin, or target the individual risk factors, as do the antihypertensives (diuretics, beta-blockers, and ACE inhibitors) or statins targeting cholesterol. Furthermore, these agents may possibly have additional properties of reducing the risk of fatal arrhythmias, improving repair after AMI (remodeling), or stabilizing the atherosclerotic plaque.

Overall, the long-term administration of antiplatelet agents in those with vascular disease leads to a 25 percent reduction in the risk of major vascular events: 33 percent for nonfatal AMI, 25 percent for nonfatal stroke, and 16 percent for any vascular death. The use of aspirin has produced similar benefits in individuals with IHD or prior stroke. Antiplatelet treatment in individuals with a previous AMI has been shown to prevent 18 nonfatal myocardial infarctions, 5 nonfatal strokes, and 14 vascular deaths for every 1,000 patients

treated for two years (Antithrombotic Trialists' Collaboration 2002).

The benefits of antiplatelet agents for those with vascular disease far outweigh the risks. The risk of intracranial bleeding increases by nearly 25 percent with the use of antiplatelet agents, but in absolute terms this risk comes to only one or two intracranial bleeds per 1,000 patients treated per year. The risk of major extracranial bleeding, mostly gastrointestinal, also increases by 60 percent, or one or two excess events per 1,000 patients per year.

The most established and commonly used agent is aspirin, although other agents (for example, clopidogrel or ticlopidine) with similar efficacy but much greater cost are available. Low doses of aspirin—75 to 100 milligrams (mg) per day—are as beneficial as higher doses.

Lowering LDL and elevating HDL cholesterol levels is one of the cornerstones of treatment of cardiovascular disease, and investigators have suggested that suboptimal levels of cholesterol contribute to almost two-thirds of the global cardiovascular risk (WHO 2002b). Although the usual target of lipid-lowering therapy has been lowering total or LDL cholesterol, medical experts are increasingly recognizing the importance of increasing HDL cholesterol and lowering triglyceride levels, especially in high-risk individuals, such as those with diabetes or metabolic syndrome, as well as in ethnic populations like Southeast Asians.

Recent evidence has demonstrated that the relationship between cholesterol levels and vascular events is continuous and occurs at much lower cholesterol thresholds than previously believed. The clinical trials have consistently demonstrated a 25 to 30 percent reduction in the risk of cardiovascular morbidity and mortality. Furthermore, the evidence suggests that more aggressive reductions in cholesterol have higher benefits than mild or moderate reductions (Cannon and others 2004; Knatterud and others 2000). No increased risk of cancers appears to exist, as was previously believed, although a small increase exists in the risk of inflammation of noncardiac muscle (myopathy) (Pfeffer and others 2002).

As with cholesterol, the relationship between blood pressure and vascular events is continuous and is discussed further in chapter 45. Even patients with presumed “normal” blood pressure and prior vascular disease benefit from lowering blood pressure (Nissen and others 2004), confirming earlier evidence that individuals with a history of AMI who have lower blood pressure are less likely to have future vascular events. Furthermore, investigators have established mortality and morbidity benefits for several specific classes of drugs to reduce blood pressure in patients with vascular disease, namely, beta-blockers, calcium-channel blockers, and ACE inhibitors (Fox 2003).

In patients with a prior history of stroke or transient ischemic attack (transient occlusion of artery supplying the

brain), the long-term benefits of lowering blood pressure have been clearly established. Lowering blood pressure reduces the overall risk of future stroke by 28 percent and of other vascular events and CHF by 26 percent in patients with a history of stroke disease, irrespective of their hypertension status. The benefits are even more pronounced for individuals with a history of hemorrhagic stroke. Larger reductions in blood pressure confer greater benefits, and benefits are present across different age groups, genders, and ethnicities and with varying comorbid status.

Beta-blockers are one of the cornerstones of long-term treatment of individuals with IHD, especially those with a history of AMI. Long-term use of beta-blockers has been associated with 23 percent relative risk reduction in mortality (Freemantle and others 1999), 25 percent relative risk reduction in nonfatal myocardial infarction, and 30 percent relative risk reduction in sudden cardiac death (Yusuf and others 1985). The benefits are larger for those at highest risk of sustaining a vascular event in the future and are present across all age groups and sexes. Furthermore, beta-blockers provide clear benefits in patients with chronic stable angina, where they provide symptom relief as well as reductions in vascular events (Heidenreich and others 1999).

ACE inhibitors have proved invaluable in preventing cardiovascular events and CHF in those with IHD. The extent to which the benefits conferred by their use are caused by their ability to lower blood pressure or by their other properties, such as cardiac remodeling and neurohormonal modulation, is not clear. Long-term use of ACE inhibitors in those with a history of myocardial infarction and in other individuals at high risk of vascular disease reduces vascular mortality by 25 percent and other nonfatal events, such as recurrent myocardial infarction, revascularization, hospitalization, progression or new onset of CHF, and stroke (Teo and others 2002). In those with asymptomatic or symptomatic left ventricular dysfunction after myocardial infarction, ACE inhibitors reduce the risk of a variety of vascular endpoints by 20 to 26 percent. Similarly, the use of ACE inhibitors even in those with no evident left ventricular dysfunction confers a 21 percent reduction in risk for major coronary events (Dagenais and others 2001), 32 percent for stroke (Bosch and others 2002), and 20 to 22 percent for composite vascular outcomes (Fox 2003).

Nonpharmacological Interventions Cessation of smoking and dietary modifications are important goals of secondary prevention of CVD. Cardiac rehabilitation, including exercise, is useful for a wide range of patients with IHD and reduces future vascular events by about 15 percent. Exercise alone reduces vascular mortality by 24 percent and vascular endpoints by 15 percent (Jolliffe and others 2000). Results of trials for psychological interventions targeted at stress, depression, low social support, and so on have been conflicting.

Congestive Heart Failure. Diuretics are standard therapy for CHF, with the loop and thiazide diuretics most commonly used. Diuretics provide relief of symptoms more rapidly than any other CHF medication because they are the only drugs that can adequately control the fluid retention associated with CHF. Using spironolactone, a neurohormonal antagonist, together with a diuretic decreased the risk of mortality by 30 percent and of hospitalization by 35 percent, compared with a placebo in patients with severely advanced heart failure (Pitt and others 1999); however, this combination requires intensive monitoring of electrolytes and testing to follow patients and thus was not included in our cost-effectiveness analyses.

Investigators have shown that ACE inhibitors reduce risks related to a variety of endpoints, including mortality, hospitalization, major coronary events, deterioration of symptoms, and progression from asymptomatic to symptomatic left ventricular dysfunction, by 25 to 33 percent. The benefit is conferred irrespective of the etiology of systolic failure; begins soon after the start of treatment; persists over the long term; and is independent of age, sex, and baseline use of other medications. Furthermore, the use of ACE inhibitors has proved to be highly cost-effective in developed countries.

Beta-blockers improve symptoms, decrease hospitalization and deterioration of heart function, and improve mortality. They should be used even when the patient becomes asymptomatic. Beta-blockers are beneficial at all stages of CHF, reducing the morbidity and mortality associated with CHF by 25 to 33 percent. Because most patients with CHF die of sudden cardiac death, the protective effects of beta-blockers are probably related to their antiarrhythmic properties.

Digitalis decreases hospitalization rates in individuals with CHF but has no effect on vascular or total mortality (Digitalis Investigation Group 1997). Given that it also has a narrow therapeutic-toxic window and requires careful monitoring, its role in standard treatment for CHF has diminished and has not been included in our cost-effectiveness analyses.

Rheumatic Heart Disease. The management of patients with ARF includes providing antistreptococcal treatment, managing clinical manifestations, and screening children. In the acute stage, all patients with ARF should be treated as if they have a group A streptococcal infection—that is, with a 10-day course of penicillin. Anti-inflammatory agents provide symptomatic relief during ARF but do not prevent RHD. Secondary prophylaxis prevents colonization of the upper respiratory tract and consists of penicillin or sulfadiazine for the first five years (and for life for patients with valvular heart disease). Noncompliance is frequent, reaching rates as high as one-third of patients (Bassili and others 2000). Tertiary treatment entails surgery for valve replacement or valvuloplasty.

Linking Costs and Effectiveness in Developing Countries

Few intervention trials have been carried out solely in developing countries, but investigators have extrapolated estimates of cost-effectiveness ratios for the developing world in general based on changes in key input prices (Goldman and others 1991); however, this process is limited by the fact that both the underlying epidemiology and the costs can differ significantly across and within countries and regions. Thus, our results reflect models that used prices and epidemiological data for World Bank regions where applicable. Intervention effects were, however, based on systematic reviews of randomized trials or meta-analyses in developed countries. Until intervention trials are conducted in developing countries, this option remains the best for evaluating the cost-effectiveness of various interventions in the developing regions. In cases in which models for diseases in selected regions were not developed, we present results of cost-effectiveness analyses from high-income countries.

We used estimates of life expectancy for the model from data supplied by the volume editors. The model includes only the costs related to the intervention itself and to CVD events and their sequelae. Costs include personnel salaries, health care visits, diagnostic tests, and hospital stays as provided by the volume editors. Our analysis does not include indirect costs, such as those arising from lost work time or family assistance. Drug costs are from McFayden (2003). All are in U.S. dollars unless otherwise specified. Disability weights were taken from Mathers and others (2006).

Ischemic Heart Disease.

Acute Myocardial Infarction We evaluated four incremental strategies for the treatment of AMI and compared them with a strategy of no treatment as a base case. The four treatment strategies were aspirin (162.5 mg per day for 30 days); aspirin and atenolol (100 mg per day for 30 days); aspirin, atenolol, and streptokinase (1.5 million units); and aspirin, atenolol, and tissue plasminogen activator (100 mg accelerated regimen). Doses for the aspirin and streptokinase were those used by the Second International Study of Infarct Survival Collaborative Group (ISIS-2 Collaborative Group 1988), the atenolol regimen was that of the First International Study of Infarct Survival (ISIS-1 Collaborative Group 1986), and the tissue plasminogen activator dosing was that used in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO)—I trial (GUSTO Investigators 1993). The relative risk of dying from AMI was reduced for all patients receiving the medications. Patients receiving the thrombolytics faced increased risks of major bleeds and hemorrhagic strokes. Because the effectiveness of streptokinase diminishes over time, we carried out two further sensitivity analyses to compare its use for patients over and under the age of 75 and for patients who receive the intervention sooner or later than six hours after the onset of symptoms.

Table 33.2 presents incremental cost-effectiveness ratios (ICERs) for each therapy by region. The incremental cost per DALY averted was less than US\$25 for all six regions for the aspirin and aspirin plus atenolol interventions; US\$634 to US\$734 for aspirin, atenolol, and streptokinase; and slightly less than US\$16,000 for aspirin, atenolol, and tissue plasminogen activator. Minor variations occurred between regions because of small differences in follow-up care costs. The results for an analysis that evaluated ICERs as cost per life year saved showed no significant differences.

Table 33.3 displays the results of the secondary analysis for streptokinase and tissue plasminogen activator. Giving the streptokinase sooner than six hours following onset reduces the incremental cost per DALY to less than US\$440 compared with more than US\$1,300 if given after six hours. Similar effects are seen when streptokinase is given to those under 75 compared with those 75 years or older.

According to meta-analyses, nitroglycerin has a modest effect on mortality in AMI: a 3 percent reduction. However, given that it can have profound effects on blood pressure that could limit the use of beta-blockers that confer more significant benefits, its use should be limited to patients with ongoing ischemic pain and systolic blood pressures greater than 90 millimeters of mercury who do not have ongoing right ventricular infarction. When modeled, it had a reasonable cost-effectiveness ratio of US\$70 per life year saved, but we did not include the analysis in the incremental analysis because of the blood pressure effects of the multiple agents.

Secondary Prevention Four medical therapies— aspirin, beta-blockers, statins, and ACE inhibitors—have been the mainstay of treatment for those with IHD in the developed world. To evaluate the best medical intervention, we used incremental cost-effectiveness analysis to examine the 15 different possible combinations of the four standard medical therapies. The four therapies were 75 to 100 mg per day of aspirin, 100 mg per day of atenolol, 10 mg per day of enalapril, and 40 mg per day of lovastatin. In addition, CABG surgery provides an invasive option that gives added mortality benefit when compared with conventional medical therapy in patients with certain anatomical obstructions in coronary circulation. Thus, we evaluated CABG in addition to all four medications for those with left main coronary artery disease or with three-vessel coronary artery disease and reduced left ventricular function. Because these therapies also have significant effects on the incidence of stroke, we included the effect on DALYs and costs for stroke in the analyses.

In addition to the mortality benefits demonstrated by trials of the individual medications or surgery, they also resulted in significant reductions in hospitalizations in developed countries. The cost savings from these reduced hospitalizations make the cost-effectiveness of such interventions quite favor-

able in developed countries; however, given that hospital facilities may not be available to most patients in many developing regions, we undertook two separate analyses, one with hospital costs and one without.

In a setting where hospitals are available, a combination of aspirin and atenolol dominated no therapy and was cost saving in all regions (table 33.2). The ICERs for the addition of enalapril ranged from US\$660 per DALY in Sub-Saharan Africa to US\$866 per DALY in Europe and Central Asia. The combination of all four medications ranged from US\$1,720 per DALY to US\$2,026 per DALY. For CABG the costs per DALY ranged from about US\$24,000 to more than US\$72,000. Despite having similar benefits as aspirin and atenolol in relation to mortality, enalapril and lovastatin demonstrated higher per DALY costs because of the added costs of monitoring renal and liver function, respectively, as is required for these two medications.

When we assumed that hospitals were not readily available (table 33.2), no therapy combination was cost saving compared with no therapy. The combination of aspirin and atenolol was the next best strategy, with ICERs ranging from US\$386 per DALY in South Asia to US\$545 per DALY in Latin America and the Caribbean. The addition of enalapril increased the range of ICERs to US\$783 per DALY to US\$1,111 per DALY, and the addition of lovastatin increased them still further. CABG was not evaluated because of the underlying assumption that hospitals were not available.

Table 33.4 shows the number of events prevented with the four-drug combination medical therapy compared with no therapy and the additional number of events averted with CABG compared with the four-drug combination. The medical regimen alone would prevent some 2,000 CVD deaths, about 4,000 myocardial infarctions, and approximately 200 strokes per million persons treated in each region. The use of CABG in addition to the medical regimen would prevent an additional 65–70 deaths, nearly 300 myocardial infarctions, and up to 30 strokes per million population.

Congestive Heart Failure. The interventions examined for CHF were the addition of the ACE inhibitor enalapril, the beta-blocker metoprolol, or both to a baseline of diuretic treatment. As for the IHD interventions, we performed separate analyses for each assumption of whether or not hospital facilities would be available. For the model of treatment for CHF assuming hospitalization (table 33.2), the addition of enalapril is cost saving and the ICER for the addition of metoprolol ranges from US\$124 to US\$219 per DALY depending on the region. When the availability of hospitals is limited (table 33.2), the enalapril plus diuretics strategy is no longer cost saving, but it costs only US\$31 per DALY or less, and the ICER for enalapril, metoprolol, and diuretics increases only to about US\$275 per DALY. These figures are probably underestimates of the cost per

DALY, given some loss in the mortality benefit for the hospitalization that the model does not capture.

Rheumatic Heart Disease. For RHD, except in epidemics, secondary prevention is more effective than primary prevention. Primary prevention by means of antibiotic treatment of streptococcus infections of the pharynx is not highly cost-effective in endemic situations, given that only 10 to 20 percent of such infections are from streptococcus, less than 3 percent of these will evolve into rheumatic fever, and only a proportion of these continue on to RHD (Strasser 1985). The development of a rapid antigen test for diagnosing group A streptococcal pharyngitis may make primary prevention more cost-effective (Majeed and others 1993). Similarly, in an epidemic in which the proportion of infections from streptococcus is higher or the rate of progression to rheumatic fever is higher, primary prevention

may be cost-effective. Secondary prevention using benzathine penicillin injections is cost-saving according to Strasser (1985) and should be considered for all developing countries with the infrastructure to perform the required follow-up.

Cost-Effectiveness Analyses in High-Income Countries

Table 33.5 summarizes the results of cost-effectiveness analyses for CVD interventions in high-income countries. These results include analyses that are similar to ours. The differences are that they reflect costs and treatment patterns in the high-income countries studied, mostly the United States. Costs in developing countries are roughly one-fifth of those in developed countries (but closer to one-third in Latin America and approaching one-half in South Africa). However, where patented drugs are involved and patent laws are enforced, the costs may be much closer to U.S. levels.

Because the cost-effectiveness studies have been undertaken largely in the United States, the results do not always readily transfer to developing countries. In some U.S. studies, the alternative procedure considered is medical management; such facilities simply may not exist in developing countries. Similarly, interventions that are cost saving in the United States may not be cost saving in developing countries but may well be cost-effective in terms of cost per DALY saved. Furthermore, the cost-effectiveness analyses reflect morbidity and mortality rates in developed countries.

Interventions that Kupersmith and others (1995) classify as highly cost-effective in the United States (less than US\$20,000 per life year saved or quality-adjusted life year saved) may be cost-effective in many developing countries. Interventions that

Kupersmith and others (1995) classify as cost-effective in the United States (US\$20,000 to US\$40,000 per life year saved or quality-adjusted life year saved) are probably borderline cost-effective for developing countries. Interventions that Kupersmith and others (1995) classify as borderline, expensive, or very expensive in the United States are unlikely to merit public funding in developing countries.

Thus, medical interventions that are likely to be cost-effective in developing countries include benzathine penicillin injections as secondary prevention for those who have had rheumatic fever (usually for five years); ACE inhibitors for CHF; and various drugs (beta-blockers, off-patent statins) for long-term care following a myocardial infarction, confirming our earlier analyses. Other therapies that are probably cost-effective but that we did not analyze include antithrombotic agents (aspirin, heparin) to prevent venous thromboembolism; anticoagulants for medium- and high-risk nonvalvular atrial fibrillation (stroke); and anticoagulants for mitral stenosis and atrial fibrillation (stroke).

Selected invasive interventions that might possibly be cost-effective for CVD in certain developing countries include pacemaker implants for atrioventricular heart block, primary angioplasty for acute myocardial infarction, and reperfusion with streptokinase. Of course, the ability to undertake these interventions assumes a cost-effective infrastructure for diagnosis and referral and an adequate volume of cases. For example, the American Heart Association recommends acute angioplasty in centers where the physician conducts at least 75 such procedures each year and the hospital conducts at least 200 per year. For stroke, carotid endarterectomy is potentially cost-effective for symptomatic patients compared with aspirin alone, again in an environment with an adequate volume of cases. Cost-effectiveness is much lower for asymptomatic cases.

Interventions that rank as cost-effective for heart disease in the U.S. context and that are borderline cost-effective in developing countries include implantable cardioverter-defibrillator for cardiac arrest, primary stenting for single-vessel disease (the study was for men over age 55), CABG for two-vessel disease, and angiography for patients with a high probability of coronary artery disease.

RESEARCH AND DEVELOPMENT

Even though most of the interventions currently available appear to be expensive and complex for developing countries, the demand for effective care for cardiovascular diseases will exert major pressure on health systems in coming decades. Increased use of these procedures is already documented in China and India (Murray and Lopez 1994, 1997; Unger 1999). In this context, cardiovascular research should be concentrated in the fields of primary prevention, health services, clinical guidelines, clinical research, and epidemiology.

Primary Prevention

Because the control of many cardiovascular risk factors is strongly related to the legislative environment—for example, that pertaining to tobacco use or nutrition—the design and implementation of appropriate laws and regulations is likely to increase in developing countries. However, any such initiatives need to be monitored and systematically evaluated, especially to estimate the magnitude of the reduction achieved.

Another area of research is the assessment of chemoprophylaxis in primary prevention. Multidrug combinations such as the hypothetical “polypill” are likely to be the first practical initiative of a long list of important innovations. Both the efficacy and the effectiveness of new interventions in primary prevention should be evaluated as a matter of urgency, because no results of large-scale clinical trials in developing countries are as yet available.

Health Services

Capacity building—more specifically, education and training—of health care workers in developing countries, is a major issue for the future, along with critical evaluations of the performance of health workers. Such evaluations should compare various capacity-building strategies; for instance, they could compare the delivery of simplified regimens of care by community health workers versus delivery of care by trained health professionals.

The dissemination of innovations deserves special attention in a context of scarce resources (Berwick 2003). The transfer of technologies to developing countries should be made on cost-effectiveness criteria, which implies analysis conducted in the specific situation of developing countries—for example, cost-effectiveness for thrombolytics in a developing country might be much worse than in the United States if getting to a hospital on time is a problem. Sensitivity analysis of the cost-effectiveness of surgical and medical interventions in developing countries is also needed.

Furthermore, the appropriate incentives for technological changes in health care should be investigated (McClellan and Kessler 1999). This line of research includes analyses of the pricing of technologies (including drugs) or of new designs for services, such as point-of-care devices for use by community health workers.

The long period of incubation of CVD opens up opportunities for extensive screening based on preclinical signs and biomarkers. However, strong lines of research are needed to secure effective and safe screening programs and should include opportunistic screening for places where visits to health centers are limited.

Finally, all assessments made in relation to health services research should take into account the costs related to scaling up any procedure evaluated.

Clinical Guidelines

The diffusion of health technologies usually leads to a widening of the clinical indication beyond the evidence-based scope of the intervention (PTCA is a classic example) (Dravik 1998), corresponding to a decrease not only in the procedure's efficacy, but also in its effectiveness (Anderson and Lomas 1988; Blustein 1993). Several studies suggest that overuse and underuse tend to coexist in the same community and that even severe scarcity of resources does not protect against overuse of cardiological interventions, at least among certain segments of the population (Joorabchi 1979; Soumerai and others 1997).

The consequences of such trends are more dramatic in developing than developed countries. Therefore, the introduction of costly care should be accompanied by a corresponding effort in relation to the provision of formal education to providers and prescribers, complemented by the development of clinical guidelines aimed at avoiding both the overuse and the underuse of procedures.

Clinical guidelines are already numerous, but all have been established in affluent countries. A new, specific effort should be made in developing countries to address local issues, such as problems related to the availability of procedures or drugs or to accessibility of services, and the development and maintenance of these guidelines should follow best available standards.

Clinical Research

In most situations, health care innovations should be introduced as experimental interventions to permit proper monitoring and evaluation. These experiments do not have to address the efficacy of the procedure (many innovations will already have been tested), but rather issues pertaining to their effectiveness and efficiency in the specific context of developing countries.

Another reason for the experimental approach is the rapidity with which the field of CVD is evolving. It is not reasonable, at the local level, to wait until the publication of trial results and meta-analyses, which often takes place years after changes have occurred in everyday practice. For this reason, a new culture of clinical research should be developed in which every innovation should be taken as an opportunity for systematic experimental evaluation.

Among various topics in clinical research, adherence deserves special mention. On average, 50 percent of patients in developed countries do not take their prescribed medicines after one year, despite having full access to medicines. In developing countries, this poor adherence is made worse by poor access to health services and drugs, to lack of education, and to other factors (Bovet and others 2002; WHO 2003a). Options for improving adherence should be designed and experimented with.

Epidemiological Research

A basic task of epidemiological research is to assess geographic and secular trends in the distribution of risk factors. Of special relevance is the movement from regional to country levels and the trend within a country. The impact of poor health status in early life should be assessed from the impact of poor fetal health to the consequence of multiple childhood infections on the risk for CVD. Because of the scarce availability of resources, the development and maintenance of health care should be supported by a comprehensive information system. Simple, affordable health information systems are preferable along the lines of the framework developed by the World Health Organization.

CONCLUSIONS: PITFALLS AND PROMISES

A global CVD epidemic is rapidly evolving, and the burden of disease is shifting. Twice as many deaths from CVD now occur in developing as in developed countries. The vast majority of CVD can be attributed to conventional risk factors. Even in Sub-Saharan Africa, high blood pressure, high cholesterol, extensive tobacco and alcohol use, and low vegetable and fruit consumption are already among the top risk factors for disease. Because of the time lag associated with CVD risk factors, especially in children, the full effect of exposure to these factors will be seen only in the future. Information from more than 100 countries shows that more 13- to 15-year-olds smoke than ever before, and studies show that obesity levels in children are increasing markedly in countries as diverse as Brazil, China, India, and almost all island states (Leeder and others 2004). Populationwide efforts now to reduce risk factors through multiple economic and educational policies and programs will reap savings later in medical and other direct costs as well as indirectly in terms of improved quality of life and economic productivity.

Inherited Disorders of Hemoglobin

David Weatherall, Olu Akinyanju, Suthat Fucharoen, Nancy Olivieri, and Philip Musgrove

As a result of carrier protection against malaria, the inherited hemoglobin disorders are the commonest diseases attributable to single defective genes. Approximately 7 percent of the world's population is a carrier, and 300,000 to 500,000 babies with severe forms of such disorders are born each year (WHO 1989). Although these disorders are most frequent in tropical regions, they are now encountered in most countries because of migrations of populations.

INTRODUCTION

If untreated, many of the inherited hemoglobin disorders result in death during the first few years of life. Their effect on the burden of disease has only recently been recognized, following an epidemiological transition caused by improvements in hygiene, nutrition, and control of infection that has reduced childhood mortality. Babies with severe hemoglobin disorders are now able to survive long enough to present for diagnosis and treatment. The impact of these diseases is being felt throughout the Indian subcontinent and much of Asia. Although the situation will worsen in Sub-Saharan Africa as it undergoes a similar transition, such diseases are already responsible for a major health burden. International health agencies and the governments of affected countries need to understand the future extent of the problem and to develop programs to control and manage these diseases.

Normal Hemoglobin

Hemoglobin (Hb), the pigment in the red blood cells that transfers oxygen to the tissues, changes structure during

human development. In adults two components exist: a major hemoglobin, Hb A, and a minor hemoglobin, Hb A₂. The bulk of the hemoglobin during later fetal life is Hb F. These hemoglobins each consist of two pairs of unlike globin chains. The adult hemoglobins and fetal hemoglobin have α chains combined with β (Hb A, $\alpha_2\beta_2$), δ (Hb A₂, $\alpha_2\delta_2$), or γ chains (Hb F, $\alpha_2\gamma_2$). Each of the different globin chains is controlled by distinct genes; two genes exist for the α and γ chains and one for each of the other chains. Their structure and the regions of the genes that control the production of the different globin chains have been determined (Steinberg and others 2001; Weatherall and Clegg 2001b).

Spectrum of Inherited Hemoglobin Disorders

Inherited hemoglobin disorders fall into two main groups: the structural hemoglobin variants and the thalassemias, which are caused by defective globin production. They all follow a recessive form of inheritance. Those with a single defective globin gene—carriers or heterozygotes—are symptomless. If two carriers marry, a one in four chance exists that each child they produce will receive defective genes from each parent—that is, they are homozygous for the particular disorder.

The structural variants result mostly from single amino acid substitutions in the α or β chains. Often these are innocuous, but in some cases they may alter the stability or functional properties of the hemoglobin and lead to a clinical disorder. They are designated by letters of the alphabet or by the place names where the condition was first discovered. Even though researchers have identified more than 700 structural hemoglobin variants, only three (Hb S, Hb C, and Hb E) are widespread.

The homozygous state for the sickle cell gene results in sickle cell anemia, whereas the compound heterozygous state for the sickle cell and Hb C genes results in Hb SC disease. Hb SC disease, although milder, also has important public health implications. Hb E, the commonest variant globally, is innocuous in its heterozygous and homozygous states, but because it is synthesized less effectively than Hb A, it interacts with β thalassemia to produce an extremely common condition called Hb E β thalassemia, which is becoming an increasingly important health burden in many parts of Asia.

The thalassemias are classified according to the ineffectively synthesized globin chains. From a public health viewpoint, only the α and β thalassemias are sufficiently common to be important.

Clinical Features

The inherited hemoglobin disorders are characterized by an extremely diverse series of clinical syndromes of varying severity.

Sickle Cell Anemia and Related Disorders. The clinical features of sickle cell disorders reflect the red blood cells' propensity to assume a sickle shape in deoxygenated blood, leading to shortened red cell survival and a tendency to block small blood vessels (Bunn 1997; Serjeant 1992). Even though patients may adapt to their anemia, their illness is interspersed with acute episodes, including: attacks of bone pain; sequestration of blood into the lungs, liver, or spleen; or thrombosis of cerebral vessels, which may cause a stroke. They are extremely prone to infection, particularly during early childhood, and to a wide range of chronic complications. For reasons not yet understood, the severity of the disease varies extensively. Even in populations in eastern Saudi Arabia and parts of India, which have a high frequency of α thalassemia and an unusual ability to produce Hb F in adult life, both of which, when inherited with sickle cell disease, result in a milder form of the illness, morbidity is still high.

Although little is known about mortality from "sickling" disorders in developing countries, in Sub-Saharan Africa many children die early because of these conditions (Akinyanju 2001; Fleming and others 1979). Fleming and others, working in rural Nigeria, found that even though more than 2 percent of all newborns had sickle cell anemia, it was absent in the adolescent and adult populations. At the same time, they found that urban centers in Nigeria, where medical care was available, had an increasing number of affected adults, and by the late 1970s, a significant improvement in survival had clearly followed the introduction of antimalarial measures (Molineaux and others 1979). Both in Jamaica and in the United States, death appears to peak between one and three years of age, usually from infection. Recent U.S. data suggest that the median age of adult death is 42 for men and 48 for women (Dover and

Platt 1998). Even though Hb SC disease is milder than sickle cell anemia, it is associated with many complications, including a higher frequency of proliferative retinopathy.

Thalassemias. The homozygous or compound heterozygous states for β thalassemia also run a variable course, although without transfusion, death usually occurs in the first few years (Weatherall and Clegg 2001b). With adequate transfusions and the administration of drugs to remove iron, children may develop well and survive to adulthood. However, these drugs are expensive, and even when they are available in poorer countries, many children receive inadequate dosages and die in childhood or adolescence from iron overload. The situation is further complicated because the common β thalassemias of intermediate severity—notably Hb E β thalassemia—exhibit a clinical spectrum ranging from transfusion-dependent disease to a condition compatible with normal survival and growth into adult life without treatment.

The α thalassemias are equally heterogeneous. The extremely common milder forms (termed α^+ thalassemias because some α chains are produced) produce only a mild hypochromic anemia in homozygotes. In contrast, the α^0 thalassemias, so called because of the absence of α chain synthesis, result in stillbirth in their homozygous states following pregnancies with toxemic and postpartum complications. The compound heterozygous states for α^+ and α^0 thalassemias result in Hb H disease, which varies in severity and may be transfusion dependent.

The thalassemias are extremely heterogeneous at the molecular level: more than 200 different mutations of the β globin genes have been found, and the α thalassemias are almost as varied. Every severely affected population in the world has a few common mutations unique to a particular region, together with varying numbers of rare ones.

Population Genetics and Dynamics

The high gene frequencies for the hemoglobin disorders are attributable to the effects of natural selection. Although severely affected homozygotes would, in the absence of medical interventions, have died early in life, asymptomatic heterozygotes for Hb S, Hb C, and probably β thalassemia and Hb E, as well as those with mild forms of α thalassemia, are more resistant to severe malarial infection than normal persons. Hence, in environments in which malaria was common, carriers were protected and survived to have more children, and the gene frequencies rose until they were balanced by loss of severely affected homozygotes from the population. Although some decline in frequency among immigrant populations may occur because of lack of exposure to malaria and outbreeding, this decline will occur over many generations, and even if malaria were completely eradicated, an equally long time would pass before any significant fall occurred in the global frequency.

Changes resulting from variation in selection or in population dynamics will, however, be small compared with the effect of the demographic and epidemiological transitions that many countries have recently undergone. For example, thalassemia was not identified in Cyprus until 1944, when major improvements in public health revealed that the disease was common. By the early 1970s, estimates indicated that, in the absence of steps to control the disease, in about 40 years approximately 78,000 units of blood would be required each year to treat all the severely affected children, 40 percent of the population would be carriers, and the cost to the health system would equal or exceed the island's health budget (Weatherall and Clegg 2001b).

Global Distribution and Frequency of the Hemoglobinopathies

Figures 34.1a and 34.1b show the global distributions of the hemoglobinopathies. Table 34.1 shows approximate carrier frequencies by region.

The gene for Hb S is distributed throughout Sub-Saharan Africa, the Indian subcontinent, and the Middle East, where carrier frequencies range from 5 to 40 percent or more. Hb E is found in the eastern half of the Indian subcontinent and throughout Southeast Asia, where carrier rates may exceed 60 percent. Thalassemia is frequent in a broad band from the Mediterranean basin and parts of Africa, throughout the Middle East, the Indian subcontinent, Southeast Asia, and Melanesia and into the Pacific islands. The α^+ thalassemias occur right across the tropical zone, reaching extremely high frequencies in some populations, whereas the α^0 thalassemias are restricted to parts of Southeast Asia and the Mediterranean basin (table 34.1).

Several World Health Organization (WHO) workshops have attempted to estimate the global burden of the thalassemias and important structural hemoglobin variants (Angastiniotis and Modell 1998; Weatherall and Clegg 2001b; WHO 1989, 1994). There are perhaps 270 million carriers and 300,000 to 500,000 annual births of infants with sickle cell

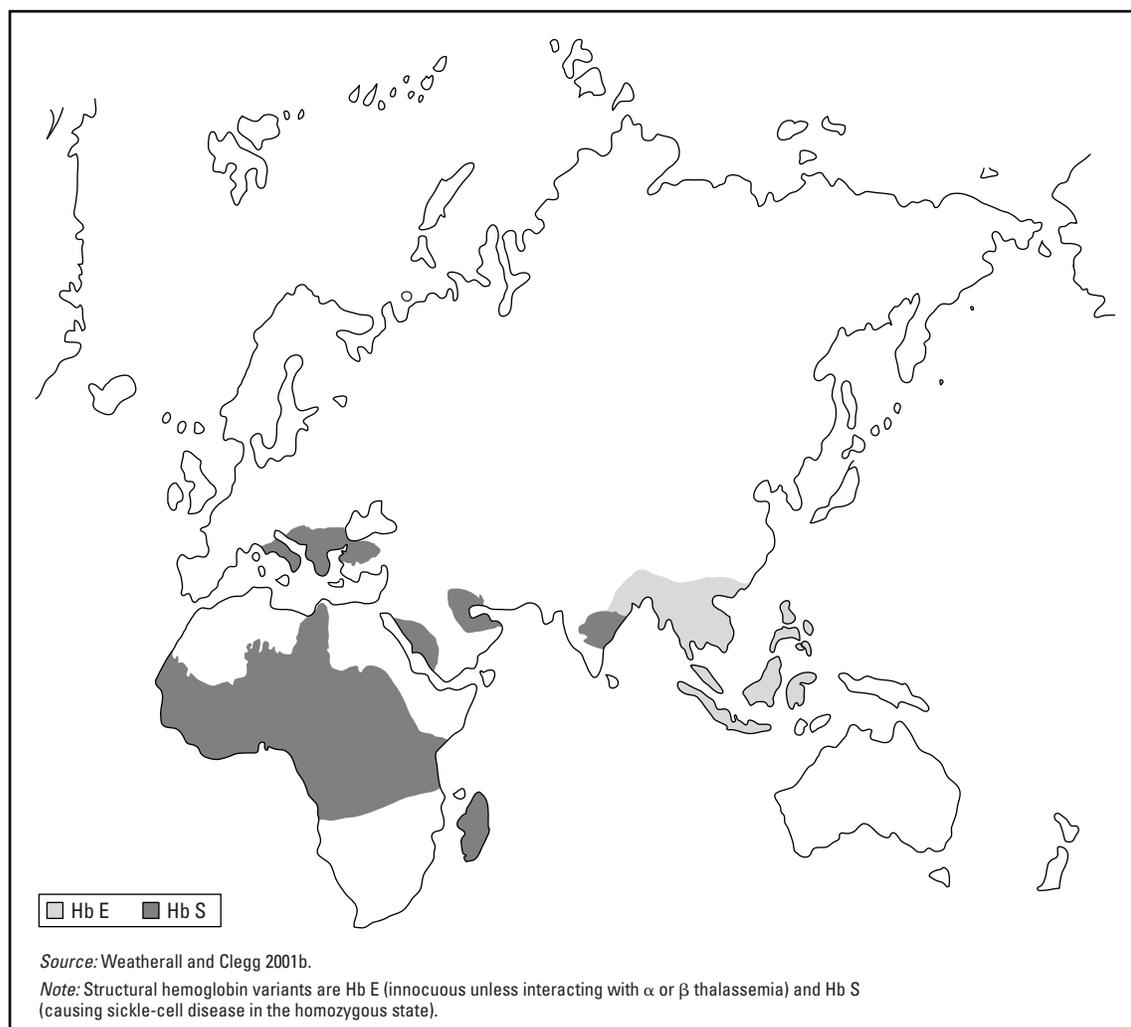

Figure 34.1a Global Distribution of Hemoglobinopathies Hb E and Hb S

Figure 34.1b Global Distribution of Hemoglobinopathies α and β Thalassemias

Table 34.1 Carrier Frequencies for Common Hemoglobin Disorders, by World Health Organization Region, 2001 (percent)

Region	Hb S	Hb C	Hb E	β thalassemia	α^0 thalassemia	α^+ thalassemia
Americas	1–20	0–10	0–20	0–3	0–5	0–40
Eastern Mediterranean	0–60	0–3	0–2	2–18	0–2	1–60
Europe	0–30	0–5	0–20	0–19	1–2	0–12
Southeast Asia	0–40	0	0–70	0–11	1–30	3–40
Sub-Saharan Africa	1–38	0–21	0	0–12	0	10–50
Western Pacific	0	0	0	0–13	0	2–60

 Note: Many of these data are derived from small population samples.

anemia or serious forms of thalassemia. Southeast Asia, where the thalassemias and Hb E predominate, is most severely affected. Sub-Saharan Africa has the second-highest burden, reflecting the high incidence of Hb S. Weatherall and Clegg (2001b)

summarize information about the different thalassemia mutations in those regions.

These data only approximate the problems for health care services that the hemoglobin disorders will pose in the future.

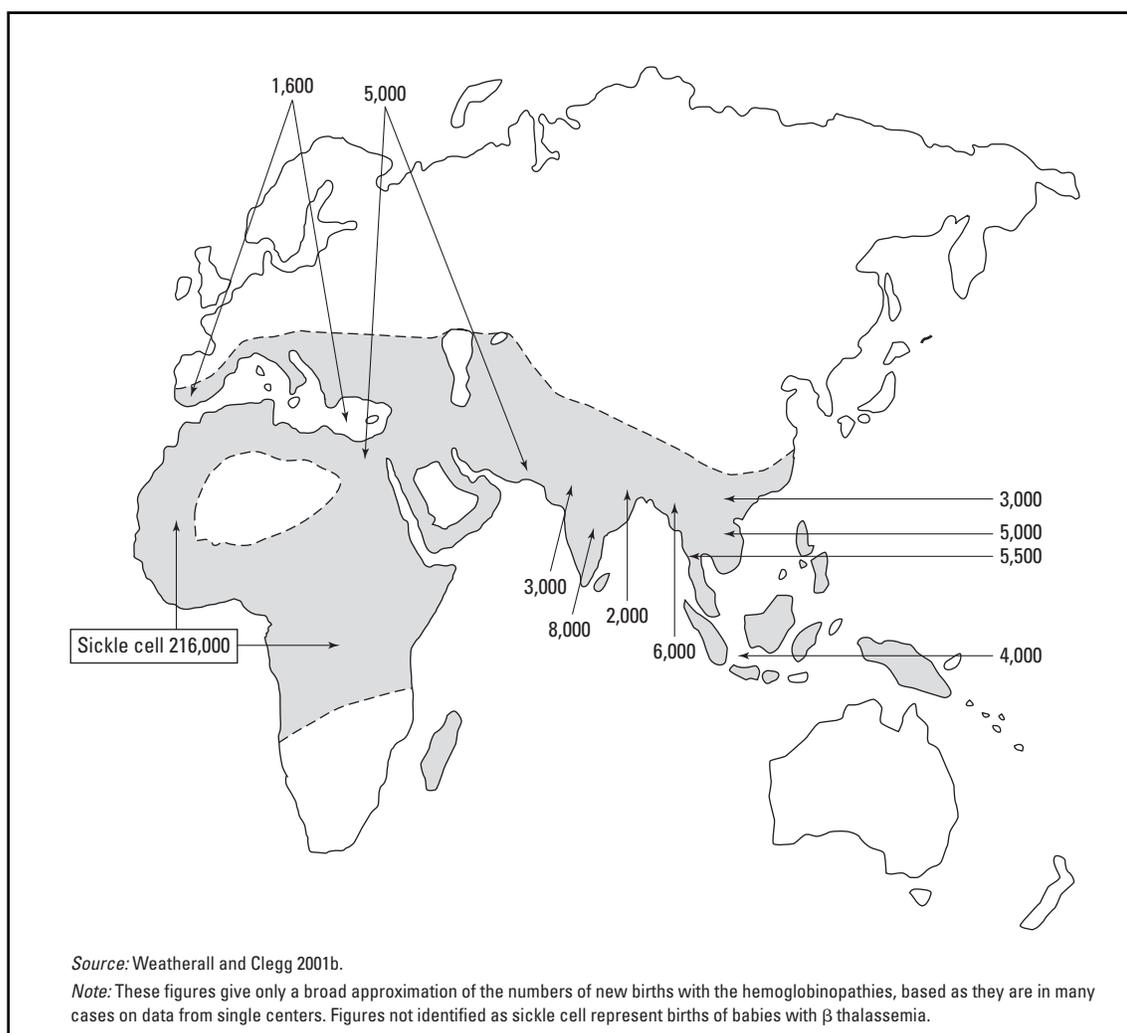

Figure 34.2 Approximate Annual Births of Babies with Sickle Cell Anemia and β Thalassemia

Unfortunately, few of the data are based on micromapping of incidence in different populations. Weatherall and Clegg's (2001b) review of studies in Indonesia, Sri Lanka, and Thailand reveals the extent of variability of incidence within relatively short geographic distances, suggesting that the number of annual births of babies with β thalassaemia major or Hb E β thalassaemia may be underestimated. Similarly, published data for the annual births of babies with sickle cell anemia in India and the Middle East are almost certainly too low, because estimates based on gene frequency suggest that the figure may be close to 100,000. The data in table 34.1 and figure 34.2, therefore, represent a minimal estimate of the future likely health burden resulting from inherited hemoglobin disorders. Furthermore, in many cases, the data are not based on projected increases in birth rates.

Because of these uncertainties, including how long countries will take to pass through the epidemiological transition,

assessing the burden that the disorders will impose on health services is difficult. As more babies survive and present for treatment, the population on long-term therapy will steadily expand; the more effective the treatment, the greater the burden will be on health services. For example, from 2005 to 2025, an estimated 100,000 cases of Hb E β thalassaemia will be added to the Thai population, and 20,000 β thalassaemia homozygotes will be born each year in southern China (Weatherall and Clegg 2001b). If these children all survive to adulthood, they will account for a large proportion of health service expenditure.

BURDEN OF DISEASE

WHO disease burden estimates do not include the incidence or prevalence of the hemoglobin disorders, nor the deaths or disability-adjusted life year (DALY) losses from sickle cell disease

or thalassemia. Neither do they treat these disorders as risk factors for anemia, infection, stroke, and other conditions or estimate the prevalence (frequency) of the underlying genetic factors. Thus, the estimates provided here are necessarily incomplete and speculative.

For severe β thalassemia, figure 34.2 suggests 43,100 births per year, nearly all in low- and middle-income countries, where affected babies are likely to die before reaching two years of age. At least 41,500 deaths probably occur each year, or 0.3 percent of all deaths of children under five. This estimate may be too low, because it does not include the estimated 20,000 births per year in China. Thus, the severe β thalassemias probably account for 50,000 to 100,000 deaths per year, or 0.5 to 0.9 percent of all deaths of children under five in low- and middle-income countries. Each death accounts for 29.2 DALYs if it occurs before the child reaches the age of one. Taken together, all the deaths contribute 1.46 million to 2.92 million DALYs to the world burden.

Treated β thalassemia victims who survive to age 40 or older contribute much less to the disease burden because they are fewer and their residual disability weight is only 0.02 to 0.10 (chapter 15 provides an explanation of disability weights). Living with poorly treated thalassemia has a weight equal to or greater than 0.1. No global estimates of the number of treated survivors are available, but estimates indicate that 500,000 may exist in Thailand alone, of which perhaps 55,000 are transfusion dependent with severe disabilities. Their total DALY loss, including disability for those with milder Hb H disease, would be only some 15,000 per year, trivial relative to the DALYs resulting from premature mortality. Deaths by age 10 from homozygous β thalassemia or by age 30 from Hb E β thalassemia would add 53,600 DALYs in Thailand.

α^0 thalassemia contributes to the burden of disease primarily through stillbirths or deaths shortly following birth and secondarily through mothers' disability during pregnancy. WHO does not count stillbirths, and no data on affected births are available except for an estimate of 1,250 per year in Thailand, which adds 37,242 DALYs. Assuming that mothers suffer a disability weight of 0.3 during the last trimester would add only 100 DALYs. Every 1,000 homozygous α^0 thalassemia pregnancies contribute about 30,000 DALYs, but insufficient information is available on incidence elsewhere to use the Thai estimate to project global or regional levels.

For sickle cell disease, the burden is harder to estimate because of the higher survival rate and the disability during crises. Figure 34.2 shows an estimated 216,000 births per year in Africa alone, but reliable data on survival are not available. Early studies suggested a mortality rate greater than 80 percent by age five, but more recent estimates indicate that the figure is probably greater than 50 percent, with the improvement resulting from treatment and from control of the infections that cause most early sickle cell deaths. Mortality of 50 to 80 percent at ages one to five implies at least 21,600 to 34,500 deaths

per year and possibly as many as 173,000. These translate into 0.5 million to 4.5 million DALYs, accounting for less than 1 percent, but perhaps as much as 2 percent, of the burden for children under five. Life expectancies and the extent of disabilities among survivors in Africa are unknown, so the low DALY number is no doubt underestimated.

Outside Africa, Weatherall and Clegg (2001b) estimate 60,000 sickle cell births per year concentrated in India and the Middle East and among descendants of Africans in the Americas. The actual figure may be as high as 100,000. Without treatment, deaths peak in the first 2 years of life, and half of all deaths occur in the first 20 years. If 25 percent of sufferers die at age 1 and 25 percent at age 10, those deaths would contribute almost 14,000 DALYs for every 1,000 births in a low- or middle-income country. Including deaths after age 20 and disability might double the estimate.

Survival elsewhere is greater than in Africa, because of lower risks of infection and greater access to treatment. The United Kingdom has about 10,000 survivors (Davies and others 2000), and the United States has some 50,000 (Ashley-Koch, Yang, and Olney 2000). No good estimates are available of the numbers or age distribution of survivors in most of the rest of the world, but Hambleton's (2004b) cohort study in Jamaica shows how treatment increased survival: 70 percent of those enrolled starting in 1973 survived to age 20, as did 80 percent of those enrolled three to six years later.

Of 1,000 babies born with sickle cell disease, Jamaican clinic records and follow-up show how many would die at each age in each year, allowing an estimate of the burden from premature mortality (Hambleton 2004a). Table 34.2 presents those results: 560 deaths per year represent almost 14,000 DALYs. Deaths after age 50 contribute less because they are fewer, and life expectancy and DALYs per death decline with age. Thus, 18,000 to 22,000 DALYs per year for deaths at all ages is a reasonable estimate of the mortality burden from 1,000 sickle cell births per year at Jamaican levels of treatment coverage and effectiveness. Applied to the estimated 60,000 to 100,000 births per year outside Africa, this figure implies at least 1.08 to 2.20 million DALYs, or 0.1 percent of the total burden in low- and middle-income countries.

Three sources of disability also contribute to the burden: anemia without painful crises or other complications; disability from mild or severely painful crises; and other clinical events, both acute and chronic (for example, leg ulcers and retinopathy).

For the first source, the disability weight is assumed to average 0.04. This source adds a constant 0.04 DALYs for every year a sickle cell patient survives. The loss per year per 1,000 births in Jamaica is multiplied by 2.5 for deaths during each five-year interval (because deaths are assumed to occur at the midpoint of the interval) and by 5.0 for survivors, who suffer disability for the entire five years. This loss adds about 10 percent to the loss from premature mortality.

Table 34.2 Burden of Sickle Cell Disease by Age Group, Assuming 1,000 Births per Year and Survival to Various Ages, Jamaica, Starting in 1973

Category	Age group (years)										Total or average
	0–4	5–9	10–14	15–19	20–24	25–29	30–34	35–39	40–44	45–49	
Number of survivors	876	834	807	777	727	680	627	564	491	440	682.3
Number of deaths	124	42	27	30	50	47	53	63	73	51	560
Death rate (percent/year)	2.61	0.98	0.66	0.75	1.32	1.33	1.61	2.10	2.73	2.17	1.63
Number of DALYs lost/death	28.90	28.59	27.77	26.84	25.82	24.69	23.43	22.00	20.39	18.58	24.70
Total DALY losses from deaths	3,584	1,201	750	805	1,291	1,161	1,242	1,386	1,488	948	13,856
Number of DALYs lost from background (chronic) anemia	188	171	164	158	150	141	130	119	106	93	1,420
Total DALYs lost from deaths and chronic anemia	3,772	1,372	914	963	1,441	1,302	1,372	1,505	1,594	1,041	15,276
Number of pain crises/year	242.7	381.0	383.8	584.4	866.7	600.5	523.6	473.4	309.6	182.2	4,548
Number of other acute clinical events	77.5	22.2		182.2							281.9
Number of other chronic clinical events	49.8	14.8	12.8	10.9							88.3

Source: Authors' calculations based on Hambleton 2004a, 2004b.

Note: The number of DALYs lost per death is calculated assuming all deaths occur at the midpoint of the age interval. Life expectancies by age are those for all low- and middle-income countries together. The number of pain crises is the total during one year for all the individuals in an age group. Those who die during the interval are assumed to die in equal numbers at the midpoint of each of the five years and, therefore, to suffer half as much disability from chronic anemia and half as many pain crises in that year as those of the same age who survive the year. Blanks in the table indicate that clinical events are rare in the corresponding age groups and their numbers are not well recorded. The totals of acute and chronic clinical events are therefore probably slight under-estimates.

For the second source of disability, even mild crises should be weighted considerably worse than background anemia, and severe crises requiring hospitalization should be weighted worse still: values of 0.2 and 0.5, respectively, are assumed. The number of crises and the share that are severe vary with age, with peak severity at ages 21 to 45 for a mean disability weight of 0.35. Because each crisis lasts only 7 to 10 days, or about 0.023 year, the loss per 1,000 births in each five-year age group never exceeds 10 DALYs and makes no difference to the total burden.

The third source of disability may carry disability weights of 0.135 for a leg ulcer, 0.276 for stroke survivors, 0.279 for acute chest syndrome, and 0.567 for retinopathy, but disability weights for a number of other conditions are unknown. Even if acute conditions last one month with an average disability weight of 0.5, they add less than 10 DALYs in any five-year interval. These conditions occur much less frequently than painful crises, but chronic ones may last much longer, contributing more or less to the burden than pain crises but adding little to mortality losses. Table 34.2 therefore includes only the estimated losses from background anemia and the frequencies, but not the DALY losses, of painful crises and other events that add negligibly to the burden.

CONTROL AND TREATMENT

With the exception of the few patients who can obtain a bone marrow transplant, no cure exists for the inherited disorders of

hemoglobin. Even though research directed at their correction by means of somatic cell gene therapy is ongoing, this technology will probably not be generally applicable for some time, and when it is developed, it may be extremely expensive. Thus, for the moment, the major approaches to the control and management of these diseases are population screening, genetic counseling and prenatal diagnosis, and management of symptoms.

Prevention

Programs to reduce the number of seriously affected individuals follow two approaches. First, population screening and counseling programs can be established to educate populations about the risks of having children with similarly affected partners. Data about the effectiveness of this approach are extremely limited. In an early study in Greece, people's knowledge of their genetic makeup had no effect on marriage patterns (Stamatoyannopoulos 1973); however, a recent study in the Islamic Republic of Iran found that about 50 percent of affected couples decided to separate, and births with severe β thalassemia fell to about 30 percent of those expected (Samavat and Modell 2004). The reasons for this remarkable discrepancy require further investigation.

The second preventive approach also involves population screening or screening in prenatal clinics. If women are found to be carriers, their partners are screened, and following counseling they are offered a prenatal diagnosis and termination of

affected fetuses. This method has been used widely in the Mediterranean region and elsewhere, resulting in a major reduction in newborns with serious forms of thalassemia (Cao, Galanello, and Rosatelli 1998; Weatherall and Clegg 2001b). Prenatal diagnosis programs are available in China, India, the Islamic Republic of Iran, Lebanon, Pakistan, Singapore, Thailand, the United Arab Emirates, the United States, and many European countries; several other countries are establishing similar programs.

Because severe thalassemia is incompatible with survival without regular blood transfusions, prenatal diagnosis is a logical approach where acceptable until more definitive treatments become available. The situation with sickle cell anemia is different. First, it is not uniformly fatal in early life, and morbidity and mortality during this period can be controlled. Second, the clinical course of the condition is unpredictable: some patients' symptoms are relatively mild, whereas others develop life-threatening complications. Hence, even though some countries are practicing prenatal diagnosis, in others neither communities nor doctors consider that it should be applied widely. This complex issue would be clarified if the reasons for the phenotypic variability of the sickling disorders were better defined.

Whether or not screening programs are backed up with an offer of prenatal diagnosis, they require an intense period of education of the population about the nature of inherited hemoglobin disorders. This education requires input from many sectors of society, including the media, public health workers, local volunteer societies, and the medical community. Programs of this type require careful planning as well as availability of facilities for screening and counseling when the program is initiated. Their development also requires prior discussion between the government, health care workers, and members of the community—including religious leaders.

Treatment

The treatment of the hemoglobinopathies varies widely depending on the disease. The severe forms of β thalassemia require lifelong blood transfusions. The family of β thalassemia intermediate diseases ranges from transfusion-dependent forms to symptomless carrier traits. Hb E β thalassemia, the commonest hemoglobinopathy in Asia, varies in severity from forms that require regular or intermittent transfusions to milder anemia that does not require lifelong transfusions unless complications arise, particularly hypersplenism. Weatherall and Clegg's (2001b) review of studies in Asia indicates that the medical community does not always appreciate these subtleties and that many patients who receive regular transfusions might well have survived without transfusions had their early management been more effective.

Thus, those managing patients with severe forms of β thalassemia must make absolutely sure in infancy that regular

transfusions are required. If so, babies and children require transfusion at monthly intervals using washed red cells rather than whole blood. In addition, blood must be screened for hepatitis B and C, for HIV, and—in some countries—for malaria. Because patients accumulate iron from transfusions, they also require lifelong treatment with a chelating agent, the most effective being desferrioxamine delivered subcutaneously overnight using a pump. Oral chelating agents, which would undoubtedly improve compliance, are available, but their efficacy and safety have yet to be verified. Some children with the major form of β thalassemia—and many with the intermediate varieties—will at some point require splenectomy, to be preceded by appropriate vaccinations and followed by prophylactic penicillin. They also require regular assessments of their iron status by measurements of serum ferritin or, better, by hepatic iron concentrations. Various complications occur, particularly for those not adequately transfused, including endocrine deficiencies, bone disease, and infection. Bloodborne infections, particularly hepatitis C and HIV/AIDS, are an increasing hazard. Most children with β thalassemia also require regular folate supplementation and vitamin C with their chelation therapy.

The serious forms of α thalassemia, α^0 thalassemia, cause stillbirth late in pregnancy and several maternal complications. Although some infants have been given exchange transfusion or transfusion in the immediate neonatal period and survived, they have gone on to a transfusion-dependent life. Because of the increased risk of congenital malformations as a result of the disease—and particularly because of maternal complications—this course of action is not recommended, and this disease is an important indication for prenatal diagnosis. Those who inherit α^0 thalassemia from one parent and α^+ thalassemia from the other have a moderately severe form called Hb H disease that is usually compatible with a life independent of transfusions except for periods of stress, such as infection. The α^+ thalassemias cause no clinical problems, either in their homozygous or heterozygous states.

Patients with sickle cell anemia are at high risk from infection early in life; therefore, diagnosis as early as possible is vital. Excellent evidence, at least in developed countries, indicates that prophylactic penicillin significantly reduces early morbidity and mortality.

Even though many children adapt well to their anemia, many eventually develop sickle cell crises (Ballas 1998). The most common form, the so-called painful crisis, is characterized by severe bone pain that often requires hospital admission and treatment with analgesics, oxygen, and infection control. More life-threatening crises, including stroke, marrow aplasia associated with viral illness, and pulmonary crises with severe hypoxia, require urgent hospital treatment. Regular Doppler testing of the cerebral blood flow can anticipate neurological complications that can be prevented by regular transfusions (Adams and others 1998), which can be continued indefinitely.

Because most aplastic crises result from human parvovirus infection, the development of a vaccine would be a great advantage. The other acute complication, splenic sequestration causing rapid enlargement of the spleen, is associated with profound anemia. It necessitates urgent hospital admission and blood transfusion, plus sometimes splenectomy. A variety of other complications require hospital treatment, including priapism, aseptic necrosis of the femoral or humeral heads, renal failure, and recurrent hematuria. At every age patients with sickling disorders seem to be more prone to infection that often requires hospital admission. In most sickling disorders, crises are more frequent and anemia worsens during pregnancy. A review of extensive clinical trials in the United States shows that the long-term administration of hydroxyurea reduces the frequency of crises and prolongs life in adult sufferers (Weatherall 2003).

Although milder, Hb SC disease is clinically important, particularly because of the relatively high incidence of ocular complications.

Requirements

Screening and diagnosis for the hemoglobin disorders requires relatively simple laboratory techniques combined with a well-organized program for their application in the community.

Screening and Carrier Detection. Unlike many genetic diseases, carrier screening for the main hemoglobin disorders is well established, accurate, and inexpensive. The initial screening for thalassemia usually measures the mean cell volume and the mean cell hemoglobin. Thresholds below which the likelihood of some form of thalassemia is great are well established. The diagnosis of β thalassemia is confirmed by finding a raised level of Hb A₂ using high-performance liquid chromatography (HPLC) or cheaper forms of chromatography or quantitative hemoglobin electrophoresis. Ideally, the initial blood count should use an electronic cell counter, and the Hb A₂ should be measured using HPLC. However, the equipment for HPLC analysis is expensive, and the cost per sample is approximately US\$2. For this reason, several more economical approaches have been developed (Fucharoen and others 2004). The initial screening can be done using a single-tube osmotic fragility test, which, even though it may result in a relatively high number of false positive results, usually gives fewer false negatives. Commercial kits for osmotic fragility testing have recently been produced, and at least one variety has been validated in Thailand. Further validation of this approach is required before it can be recommended. Various cheaper methods for measuring the Hb A₂ level are available.

When the red cell indices suggest thalassemia or an osmotic fragility test is positive but the Hb A₂ level is normal, it is vital to distinguish between iron deficiency and α thalassemia.

Several simple, cheap tests are available for diagnosing iron deficiency, but α thalassemia presents more of a problem. Screening tests will identify those heterozygous for α^0 thalassemia or homozygous for α^+ thalassemia but will miss most cases of heterozygosity for α^+ thalassemia. However, given the restricted distribution of α^0 thalassemia, these distinctions are clinically important only in areas where α^0 thalassemia is common. Further diagnosis of the α thalassemias requires DNA analysis.

Several simple and cheap screening tests are available for sickling disorders, but all of them require confirmation of the genotype by hemoglobin electrophoresis. Neonatal screening requires electrophoresis because the solubility test, which is used widely for adult screening, is unreliable in the first months of life.

Throughout Asia, screening for Hb E is also necessary, either with a one-tube dye test or by hemoglobin electrophoresis. The Hb E trait is missed by measuring cell size or osmotic fragility.

Initial Diagnosis of More Severe Hemoglobinopathies. The initial diagnosis of β thalassemia is usually clinical. It can be confirmed by finding typical thalassaemic changes of the peripheral blood, together with an elevated level of Hb F. A variety of cheap tests for measuring Hb F levels are available, or HPLC analysis can be used. Hemoglobin electrophoresis or HPLC is used to diagnose α^0 thalassemia homozygotes and children with Hb H disease.

Sickle cell anemia, Hb SC disease, or combinations of the sickle cell gene with forms of β thalassemia can all be identified by hemoglobin electrophoresis and can be confirmed by a family study.

Further Analysis. More detailed confirmatory analysis, including identification of the underlying mutation, is required for the β thalassemias as a prerequisite for prenatal diagnosis. A variety of approaches to mutation analysis based on the polymerase chain reaction, which amplifies particular regions of DNA, are available, but because every population has a number of less common mutations, a central reference laboratory in each country must be able to sequence the β globin genes. Rapid DNA-based techniques for identifying the different deletion and nondeletion forms of α thalassemia are also available (Weatherall and Clegg 2001b).

Facilities and Organization. To provide an adequate laboratory service, each country with a high incidence of β thalassemia or sickle cell anemia (a carrier rate equal to or greater than 1 to 2 percent) requires at least one central reference laboratory to carry out accurate hemoglobin and DNA analyses. Peripheral hospital laboratories with expertise in screening tests and their quality control are also required.

General pediatricians, pediatricians with a special interest in blood diseases, or pediatricians or other clinicians who devote their entire time to the management of such diseases may care

for children with severe hemoglobin disorders. A problem arises for older patients, who must often change their doctors during adolescence. There is a serious dearth of physicians trained to care for older patients. Ideally, every country with a high incidence of inherited hemoglobin disorders should have centers specially designated for treating patients of all ages. Such centers require outpatient transfusion facilities, space for parents to wait while their children are being transfused, inpatient facilities, and access to basic laboratory diagnostic services. Centers involved in prenatal diagnosis require access to appropriate obstetric services. The advantage of specialist centers is continuity of care. Patients with chronic disease must have confidence in their medical advisers. Such confidence can be achieved only if they see the same staff over the entire course of their illness.

As concerns personnel, a WHO working group has recommended one doctor, three nurses, one laboratory technician, one counselor, and one administrative assistant for every 50 to 100 patients (WHO 1994). Overall, the workload is higher in centers for thalassemia than for sickle cell anemia, largely because of the lesser need for regular blood transfusions for those with the latter condition. However, sickle cell anemia is associated with more acute inpatient episodes per year.

The other major role of centers of this type is education, including training other clinicians, medical students, counselors, nurses, and others needed to provide information to local communities.

A number of publications describe treatment protocols to use in managing patients (Weatherall and Clegg 2001b; WHO 1985, 1987, 1989, 1994). Treatments include the following:

- *Blood transfusion.* Although regular transfusion is required most frequently for managing the thalassemias, it is increasingly being applied for the prophylaxis of serious complications of sickle cell anemia. Treatment centers need to cooperate closely with national blood transfusion programs. Washed or otherwise leukocyte-depleted blood should always be used. Blood has to be screened for hepatitis B, hepatitis C, HIV, and—in some populations—malarial parasites. Blood requirements for patients with thalassemia range from 500 to 1,500 liters per 100 patients per year, depending on their age distribution.
- *Iron chelation.* Transfusion-dependent thalassemic patients and patients with sickle cell anemia maintained on transfusion for prophylactic purposes require 30 to 50 milligrams per kilogram per day of desferrioxamine infused subcutaneously by pump. One pump is required per patient. Regular assessment of body iron and assessment for complications are essential.
- *Immunization and other prophylactic measures.* Every child with sickle cell anemia should receive oral prophylactic penicillin from the time of diagnosis. Some centers now

routinely immunize patients with polyvalent pneumococcal, meningococcal, and *Haemophilus influenzae* vaccines. However, the effectiveness of regimens of this type has not been clearly established even for splenectomized patients.

- *Splenectomy.* Each year, 2 to 3 percent of patients with severe β thalassemia require splenectomy. When patients who have received suboptimal treatment first receive standard treatment, the proportion needing splenectomy can be much higher—up to 30 percent in the first one or two years (WHO 1994). Because of the spleen's natural tendency to atrophy, splenectomy is required only in patients with sickle cell anemia who are having repeated splenic sequestration episodes or who develop hypersplenism.
- *Bone marrow transplantation.* Given the continuing improvement in results, bone marrow transplantation is now a realistic option for patients with severe forms of β thalassemia and sickle cell anemia who have histocompatible related donors and, in particular, are relatively free of complications, particularly chronic hepatitis and severe iron loading (Giardini 1997). Marrow transplantation requires specialized facilities and a trained staff, and the initial capital expenditure is high, but it should be considered wherever the serious hemoglobinopathies are a major problem if the alternative is lifetime treatment.
- *Prenatal diagnosis programs.* If prenatal diagnosis programs are part of an existing genetic and diagnosis service, fetal sampling will involve only marginal costs. If they must be set up from scratch, they require at least two obstetricians trained in fetal medicine, access to ultrasound, and a specialist nurse. Disposable or reusable sampling equipment is also required, together with suitable sterile facilities for amniocentesis, facilities for termination of pregnancy in the first or second trimesters, and access to experienced bereavement counselors. Access to a laboratory able to carry out mutation analysis is also required.
- *Other treatments.* Patients with hemoglobinopathies require folate supplements. Those infected with hepatitis C require treatment with antiviral agents. Those with endocrine damage caused by iron loading may require hormone replacement therapy.

In addition, centers for hemoglobin disorders require a trained counselor or clinical psychologist to handle both genetic and social issues. They should interact with local public health organizations to disseminate information about inherited hemoglobin diseases to schools and to the community at large. Many countries have parent support groups. The Thalassemia International Federation, an international body run largely by parents and lay members, provides advice and support for national parent associations and hemoglobinopathy programs.

COSTS AND EFFECTIVENESS OF DIAGNOSIS AND MANAGEMENT

Defining the full costs of treating patients with inherited disorders of hemoglobin is difficult, and comparing them between countries is even harder. The variables that confound such estimates include different health care systems, varying methods of obtaining donated blood, widely varying practices in screening blood for pathogens, and differing costs of drugs and equipment. WHO working parties and others have produced approximate data (Alwan and Modell 1997; WHO 1985, 1987, 1989, 1994).

Thalassemias

Information about the economic aspects of the thalassemias is sparse, including the costs and effectiveness of different interventions, three of which are discussed here: screening and counseling, treatment using transfusions and chelation, and cure by means of bone marrow transplant.

Screening and Counseling. Screening and counseling are cost-effective to the extent that they avert an affected birth or ensure early and adequate treatment of an affected child. Several studies, beginning with community screening programs in Montreal (Scriver and others 1984), have provided strong evidence that screening and prenatal diagnosis are highly effective in relation to control of the thalassemias. Alwan and Modell (1997), Davies and others (2000), and Modell and Kuliev (1991, 1993) provide detailed discussions of the issues involved, together with estimates of the costs of screening and counseling programs compared with the treatment of established disease, and even though the estimates are based mainly on studies in developed countries, the findings are probably more generally applicable.

The effectiveness of prenatal diagnosis programs can be quite high if more than 2 percent of the population is a carrier and the public education programs that precede their establishment are well designed. In Europe, 80 to 90 percent of counseled at-risk couples now request prenatal diagnosis, and a rapid reduction in affected births has been observed. The thalassemia birth rate fell almost 100 percent between the late 1970s and the late 1980s in Cyprus and Sardinia and about 80 percent in mainland Greece and Italy (Modell and Kuliev 1991). Between 1974 and 1986, such births fell by 40 percent in the United Kingdom (Modell and Kuliev 1991).

In terms of cost-effectiveness, terminating a pregnancy cannot be compared with improving the health of a child carried to term, but it is clearly cost saving compared with treatment. Modell and Kuliev (1991) estimate the cost of replacement (when a couple terminates an affected pregnancy and subsequently has a normal child) at only 30 percent of the annual

cost of treatment, or 2 percent of the discounted lifetime cost. Similarly, Scriver and others (1984) estimate the costs of preventing an affected birth in Canada as less than annual treatment costs and about 4 percent of lifetime costs.

Treatment. Investigators have made several estimates of the costs of treating the β thalassemias. Approximate annual costs of care in Thailand in 2003 were as follows (authors' estimates updated from unpublished Thai sources):

- homozygous β thalassemia: US\$19.84 million for patients in their first year of treatment and US\$17.7 million per year for patients in subsequent years of treatment
- Hb E β thalassemia: US\$100.3 million for patients in the first year of treatment and US\$92.4 million for patients in subsequent years of treatment
- homozygous α^0 thalassemia: US\$727,000
- Hb H disease: US\$7.49 million.

The life expectancy of a child in Thailand homozygous for β thalassemia is only 10 years, reflecting an inability to provide the bulk of patients with expensive chelating drugs. These costs are therefore not fully comparable to those from more developed countries, where better care means that children live longer. Han, Han, and Myint (1992) provide data for Myanmar that are comparable to those for Thailand.

Table 34.3 shows the annual costs for a program in Toronto that offers a high level of symptomatic care, and table 34.4 presents treatment costs for the eastern Mediterranean, taking into account the increasing expenditure required as children grow and require higher doses of maintenance drugs and more units of blood each year. Despite the difficulties of making comparisons, tables 34.3 and 34.4 indicate that the costs for managing β thalassemia in the eastern Mediterranean are roughly similar to those in Toronto, exclusive of transfusion, and are therefore probably reasonable estimates of the costs of managing thalassemias in developed countries.

Transfusion is required to keep a child with severe thalassemia alive beyond age one or two, but by itself prolongs life only to age 10 to 15. The gain is the added 9 to 14 years lived with disability weights of 0.1 to 0.5, implying 0.50 DALY gained for the last years and 0.75 to 0.90 per year earlier. Table 34.4 shows the costs of transfusion at ages 7 to 11, and figures in parentheses in the table show the costs at age 2 and for adults. Costs and health gains run parallel, so it makes little difference whether they are discounted when summed over an interval. Table 34.5 shows discounted total costs and DALYs gained for death at age 10 or 15 and using disability values of 0.1 and 0.25. For both ages, the cost per DALY is about US\$2,000 for low disability and about US\$3,000 for high disability for transfusion only.

Table 34.3 Annual Costs of Hemoglobinopathy per Outpatient, Excluding Transfusion, Toronto (2001 US\$)

Category	Thalassemia		Sickle cell disease

Note: n.a. = not applicable. The figures in parentheses show the range of costs for a two-year-old and an adult; where no range is shown, the cost is independent of age. Both minimum and full treatment include transfusion and chelation. Full treatment means more frequent transfusion and consultations, more laboratory work, and more surgery.

A thalassemic patient can be kept alive beyond adolescence, possibly for a normal life span, if also chelated. This treatment means added annual costs of about US\$3,000, or about US\$6,000 (table 34.4) for full treatment, plus higher costs of transfusion and other components. Besides prolonging life, full treatment is assumed to reduce disability from 0.10 to 0.02 and from 0.25 to 0.10. Table 34.5 also shows discounted incremental costs, DALY gains, and cost per DALY of full treatment compared with those of minimal treatment. The incremental cost per DALY is high up to age 15 because of the modest gain compared with prolonging life with greater disability. From age 15, the cost drops because the child would otherwise die. If a life expectancy of 80 years is assumed, lifetime costs are some US\$9,000 to US\$11,000 per DALY at a disability weight of 0.1 and roughly US\$10,000 to US\$12,000 at a disability weight of 0.25.

Comparing full treatment to none, annual costs rise with age from US\$6,190 to US\$15,110 (table 34.4). As table 34.5 shows, up to age 15, 10.8 to 11.8 discounted DALYs are gained at a total cost of US\$121,284 and a cost per DALY of approximately US\$10,300 to US\$11,200, comparable to lifetime incremental costs. Beyond age 15, the cost per DALY is some US\$16,000 to US\$17,000, and over the lifetime it is between US\$13,000 and US\$15,000. Because costs and gains run parallel—and also because of discounting—the lifetime cost per DALY is not sensitive to age at death of 45 or older, so differences in regional life expectancies do not matter.

These cost estimates come from the eastern Mediterranean. In Thailand, the first-year costs are much higher than the costs shown in table 34.5 and include the costs of delivering the child and protecting it from infection. Thereafter, the cost per year of treating the 6,250 survivors of each birth cohort

Table 34.5 Cost-Effectiveness of Treatment for Homozygous β and Transfusion-Dependent Hb E β Thalassemia

Note: Differences in DALYs gained for a given age range and disability weight depend on how rapidly health is assumed to deteriorate in the years immediately preceding death.

with transfusion alone (assuming they live only 10 years) drops, implying a cost per DALY of US\$3,146 to US\$3,776. Half the 97,500 people with Hb E β thalassemia are assumed to require treatment, leading to a cost per DALY of US\$2,100 to US\$2,500, consistent with costs in the eastern Mediterranean. For chelated patients in Toronto, the estimate of US\$5,927 per year (table 34.3) implies a cost per DALY of US\$6,600 to US\$8,000, considerably less than in the eastern Mediterranean, but the costs do not include transfusion. Thus, data from three different regions on the cost-effectiveness of full therapy for victims of the common treatable forms of thalassemia are roughly comparable.

De Silva and others' (2000) study provides approximate costs for treating thalassemia in Sri Lanka. If we assume that a prevention program will probably not be developed in the near future, the data suggest that management of the disease will consume approximately 5 to 8 percent of the country's health budget based on 1999 figures. Those estimates have not been used to derive cost-effectiveness results.

Bone Marrow Transplantation. Angelucci and Lucarelli (2001) discuss the economic aspects of bone marrow transplantation. The 1991 cost was US\$73,250, excluding follow-up but including the expense of setting up a program. This amount is almost certainly cost saving compared with lifelong transfusion and chelation, and it is also more cost-effective, given the reduction in disability from curing the disease.

Sickle Cell Disease

Extensive data on the costs of sickle cell anemia come from Davis, Moore, and Gergen's (1997) analysis in the United States. An estimated 75,000 hospitalizations of both children and adults occurred each year from 1989 through 1993. The average cost of hospitalization in 1996 was estimated at US\$6,300, resulting in a total direct cost of US\$575 million per year. In this and subsequent studies, the bulk of hospitalizations was confined to a subset of about 10 percent of the total patient population.

In the United States, specialized treatment centers provide a cost-saving approach to the care of sickle cell anemia. Patients enrolled in these centers used emergency rooms and inpatient units significantly less frequently than those cared for in the general hospital community, resulting in significantly lower health care costs (Nietert, Silverstein, and Abboud 2002; Yang and others 1995). Currently, only a small proportion of patients are treated in centers of this kind, even in developed countries. A pilot study in Benin found that the development of a comprehensive clinical care program reduced the frequency and severity of acute complications related to sickle cell anemia (Rahimy and others 2003). The annual cost per family using the program was US\$40, and the annual cost for each hospitalization was US\$100.

Neonatal Screening and Prophylaxis. Extensive controlled trials in several developed countries have demonstrated the

Table 34.6 Cost-Effectiveness of Penicillin Prophylaxis for Sickle Cell Disease Detected by Newborn Screening, Jamaica

a. Two exchange rates are shown because the exchange rate changed during the course of the study.

life-saving effect of giving prophylactic penicillin from birth. A randomized trial suggested that this approach would save significantly more lives than starting prophylactic penicillin when an infant presents with symptoms of the disease. Without treatment, pneumococcal infection is the leading cause of death before age five. Penicillin by monthly injection or daily oral dose from about age four months to four years reduces bacteremia by 83 to 86 percent (D. Bonds, personal communication, September 28, 2004; Gill and others 1989, 1995; Panepinto and others 2000). Prophylaxis also reduces the case-fatality rate from infection from 27 to 18 percent.

Data from the United States show that neonatal screening for sickle cell disease followed by the use of appropriate prophylactic treatment prevents deaths (Tsevat and others 1991). With 16 percent of the U.S. population being African American, without screening and treatment 13 deaths would occur per million infants. Six of these deaths could be prevented by targeting only African Americans, and two more could be prevented by universal screening. Ignoring disability and discounting at 3 percent, we find that targeted screening costs US\$6,709 per life year saved, or somewhat more per DALY. At more than US\$30,000 per life year saved, universal screening would not be cost-effective compared with targeted testing (Panepinto and others 2000).

Data from a Jamaican cohort of 315 children with sickle cell disease allow for a similar cost-effectiveness analysis in a middle-income country (Hambleton 2004a, 2004b). They suggest that treatment averts seven to eight deaths, or that a newly diagnosed child's chances of dying before age four are reduced by 2.4 percentage points. Because bacteremia becomes less frequent with age, few cases occur—and little is known about the mortality risk—after childhood.

In the Jamaican cohort, up to 2 percent of children take prophylactic penicillin orally; the rest receive monthly injections requiring 10 minutes of a nurse's time. A clinician sees each child for 20 minutes four to six times a year. Table 34.6 shows the costs of personnel and penicillin. Other recurrent costs, such as those for syringes, will be low in comparison. No allowance is made for capital costs. The marginal cost of detecting sickle cell disease in newborns who have already been screened for other conditions such as phenylketonuria is only about US\$3.30 (D. Bonds, personal communication, September 28, 2004). The cost of screening children who do not have sickle cell disease depends on prevalence and is not included in the estimates. It becomes unimportant as more of the population is at risk.

On average, preventing a death costs about US\$8,000 to US\$12,000 by means of injection and about US\$5,000 more when oral penicillin is used. Because death would typically occur between one and two years of age, each death averted saves 29 DALYs and costs about US\$270 to US\$400 per DALY. Penicillin prophylaxis is probably more cost-effective than any other intervention. It is standard practice in Jamaica and the United States and can be recommended for middle-income countries where the prevalence is high enough—in the general population or in those of African origin—to justify screening.

Application to Other Countries. The limited data available indicate that specialized treatment centers and neonatal screening programs are effective approaches toward the control of sickle cell anemia. Although these conclusions should be valid for developing countries, many uncertainties remain. In particular, data on the causes of infection in infants with sickle cell disease in Africa are sparse. Because the spectrum of infection

may be different, the value of penicillin prophylaxis in Africa is unknown.

Laboratory diagnosis is well defined, is cheap, and does not differ depending on the level of available technology. The major uncertainty is whether the increasing indications for prophylactic transfusion in developed countries will be mirrored in other populations.

Other Treatments. As indicated in the discussion of the burden of disease, sickle cell patients suffer various clinical events for which treatment may be life saving, such as transfusion for aplastic crises. For painful crises, intervention (analgesics and possibly hospitalization) is only palliative. Because of the lack of information on costs and of consensus on the associated disabilities with and without treatment, we have not assessed the cost-effectiveness of any of these treatments.

OPTIONS FOR CONTROL AND MANAGEMENT OF INHERITED HEMOGLOBIN DISORDERS

Even though much more work is needed on both the scientific and the economic aspects of the hemoglobinopathies, certain issues are now clear. Until more definitive ways of treating them are available, reliable knowledge exists on how they can best be managed symptomatically. Furthermore, compelling evidence suggests that population screening programs combined with prenatal diagnosis can reduce the financial burden these increasingly common diseases impose on health services. Defining several options for their control and management is therefore possible. These are based, with some modifications, on Alwan and Modell (1997).

Severe β Thalassemias

This list provides most of the possible options for the control and management of β thalassemia in developing countries.

- *Option one:* best possible patient care, together with retrospective genetic counseling after the first affected child is diagnosed
- *Option two:* best possible patient care, together with retrospective genetic counseling and the option of prenatal diagnosis for subsequent pregnancies
- *Option three:* best possible patient care, together with retrospective genetic counseling and prospective (premarital) carrier screening and counseling, but no prenatal diagnosis
- *Option four:* best possible patient care with premarital, family-based, and population-based prospective carrier screening and genetic counseling, but no prenatal diagnosis
- *Option five:* best possible patient care, premarital and prenatal prospective carrier screening and genetic counseling, and the option of prenatal diagnosis

- *Option six:* based on option four or five but includes the availability of a bone marrow transplant program.

Options one and two, though still commonly practiced in many countries, offer little prospect of reducing the frequency of serious forms of thalassemia. Overall, that reduction is best achieved by option five, which combines maximum possibilities for reducing the frequency of severe disease with the best possible care for affected children. Although thalassemia births have fallen sharply in some developed countries, the effect of prenatal screening is likely to be lower for the large mainland populations of Asia if this policy is implemented, which is why this option includes best-practice treatment. Limited studies also suggest that families that undergo prenatal diagnosis tend to settle at the population norm for the number of children that they subsequently have and that their views on their ability to have unaffected children are extremely positive. For those countries or groups in which termination of pregnancy is unacceptable for religious or cultural reasons, option four is recommended. Option six, which is possible only in countries where bone marrow transplantation is available, should be exploited by any country with a high frequency of the disease, because it offers a potentially cost-effective approach to managing some proportion of affected children.

For the extremely heterogeneous intermediate forms of β thalassemia, notably Hb E β thalassemia, options three and four would probably be best, at least until a better understanding has been gained of the clinical heterogeneity of these thalassemias.

α Thalassemias

Few options are available for the α^0 thalassemias. Homozygous babies with this condition are stillborn. However, because of the serious maternal complications of carrying these babies, this condition should be screened for prenatally, and affected babies should be identified by prenatal diagnosis with a view to terminating the pregnancy.

Hb H disease, the compound heterozygous state between α^+ and α^0 thalassemia, is generally a relatively mild disorder that simply requires careful follow-up and treatment of complications. Although some have suggested that screening and prenatal diagnosis may be relevant for the more severe forms, more data are required to reach a conclusion.

Sickle Cell Disorders

These options for the management of the sickle cell disorders are directed particularly at the populations of developing countries, although, overall, they are relevant to most countries:

- *Option one:* best possible patient care with the use of prophylactic penicillin following diagnosis, together with retrospective genetic counseling

- *Option two:* best possible patient care, together with a neonatal screening program and the use of penicillin for all homozygous babies, together with retrospective screening and counseling
- *Option three:* best possible patient care, together with neonatal screening and the use of prophylactic penicillin from birth for homozygotes, together with population screening and prospective genetic counseling
- *Option four:* as for option three, plus the availability of prenatal diagnosis, bone marrow transplantation, or both.

Option three would be required to combine best management with the possibility of reducing the frequency of the disease, although whether this option would have any effect by altering the pattern of marriage is not clear. Whether prenatal screening of mothers would be valuable is also not clear: it would reduce the number of neonates who require screening, but because the cost of screening for sickle cell trait is so small, the issue is probably not important. Prenatal diagnosis can be developed (option four), but this option does not seem to be a high priority for sickling disorders in many developed countries, at least until more is known about the reasons for their phenotypic heterogeneity. By contrast, demand is greater in developing countries with limited facilities for the care of these patients. Some developed countries are beginning to immunize children with sickling disorders against infections with pneumococcus, *H. influenzae*, and meningococcus, but in developing countries, this treatment would add enormously to the burden of management programs. Clinical trials to test the efficacy of prophylactic penicillin with or without these vaccine regimens are urgently needed. Similarly, more information about the pathogens that cause early deaths in developing countries is required before the widespread use of prophylactic penicillin can be recommended.

Bone Marrow Transplantation

Experience in developed countries indicates that bone marrow transplantation may offer a cost-effective approach to managing a subset of patients with inherited disorders of hemoglobin (Borgna-Pignatti 1985). In developing countries, if this service is available at all, it is usually confined to the private sector or to those who can pay the fees teaching hospitals require. Given this context, defining the role of bone marrow transplantation in the global control of these diseases is difficult.

International and National Support Groups

Largely through the efforts of parents with affected children and clinicians who have taken an interest in the hemoglobin disorders, many countries have developed national thalassemia or sickle cell anemia societies that provide support for parents, workshops for doctors, and a variety of other important inputs.

In the case of thalassemia, the Thalassemia International Federation acts as an international coordinating body that helps countries develop workshops for training in diagnosis and treatment and organizes international meetings at which experts from different countries share their research and clinical experiences. In 1996, a group of doctors formed the Fédération des Associations de Lutte contre la Drépanocytose en Afrique (Federation of Associations to Control Sickle Cell Anemia in Africa). The membership has grown to 13 Sub-Saharan countries. The federation represents a major initiative in relation to regional training in both the diagnosis and the treatment of sickle cell disease in Sub-Saharan Africa. Unfortunately, it has been unable to raise sufficient funds to equip and run even a modest secretariat. Considering the success of the Thalassemia International Federation, particularly in countries with limited facilities for managing the hemoglobin disorders, the lack of support for this initiative in Africa is a clear indication of the importance of educating nongovernmental organizations and similar bodies about the increasing public health problems resulting from the inherited hemoglobin disorders.

Ethical and Social Issues

The various options for controlling and managing the hemoglobin disorders raise many ethical and social issues (see Weatherall and Clegg 2001b for more details). These issues arise most often in developing countries, where the level of education is often low and understanding of genetic diseases is limited. Serious genetic diseases such as thalassemia are associated with social problems such as patient stigmatization and broken marriages because one partner blames the other for the birth of an affected child. In countries where arranged marriages are still common, screening programs for heterozygotes may make it difficult for female carriers to find husbands. In addition, cultural and religious objections about interfering with nature arise when pregnancies are terminated because children have serious genetic diseases. At the same time, if governments perceive prenatal diagnosis and termination of pregnancy to be a highly cost-effective way of controlling these diseases, which they are, the danger arises that governments will pressure women to undergo these procedures. Therefore, before any programs are established, extensive discussions between governments, the medical profession, and the community about how to control these diseases are vital.

FURTHER RESEARCH

Despite the progress made toward understanding the molecular pathology, pathophysiology, and management of the inherited hemoglobin disorders, many gaps persist:

- First, much better data are required about their frequency and distribution in many developing countries.

- Second, more information is required about the reasons, both genetic and environmental, for the remarkable clinical heterogeneity of these conditions.
- Third, much better criteria are required for the management of the intermediate forms of thalassemia and of sickle cell anemia.
- Fourth, much more work is required on the role of the environment, a topic that has been badly neglected compared with research on the genetics of these conditions.
- Finally, further studies are required on better methods for their symptomatic management or a definitive cure.

One important approach toward progress in controlling these diseases is further development of North-South partnerships (WHO 2002). Arrangements of this kind have been extremely successful for thalassemia but have not evolved for sickle cell anemia research. In both cases such partnerships should evolve and lead to local South-South networks allowing individual countries to share their expertise about these increasingly important conditions.

Finally, a great deal more work needs to be carried out, particularly in developing countries, to investigate the economic aspects of these diseases, in terms of both their overall health burden and their control and management.

CONCLUSIONS

The inherited hemoglobin disorders are posing an increasing global health problem, killing thousands of children because of the inadequacy or unavailability of treatment. With appropriate therapy, many children can survive and have an excellent quality of life, despite requiring lifelong treatment. Even though the full economic burden of managing these disorders is currently unknown, in the case of thalassemia, screening and prenatal diagnosis are cost-effective means of prevention. Penicillin prophylaxis provides cost-effective protection from infection for babies with sickle cell disease and should be standard practice wherever it is affordable.

Respiratory Diseases of Adults

Frank E. Speizer, Susan Horton, Jane Batt, and Arthur S. Slutsky

Adult respiratory diseases in the developing world are a major burden in terms of morbidity and mortality and, particularly as related to chronic respiratory disease, are of increasing concern (Murray and Lopez 1996). For many years, the leading cause of adult respiratory disease mortality has been tuberculosis, which still kills far more people than it should, given the increased efficacy of treatment and preventive regimens (see chapter 16). However, the burden of other acute and chronic adult respiratory diseases, which is the focus of this chapter, has been rising throughout the world. These diseases fall into four categories: acute diseases, such as pneumonia and influenza; chronic diseases, such as chronic obstructive pulmonary disease (COPD) and asthma; occupational lung diseases, such as byssinosis, asbestosis, and coal worker's pneumoconiosis; and other parenchymal lung diseases, such as immune-related lung diseases. Lung cancer, tuberculosis, and AIDS-related lung diseases are dealt with in chapters 29, 16, and 18, respectively.

ACUTE DISEASES: PNEUMONIA AND INFLUENZA

Obtaining figures on the incidence and burden of pneumonia and influenza in adults throughout the developing world has been surprisingly difficult. Much of the research and surveillance has been directed toward the pediatric age group (see chapter 25). In 2000, fatal lower respiratory infections, as a class that represents serious pneumonia and influenza, were reported as the cause of 120 deaths per million men and 76 deaths per million women worldwide for the 15 to 59 age group (WHO 2000). For both sexes in this age group, this statistic represents approximately one-third of the deaths caused by tuberculosis. However, for the age groups over 60, rates of death from lower respiratory disease more than double

for each decade of life, whereas rates of death from tuberculosis remain relatively constant. Notably, acute respiratory diseases—in addition to tuberculosis—remain major concerns among adults with AIDS.

The diagnosis of pneumonia varies according to the patient's access to medical care. Often the diagnosis is made simply on the basis of cough and fever. For patients with access to a hospital, the likelihood of obtaining a chest x-ray increases; generally the infection is bacteriologically confirmed only in the most sophisticated medical centers. The natural history of pneumonia without antibiotic treatment varies with the etiologic agent and the patient's underlying comorbid conditions and age. Mortality resulting from these lower respiratory diseases is approximately 10-fold higher in people age 60 to 69 than in people age 15 to 59 (WHO 2000). Comorbid conditions, malnutrition, low socioeconomic status, and cigarette smoking each play a role in increasing the incidence of disease and worsening the prognosis, both with and without treatment.

From studies conducted in the developed world, it would be reasonable to conclude that common antibiotics for pneumonias that occur outside a hospital setting would effectively reduce days lost from work and, in the absence of other morbid conditions, mortality. The few studies in which sputum specimens have been cultured suggest that *Streptococcus pneumoniae* is found in between 40 and 50 percent of the cases. Gram-negative organisms or mixed infections are often isolated, and thus, the use of broad-spectrum antibiotics is warranted (Hooi, Looi, and Ng 2001; Hui and others 1993; Lieberman and others 1996). As would be expected, increased use of antibiotics has resulted in increased resistance to common antibiotics. In addition, 10 to 15 percent of these cases may be tuberculosis (Dolin, Raviglione, and Kochi 1994).

Scott and others (2000) suggested that, despite the similarity of the mortality rates for hospital-treated pneumonia in developing and developed countries, there are important differences in the age distributions. The median age at death among Kenyan adults was 33 years, in contrast to more than 65 years in more developed countries. Many patients in developing countries present late in the course of the disease. Often they die before an appropriate diagnostic workup can be completed, thus leading to an underestimate of case-fatality rates.

Signs and symptoms of influenza can vary from trivial to explosive. Although the disease is usually self-limiting, it can result in both severe incapacity and, when not properly treated, potentially fatal secondary pneumonia. Clearly, patients with comorbid conditions, the very young, pregnant women, and

the elderly are at greater risk of suffering from complications from influenza. Those criteria, along with the adequacy of supply, form the basis for choosing who should be considered for vaccination each year. Because the symptoms of influenza can be quite similar to those of bacterial pneumonia, influenza may often be misdiagnosed as pneumonia. Generally, influenza is more self-limiting than pneumonia, although the infectivity and transmission of influenza from person to person can be substantial. The current threat of H5N1 influenza has resulted in increased human and avian surveillance and preparations for a possible pandemic (box 35.1).

The recent 2003 outbreak of severe acute respiratory syndrome (SARS; see chapter 53) emphasizes the importance of accurate and open surveillance and a coordinated response in

Box 35.1

H5N1 Influenza

Clearly, of even greater concern is the potential for a new influenza A pandemic, as occurred in 1918 and more recently in 1958 and 1968, from a newly altered strain of avian influenza. With each additional bird-to-human case, modest genetic mutation or re-assortment increases the chance for the avian virus to be altered to become established and virulent in mammalian species. This may result in the establishment of sustained transmission among humans. While the pandemics of 1958 and 1968 were together responsible for approximately 3 million deaths, mostly in the very young, the elderly, and in those with comorbid conditions, the 1918 episode is believed to have caused over 40 million deaths, mostly in the age group 15 to 35 years. This potential for greatly increased mortality among such a robust population has fueled recent concern (WHO 2005a).

This concern has become more immediate with the identification of a sub-strain of influenza A, H5N1, first identified in 1997 in Hong Kong when it jumped from poultry to humans and killed six of 18 infected people. Virtually all of the original cases were believed to have been bird-to-human transmission. Since that time there have been a few hundred serologically confirmed cases in Cambodia, Indonesia, Thailand, and Vietnam, with high case fatality but no sustained evidence of ongoing human-to-human transmission (WHO 2005b).

The H5N1 strain is highly pathogenic among poultry. During 2003–2004 it resulted in outbreaks in 8 countries in Asia, with over 100 million birds dying from disease or being culled. More recently, though an additional 150 million birds have been culled, because much of the developing world's poultry economy depends on rural backyard

sources, it is not clear how effective these control measures have been. Although these efforts were thought to help control the spread of the virus, permanent ecological reservoirs appear to have become established in wild fowl and domestic chickens over a relatively broad region of Southeast Asia. WHO authorities have expressed concern about the finding that migratory birds that are infected with H5N1 but are relatively asymptomatic have spread viable viruses over large regions with subsequent infection in domestic poultry. Furthermore, more recently there has been evidence of disease in wild and zoo mammals as well as isolated cases of infection in domestic cats. Recent reports from Vietnam include two cases in humans infected through the consumption of uncooked duck blood. Further investigation of possible person-to-person transmission is underway. Recently, WHO (2005b) stated, “The possible spread of H5N1 avian influenza to poultry in additional countries cannot be ruled out. WHO recommends heightened surveillance for outbreaks in poultry and die-offs in migratory birds, and rapid introduction of *containment measures*, as recommended by FAO and OIE. Heightened vigilance for cases of respiratory disease in persons with a history of exposure to infected poultry is also recommended in countries with known poultry outbreaks. The provision of clinical specimens and viruses, from humans and animals, to WHO and OIE/FAO reference laboratories allows studies that contribute to the assessment of pandemic risk and helps ensure that work towards vaccine development stays on course.”

Humans have little natural immunity to the H5N1 viruses. Thus, in contrast to the usual influenza epidemics, which affect the very young, elderly, and those with

comorbid conditions, virtually the entire population in an exposed community is at risk. In human cases of avian influenza, following the initial respiratory infection, mortality results from two distinct processes. One process begins with relatively rapid onset of respiratory distress from hypoxia associated with ARDS.^a The alternative process results from secondary bacterial infection with a variety of organisms. In the documented H5N1 influenza infections in humans, respiratory symptoms are most prominent. However, in one case of encephalitis in a child from Vietnam, H5N1 influenza virus was identified in cerebrospinal fluid and fecal matter, and in throat and serum samples. Isolates from several cases were resistant to two commonly used antiviral medications (amantadine and rimantadine), while two other antiviral medications (oseltamivir and zanamivir) still appear to be effective.

There is no way to predict the outcome of these ongoing events. What seems evident is that if human-to-human transmission becomes established, a pandemic will follow.

Source: Authors.

a. ARDS is defined as Acute Respiratory Distress Syndrome resulting from multiple causes, the most likely in this situation being an immunological reaction to the virus.

Given the lack of natural immunity, there is considerable concern that even if adequate vaccines were available, distribution on a worldwide basis would be limited by economic considerations as well as distribution problems in the developing world. Efforts are underway to identify the genetic make-up of the strains of H5N1 that will yield the most effective vaccines and to produce such vaccines in a cost-effective manner. Testing H5N1 vaccines based on recently identified viruses in normal healthy volunteers suggests the immunologic response may be adequate, but several months of production would be necessary to produce adequate supplies for one region, let alone for worldwide distribution. Stockpiles of effective antiviral medications are being generated in some countries. In the interim, WHO has encouraged the rapid reporting of cases and the establishment of procedures for better public health intervention strategies before and during a pandemic (WHO 2005c). Many countries have developed pandemic influenza preparedness plans in anticipation of such an event.

Table 35.1 Public Health Measures in the SARS Episode, 2003

Procedure	Comment
1. Isolation of patients	Isolate rapidly after onset of symptoms.
2. Quarantine of contacts	Usually at home, but separate from patients. When in contact with unexposed subjects, wear masks and avoid public transportation and visits to crowded places.
3. Education	Reduce delay between onset of symptoms and isolation. In endemic areas, get subject to monitor temperature daily. Use fever hotlines, fever evaluation clinics.
4. Thermal screening	Monitor temperature of travelers from endemic areas (not proven effective).
5. Increased social distance	Cancel mass gatherings. Close schools, theaters, public facilities. Require use of masks in public settings.
6. Disinfection	Practice frequent hand washing. Use aerosol disinfectant agents.
7. Travel advisories	Postpone unessential travel. Screen travelers at entry and exit (not proven effective). Distribute health notices to travelers.

Source: Data compiled and summarized from Bell 2004.

controlling the spread of newly active influenza strains. The potential for global spread and the occurrence of worldwide epidemics of influenza (presumed to be transmitted to humans from domesticated or wild animals and then through close proximity to humans with symptomatic disease—generally to caregivers) points out the importance of continued surveillance for such episodes (Low and McGeer 2004). The lessons learned from the SARS epidemic reinforce the importance of proven traditional public health measures, such as finding and isolating cases, quarantining close contacts, and improving infection control practices (Bell 2004). Those methods, along with several other, less traditional efforts, were presumed to be

part of the reason the epidemic was contained as promptly as it was (see table 35.1). However, because of the high case-fatality rate, the disease caused significant disruption throughout the world.

Economic Impact of Influenza and Cost-Effectiveness of Interventions in the Developed World

Influenza is common in developed countries. Annually, it affects 10 to 20 percent of the U.S. population (Lee and others 2002); those affected experience on average a loss of 2.8 workdays per episode. Those over 65 years of age are more

susceptible to complications, increased costs of hospitalization, and even death. The cost of outbreaks can be large. The costs of the 1996–97 epidemic in Germany were estimated at US\$1,045 million, and the annual costs of outbreaks at US\$11 million to US\$18 million (WHO 2002a).

For those over age 65, many countries encourage preventive vaccinations annually, on the basis of studies suggesting that vaccination (either opportunistic or in a campaign) is cost-effective in elderly populations (for example, see the model of Scuffham and West 2002). Given a good antigenic match, inactivated influenza vaccines prevent laboratory-confirmed illness in 70 to 90 percent of healthy adult vaccine recipients (WHO 2002a). Vaccination is less costly than chemoprophylaxis (with ion-channel inhibitors such as amantadine and rimantadine, or with neuraminidase inhibitors such as zanamivir and oseltamivir) or early treatment with the same drugs. In both the institutionalized and the healthy elderly, vaccination substantially reduces overall mortality from influenza (by 40 to 68 percent).

The cost-effectiveness of vaccination for healthy working-age adults, taking into account workdays lost, is a matter of debate. Demicheli and others (2000) concluded that the most cost-effective option for healthy adults age 14 to 60 was to take no action. However, these authors include only medical costs in their calculations. Postma and others (2002) reviewed 11 studies. Only one shows cost savings on the basis of medical costs alone, but nine of them implied cost savings from vaccination if the value of lost work is included. Because of differences in costs and health care usage patterns, data on cost savings in developed countries cannot be helpfully extrapolated to developing countries.

Economic Impact of Influenza in the Developing World

In Hong Kong, China (where there is a milder year-round pattern of infection, little influenza-related mortality, and low reported work losses), a model suggested that vaccination was not cost saving, even if targeted to the elderly (Fitzner and others 2001). The only case for vaccination was if it controlled the emergence of highly virulent strains and prevented transmission to the rest of the world. According to the World Health Organization (WHO), much less is known about the impact of influenza in the developing world. However, in the tropics, where viral transmission normally continues year-round, influenza outbreaks tend to have high attack and case-fatality rates. For example, during an influenza outbreak in Madagascar in 2002, more than 27,000 cases were reported within three months and 800 deaths occurred despite rapid intervention. An investigation of this outbreak, coordinated by WHO, found that health consequences were severe in poorly nourished populations with limited access to adequate health care (WHO 2002b). It is not possible to extrapolate the exact

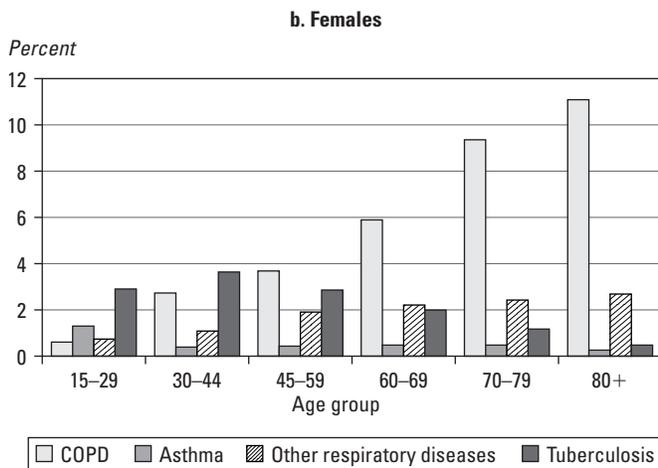

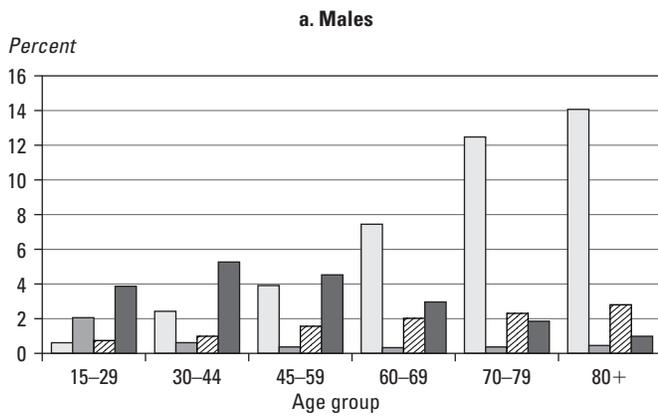

annual burden of influenza in the tropics from data on such occasional and severe outbreaks. Because many areas (for example, Sub-Saharan Africa) do not have surveillance centers, not enough is known at this point to make policy recommendations. There are also no readily available estimates of the cost-effectiveness of influenza vaccination in those environments. (For further discussion of the role of vaccination, see chapter 20.)

CHRONIC RESPIRATORY DISEASES: NATURE, CAUSES, AND BURDEN

COPD and asthma have very different diagnoses and causes; hence, they are discussed in separate sections. However, the treatments for these different chronic respiratory diseases share similarities, and that discussion is therefore combined. One of the difficulties in defining COPD on a worldwide basis is that three distinct levels are used, depending on the sophistication of the health care system in the country where the patient is being evaluated:

- *Chronic bronchitis* with and without obstruction, which may be part of the COPD diagnosis, is defined by the presence of chronic cough and phlegm for three months per year for two or more years and is generally assessed by standardized questionnaires.
- *Obstructive airways disease* is often assessed by reduced pulmonary function as measured by simple spirometry and the presence of a reduced ratio of the forced expiratory volume in one second (FEV_1) divided by the vital capacity (VC).
- For *emphysema*, which is also part of the syndrome of COPD, pulmonary function (changes in lung volume and reduced diffusion capacity), x-ray evidence of bullae formation, hyperinflation of the chest, and (with the use of high-resolution CT scanning) the presence of characteristic changes in lung architecture all may contribute to the diagnosis.

What is apparent is that not all these diagnostic procedures are applied equally, particularly in the developing world; thus, COPD may be seriously underreported. The 1998 Workshop Report by the WHO and the National Institutes of Health (NIH) on “Global Strategy for the Diagnosis, Management, and Prevention of COPD,” developed as part of the Global Initiative for Chronic Obstructive Lung Disease (GOLD 2001), uses an international standard for defining the level of obstruction from COPD. This strategy should improve worldwide estimates. This standard definition will still require the use of equipment that measures pulmonary function (Buist 2002). Over the next several years, as the price and distribution of this equipment becomes more favorable and as more groups

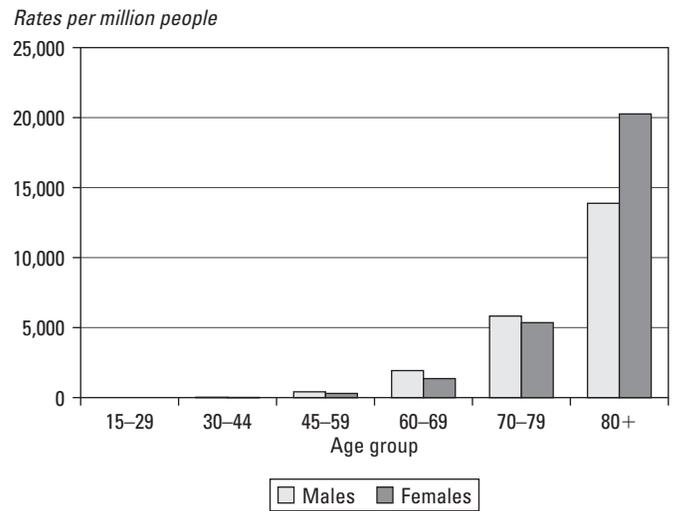

Source: WHO 2000.

Figure 35.1 Chronic Respiratory Diseases DALYs as a Percentage of World Totals

undertake the training in its use and in the interpretation of results from the tests, diagnostic uniformity will improve. Unfortunately, as pointed out by Ait-Khaled, Enarson, and Bousquet (2001), the applicability of these guidelines has not been effectively tested in developing countries.

In adults, COPD dominates all other chronic respiratory diseases in accounting for 2 percent to more than 10 percent of lost disability-adjusted life years (DALYs) on a worldwide basis. Its incidence increases dramatically with age (figures 35.1a and 35.1b). Of note, mortality from COPD is low before age 45. Over age 45, death rates increase from 50 to 200 per 10,000 individuals and are consistent across age groups in men and women, with the exception of death rates in women over age 80, which exceed those in men in that age group (figure 35.2).

Much of COPD in the developed world is related to cigarette smoking, and there is no question that progression of the disease is related to the number of cigarettes smoked and the years of smoking. Smoking cessation has been associated with

Source: WHO 2000.

Figure 35.2 COPD by Age and Sex, Worldwide

reduced mortality from COPD, presumably through a mechanism that results in a modest improvement in pulmonary function that appears to be related primarily to the extent of chronic bronchitis and mucus hypersecretion (Scanlon and others 2000; Speizer and others 1989). Within a few years of stopping smoking, smokers' rate of decline of pulmonary function (that is, FEV_1) returns to the rate found in nonsmokers, although little of the lost pulmonary function is regained (Fletcher and others 1976). Similar effects are seen in the developing world. However, because smoking is far less prevalent in developing countries, especially among women, other exposures are related to the development of disease (see also chapter 46). One of the most important exposures, particularly for women, is to unvented coal-fired cooking stoves, starting during childhood and continuing into adult life (see chapter 42).

Because the interventions and treatments for COPD overlap with those for asthma, they will be treated together.

The diagnosis of asthma has been debated for centuries. Health care providers can generally agree on the diagnosis in the individual patient who is wheezing and in whom other etiologic factors are ruled out. They would also agree on the definition of the disease as an inflammatory response in the airways that results in variable and generally reversible airflow obstruction with or without treatment. However, depending on the training of health care providers, the nature of surveillance, the characteristics of a given community, and the particular environment of the community, the accuracy of the estimate of the prevalence of asthma in a community may vary much more. The reported prevalence of the disease may be based on no more than an answer to this question: "Has a

provider ever told you that you (or your child) has had asthma?" The response to this question has been validated in a number of studies. In contrast, the diagnosis may depend on examination of the patient's chest, physiological testing, responsiveness to provocative stimuli to the airways, and specific response to therapy. Thus, estimates of community burden from asthma may depend on the threshold used in making the diagnosis.

Despite variations in diagnostic criteria, worldwide estimates of the asthma burden among adults have generally come from surveys within selected communities. In contrast to other adult respiratory diseases, the prevalence of asthma is relatively low (figures 35.1a and 35.1b). In adults, the DALYs for asthma are at a peak of about 2 percent of the total worldwide in people age 15 to 29, and they decline in each older age group. This pattern is also reflected in mortality rates, with the highest rates occurring in young people and equal rates in men and women about age 60. After age 60, reported rates of death caused by asthma in men begin to exceed those in women, and both become substantial. That shift reflects primarily either increasingly questionable diagnostic accuracy or misclassification of other obstructive respiratory diseases such as COPD.

Economic Impact of Asthma and COPD in the Developed World

In the United Kingdom (where asthma rates are particularly high), respiratory disease accounts for 6.5 percent of hospital admissions. Fifteen percent of the working population report work-limiting health problems caused by respiratory disease, and 18.3 million workdays were lost to asthma problems in 1995–96 (Chung and others 2002).

In the Netherlands, annual costs associated with asthma and COPD (direct and indirect) were estimated to exceed US\$500 million for a population of about 14 million (data for the 1980s). Asthma or COPD was responsible for 3 percent of absenteeism caused by illness, and asthma was also the main reason for absence from school among children age 4 to 12 (Rutten–van Mólken and others 1992).

In the United States in the early 1990s, health care costs attributable to respiratory disease were US\$11 billion (about 2 percent of total health care costs), and an estimated 3 million workdays and 10 million schooldays were lost to respiratory disease (Stoloff, Poinsett-Holmes, and Dorinsky 2002).

Another survey (Weiss and Sullivan 2001) estimated the costs of asthma in 1991 US dollars for four developed countries (Australia, Sweden, the United Kingdom, and the United States) and one state (New South Wales in Australia). Per patient costs of asthma ranged from US\$326 (Australia) to US\$1,315 (Sweden) annually, with direct costs accounting, in most cases, for more than half of total costs.

Economic Impact of Asthma in the Developing World

Data for developing countries are much scarcer. For Estonia, Kiiwet and others (2001, cited in Lee and Weiss 2002) estimated the direct annual costs of asthma to be US\$104 per year per asthma patient, equivalent to 1.4 percent of direct health care costs. In Singapore, medical costs for asthma constitute 1.3 percent of total health care costs (Chew, Goh, and Lee 1999, cited in WHO 2001).

One study (Ait-Khaled, Enarson, and Bousquet 2001, cited in Weiss and Sullivan 2001) found that asthma drugs cost between 3.8 and 25 percent of the patient's monthly income in 24 developing countries in Asia and Africa. K. R. Smith (2000) estimates the burden of respiratory disease in India that is attributable to indoor air pollution (only a fraction of all respiratory disease) as 1.6 billion to 2 billion sick days per year. Of that total, asthma is responsible for about one-third, acute respiratory infection is responsible for about one-third, and the remainder is attributable to COPD, tuberculosis, and ischemic heart disease. Asthma and COPD combined account for 44 percent of the burden.

Cost Effectiveness of Interventions for COPD and Asthma in Developed Countries

Five recent overviews of the economics of chronic respiratory disease, COPD, and asthma (Friedmann and Hilleman 2001; Lee and Weiss 2002; Ruchlin and Dasbach 2001; Sullivan and Weiss 2001; Weiss and Sullivan 2001), in addition to many individual studies, focus on developed countries.¹ Only a limited number of studies use cost- or quality-adjusted life years (QALYs) saved as the outcome (others use life years saved). (Studies focusing on intermediate health outcomes and on cost minimization are not discussed here.) In general, costs in developing countries would be about 20 percent of those reported here, according to detailed unit cost data by region from WHO-CHOICE (Choosing Interventions That Are Cost-Effective) and on comparisons of respiratory drug prices from online pharmacies in the United States and from the International Drug Price Indicator Guide (<http://erc.msh.org>). The exceptions are interventions involving nondiscounted drugs that are still under strictly enforced patents, for which the costs in developing countries would be closer to those in the United States. Table 35.2 summarizes the results.

Inhaled salbutamol (short-acting beta-2 agonist) is the first line of treatment for both intermittent asthma (daytime symptoms less than once per week, nocturnal symptoms less than twice per month, and normal spirometry between episodes) and COPD (mild to severe) in both developed and developing countries. This treatment became standard practice beginning in the 1970s, so there are no cost-effectiveness studies of salbutamol compared with placebo. This medical intervention is likely the most cost-effective one, but it is still likely to cost

Table 35.2 Cost-Effectiveness of Interventions for Asthma and COPD in 2001

Reference	Intervention	Alternative	Cost-effectiveness
<i>Pharmacological</i>			
Authors' estimates	Inhaled ipratropium bromide	Placebo	US\$6,700–US\$8,900/QALY for moderate COPD
Paltiel and others 2001	Quick relievers ^a and inhaled corticosteroids	Quick relievers only	US\$13,900/QALY in adults with mild to moderate asthma: US\$10,600 for moderate only
Van den Boom and others 2001	Inhaled corticosteroid (fluticasone propionate)	Placebo	US\$13,400/QALY COPD treatment
Akins and O'Malley 2000	A-1 antitrypsin augmentation therapy	Standard care ^b	US\$14,400/QALY, severely deficient individuals
Hay and Robin 1991, in Ruchlin and Dasbach 2001	A-1 antitrypsin augmentation therapy	Standard care ^b	US\$45,000–US\$215,000/life year, depends on age, efficacy, and so forth
<i>Education</i>			
Toeve, Kaplan, and Atkins 1984, in Ruchlin and Dasbach 2001	Education and exercise program	Exercise program only	US\$71,500/QALY
<i>Long-term oxygen</i>			
Authors' estimate	Home oxygen therapy for COPD	No oxygen	US\$19,000/life year (US\$26,700–US\$38,000/QALY)
<i>Mechanical ventilation</i>			
Schmidt and others 1983, in Rutten–van Mölken	Mechanical ventilation	Standard hospital care ^c (excluding ventilation)	US\$6,400–US\$23,600/life year (COPD, asthma, cardiac patients) excluding physician costs
Anon and others 1999 in Ruchlin and Dasbach 2001	Mechanical ventilation in intensive care unit, asthma, and COPD patients	Standard hospital care ^c (excluding ventilation)	US\$35,000–US\$60,700/QALY
<i>Surgery</i>			
Al and others 1998, in Ruchlin and Dasbach 2001	Lung transplant in end-stage disease	No transplant	US\$464,000/QALY
Ramsey and others 1995, in Ruchlin and Dasbach 2001	Lung transplant in those eligible	No transplant	US\$238,200/QALY

a. *Quick relievers* refer to rapid-acting bronchodilators (for example, salbutamol) that act to relieve bronchoconstriction and accompanying acute symptoms of wheeze, chest tightness, and cough.

b. Standard care includes medical management (ipratropium bromide, beta-2 agonist, steroid) and home oxygen as needed.

c. Standard care includes medical management and oxygen.

some thousands of dollars per life year saved in the United States.

The next line of treatment currently recommended for developing countries is inhaled corticosteroids (for example, beclomethasone) for mild to severe persistent asthma (disease ranging from daytime symptoms greater than once per week, nocturnal symptoms more than twice a month, and normal spirometry between episodes to daily frequent symptoms associated with severe obstruction) and inhaled ipratropium bromide for COPD. Both first-generation corticosteroids and ipratropium bromide are off patent. However, as pointed out by Chan-Yeung and others (2004), the use of corticosteroids either intermittently or chronically is commonly recommended in developed countries, where the background level of tuberculosis among patients is considerably lower. In developing countries with higher tuberculosis rates, corticosteroids must be used with greater caution.

Inhaled steroids cost about US\$13,900 per QALY for mild to moderate asthma or when used in early treatment of

COPD. The cost per QALY is likely to be lower for severe asthma, but ethical considerations render random controlled trials unfeasible.

No cost-effectiveness study could be found for ipratropium bromide compared with placebo. We estimate that the cost per QALY saved would be between one-half and two-thirds of that for a new-generation inhaled steroid such as fluticasone propionate. This estimate, which is based on the relative cost of the two drugs in the United States and assumes similar effectiveness of the two drugs, would put the cost of ipratropium bromide between US\$6,700 and US\$8,900 per QALY.

Most of the other interventions summarized in table 35.2 have a higher cost per QALY. For individuals who develop COPD related to a severe deficiency in alpha-1 antitrypsin, alpha-1 antitrypsin therapy is sometimes considered, at a cost of between US\$45,000 and US\$215,000 per life year.² The use of long-acting beta-2 agonists and leukotriene modifiers is now an accepted and integrated component of the treatment of moderate to severe asthma in the developed world. However,

the cost savings for the developing world are difficult to demonstrate because the endpoints of studies using those drugs are often changes in spirometric testing, improved quality-of-life measures, steroid-sparing effects, or altered hospital admission rates.

Likewise, oral or intravenous steroids play a crucial role in the treatment of acute exacerbations in both asthma and COPD, but endpoint assessments in studies typically address decreases in the duration of hospital stays and increases in the use of emergency department facilities, which result in decreases in health costs in the developed world. Oral steroids are inexpensive, even by standards in developing countries, and in the short term might appear to be cost-effective, but they are associated with major medium- to long-term consequences and are not recommended as standard therapy.

Educational programs tend to be cost saving in developed countries, where uncontrolled exacerbations are extremely costly in terms of hospital care (six such programs are surveyed in Van Mólken and others 1992 and one in Ruchlin and Dasbach 2001). Similarly, exercise rehabilitation programs (six surveyed in Ruchlin and Dasbach 2001) can also be cost saving. WHO (2001) has commented on cost savings achieved by education programs for asthma from four different U.S. studies. Only one of these studies addressed cost per well year, which was estimated at US\$71,500 in 2001 (Toevs, Kaplan, and Atkins 1984, cited in Ruchlin and Dasbach 2001). However, there are likely to be monetary savings from fewer workdays lost, which are not factored into this analysis.

WHO (2001) surveyed one self-management training program for chronic asthma in India (Ghosh and others 1998), which resulted in improvements in health status, reduced use of emergency departments and hospitals, and savings on health costs. Sudre and others (1999) pointed out that studies of education programs tend not to provide a good description of the actual program content and that a more systematic description of these interventions needs to be promoted to replicate best practice.

Long-term oxygen therapy is a life-prolonging intervention in advanced stages of COPD. Recent studies do not quantify the cost per QALY but instead compare different methods of oxygen delivery (cylinder or concentrator). These authors' crude estimate for long-term oxygen use is US\$19,000 per life year saved.³ If the quality-of-life scores of patients on long-term oxygen were 0.8 or 0.6, the cost per QALY would be US\$22,750 or US\$31,700, respectively. (K. J. Smith and Pesce 1994, cited in the Harvard Catalogue of Preference Scores, assign a median score of 0.4 to quality of life for patients with severe COPD with high supportive care needs and poor functional status.)

In hospitals, mechanical ventilation in the intensive care unit has been estimated to cost US\$35,000 to US\$60,700 per QALY in 2001 (Anon and others 1999, cited in Ruchlin and Dasbach 2001). Studies suggest that noninvasive positive

pressure ventilation, where it is feasible, is less costly than invasive mechanical ventilation for specific indications. Finally, costs of lung transplants are at a level scarcely affordable even in developed countries; Al and others (1998, cited in Ruchlin and Dasbach 2001) estimated costs at US\$464,000 per QALY, and Ramsey and others (1995, cited in Ruchlin and Dasbach 2001) estimated costs at US\$238,000 per QALY (in 2000 U.S. dollars).

All those interventions compare unfavorably with the cost-effectiveness of smoking prevention for preventing COPD (discussed in chapter 46). Smoking prevention is one of the most cost-effective health interventions that exists, and there is a strong case for moving resources from expensive curative interventions to that intervention. Likewise, prevention of COPD by switching the cooking source from unventilated stoves that burn biomass to either improved stoves or kerosene stoves is more cost-effective than treatment (see chapter 42).

Cost-Effectiveness of Interventions for COPD and Asthma in Developing Countries

It is difficult to transfer the costs per QALY saved in developed countries to developing countries. The cost of patented drugs in developing countries should be the same as that in developed countries, whereas the costs of education and of the time of medical personnel should be substantially lower (on the order of 20 percent of U.S. levels). In practice, the costs of off-patent drugs also vary considerably. Beclomethasone dipropionate (one of the older, off-patent inhaled steroids) is available for about US\$15 per 200-dose inhaler in Canada in online pharmacies but is quoted at US\$1 to US\$3 by agencies and suppliers on the International Drug Price Indicator Guide (<http://erc.msh.org>). A similar price difference exists for salbutamol inhalers. Hence, the most cost-effective therapies in developed countries (inhaled salbutamol and first-generation corticosteroids for asthma and ipratropium bromide for COPD) are also likely to be cost-effective in the wealthier developing countries—or more broadly if inexpensive drug supplies are available. Those drugs are likely to be particularly cost-effective for those with severe and moderately severe asthma or COPD but less cost-effective for those with mild disease. Recent practice suggests that a combination of long-acting beta agonists and inhaled corticosteroids can control moderate to severe disease more rapidly. However, to make this form of therapy cost-effective, the patient needs to be reevaluated to determine whether one or the other drug can be removed. Because of cost considerations, that may not be feasible in the developing world.

Once control has been obtained, education alone appears to be ineffective when only respiratory outcomes are considered (although education on the benefits of exercise has other health benefits: see chapter 44 on lifestyles). However, education

addressing the appropriate use of medication is extremely important, particularly in developing countries, where timely emergency care for severe exacerbations may not be readily available. Although the cost of educational efforts would be expected to be considerably lower in developing countries, this area requires more systematic research.

Long-term oxygen is also an option for high-income households in middle-income developing countries. The costs are likely to be lower than in developed countries. In Brazil the monthly cost for supplemental home oxygen therapy is close to US\$150 (Sant'Anna and others 2003), compared with US\$400 per month paid by Medicare, which would bring the cost-effectiveness to US\$7,000 per life year by these authors' crude estimates, or between US\$8,750 and US\$11,700 per QALY. Publicly funded systems are unlikely to be able to pay this rate, although private insurers and wealthy households might pay because such therapy prolongs life.

The other interventions in table 35.2 are likely to be too expensive for most developing countries to use at present.

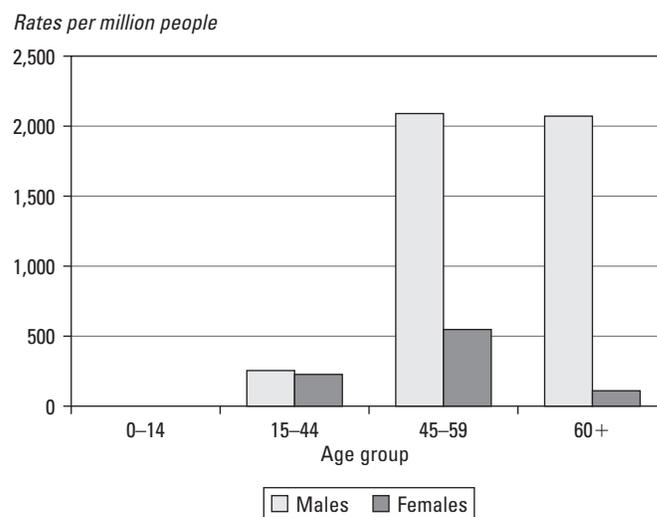

OCCUPATIONAL LUNG DISEASE AND OTHER RESPIRATORY DISEASES

Although occupational lung diseases are often considered diseases of the industrial world, they are occurring with increased frequency in the developing world, where guidelines for worker safety are generally more lax or nonexistent. In addition, because of increased migration from rural areas to more urbanized centers and the transfer of major manufacturing activities from the developed market economy countries to the less developed countries, the number of employees with potentially harmful occupational exposures has increased exponentially in the past 30 years. The general discussion of occupation-related diseases is reviewed in chapter 60. We focus here on specific occupation-related lung diseases.

Occupational lung diseases are, for the most part, characterized as related to particular occupational exposures and generally fall into two broad pathophysiological types. One type may result in pulmonary fibrosis, which is manifested by restricted lung volume and decreased diffusion capacity on pulmonary function testing and increased interstitial pulmonary markings on chest x-ray. Certain occupational lung diseases, such as silicosis, are complicated by a substantially increased risk of tuberculosis, which contributes to the overall burden of respiratory disease in the developing world. The second pattern of occupational lung disease is that of obstructive airways disease, which may be reversible (occupational asthma) or irreversible (chronic bronchitis with or without obstruction or emphysema or COPD), in which the chest x-ray often is negative and the diagnosis is dependent largely on reported histories of exposures, symptoms, and pulmonary function testing.

There are few reliable estimates of the global burden of occupation-related respiratory diseases. Because of the lack of systematic surveillance in most developing countries, the few published estimates of occupation-related respiratory diseases have relied on selected studies involving particular industries that investigators have had unique opportunities to explore. For example, Trapido and others (1996) conducted a survey in a relatively small group of former mineworkers and found that approximately 55 percent had pneumoconiosis with or without tuberculosis. They estimated that about 25 percent of migrant and former mineworkers in South African gold mines with 15 to 25 years of exposure had occupational lung diseases. Loewenson (1999) pointed out the difficulties in making assessments of occupational risk throughout the African countries and suggested a series of methodological issues that need to be considered.

Leigh and others (1999) estimated the global burden of diseases related to occupational factors at 4.2 million to 10.0 million cases per year. If one subtracts the rates for established market economy countries, the total burden for the rest of the world is approximately 3.4 million to 9.1 million cases per year. Using limited data and applying rates from individual nations and regional groups of countries, the authors made an indirect calculation for the expected number of cases of occupation-related diseases globally. Figure 35.3 summarizes their estimates for pneumoconiosis and other chronic respiratory diseases by age and gender. Notably, these two categories of disease account for approximately 30 percent of all occupational diseases. The prevalence of these diseases increases with age and is higher among men.

Source: Leigh and others 1999.

Figure 35.3 Estimated Combined Pneumoconiosis and Other Occupation-Related Chronic Respiratory Diseases

Asbestosis and asbestos-related cancers present a particular problem in developing countries. Asbestosis can manifest both as other interstitial lung disease, as described above, and as obstructive airways disease. In addition, occupational exposure is associated with the occurrence of lung cancer, and according to studies in developed countries, the rate of occurrence is synergistically associated with smoking. Because the cost of health care compensation in the developed world exceeds the potential profit from mining and manufacturing of asbestos products, much of the industry has moved to the developing world.

LaDou (2004) has recently summarized the status of the potential for reducing occupational exposure on a worldwide basis and suggests that upward of 10 million lives will be lost if the current lack of controls and continued increases in mining and manufacturing are not changed. In 2000, more than 2 million tons of asbestos products were produced, whereas 25 years earlier the total production was 350,000 tons each year. Except for the Russian Federation and Canada, virtually all the larger producers are in the developing world, where the recognition and reporting of health effects are less well established. The likelihood of reversing this trend and developing an international ban on asbestos use is small, particularly because it is the nations that produce more asbestos products that are, in fact, increasing consumption.

The economic burden of occupational lung diseases is surprisingly difficult to document. Most developed countries and some developing countries (for example, South Africa) have legislation protecting workers from exposure and compensating those who have contracted chronic conditions. In the United States, compensation payments from the Social Security Administration and the Department of Labor for black lung disease totaled US\$1.6 billion in 1996 (NIOSH 1999). Data exist on compensation for claims for various occupational lung diseases for the United States and the European Union countries. However, claims data represent only a small fraction of the true economic cost (for example, not all workers make claims; compensation payments lag considerably). For the United States, the annual costs of complying with the revised respirator standards for 1993 were US\$111 million for about 5 million workers needing to use a respirator (presumably these costs of prevention were far lower than the economic cost of unprotected work) (OSHA 1998). The primary treatment for affected workers is to remove them from the inciting exposures. (See chapter 60 for discussion of preventive strategies that need to be considered to reduce the risk of occupational disease.)

Some of the other major classes of adult respiratory diseases are discussed in other chapters: tuberculosis, in chapter 16; AIDS-related lung disease, in chapter 18; and lung cancer, in chapter 29. Other diseases that have been studied, particularly in the developed world, include the hypersensitivity or

immunologically related pulmonary diseases most often associated with environmental exposures to specific inhaled antigens or interstitial inflammation and fibrosis, often of unknown origin. In the developing world, little systematic work has been done on these diseases to assess incidence or prevalence. These conditions probably occur considerably less frequently than asthma and COPD. However, they are likely to have a higher prevalence in developing countries than is reported in the developed world simply because of the presumed associations with exposures to organic dusts and the increased prevalence of malnutrition (see chapter 56), both of which are likely to occur in more rural and less developed areas of the world.

See chapters 16, 18, and 29 for interventions for tuberculosis, AIDS-related lung disease, and lung cancer, respectively. Managing immunologic and fibrotic respiratory diseases with medication is extremely difficult and expensive. Therapeutic trials often fail, presumably because the treatments are not aimed at a particular antigen. The most effective way of managing these respiratory diseases is to reduce exposure to the inciting agents, an approach that hinges on two strong premises, which are not always applicable in the developed world. First, the disease must be recognized as related to a common environmental contaminant encountered in an occupational or avocational exposure—for example, exposure to thermophilic actinomycetes in moldy hay or sugarcane results in farmer's lung, and exposure to bird feathers or droppings results in bird fancier's disease. Second, community resources must be directed toward educating the public about the importance of limiting exposure to these agents.

GENERAL APPROACH TO LOWERING RISK OF ADULT RESPIRATORY DISEASE

Although interventions of various sorts are indicated for each of the disease categories discussed, these interventions are often costly and sometimes ineffective in lowering or preventing premature mortality. Thus, from an operational perspective, it is important to consider preventive and therapeutic strategies that will have greater societal effect than will the management of the manifestations of diseases as they arise in individuals. This approach applies to acute diseases (vaccination schemes to reduce the burden of influenza, in contrast to individual management of community-acquired pneumonia) and chronic diseases (smoking prevention and reduction programs, compared with availability of routine asthma medication). Primary prevention strategies should include efforts by multiple agencies of government and the community coming together to establish appropriate priorities for action. Four sources of exposure stand out: tobacco smoke, indoor smoke, outdoor air pollutants, and occupational exposure (see chapters 46, 42, 43,

and 60, respectively). Of these, the most pressing and cost-effective is a cohesive policy to control tobacco smoking.

In conjunction with the International Union against Tuberculosis and Lung Disease (IUATLD) and selected universities and health institutions in various countries, WHO is developing the Practical Approach to Lung Health (PAL, previously known as the Adult Lung Health Initiative). The program is focused on improving primary care services, as well as appropriate referral to secondary health care facilities, for individuals with tuberculosis, acute respiratory infections (especially pneumonia), asthma, and COPD. Four countries (Chile, Morocco, Nepal, and South Africa) are serving as the pilot implementation sites (WHO 2003).

In Chile, where respiratory symptoms account for one-third of primary health care visits, a respiratory disease program was initiated in 2001 as part of ongoing efforts to strengthen primary health care. The pilot program was implemented in 15 centers. Standard formats are used to devise scores to determine follow-up for asthma and COPD. Sentinel centers are used to provide epidemiologic information. Influenza immunization coverage of the elderly and at-risk population has reached 85 percent (WHO 2003).

In Morocco, survey work done before establishing a PAL strategy showed that 31 percent of patients who consult primary health care centers present with respiratory symptoms. Of those patients, 85 percent have acute respiratory infections, 14 percent have chronic conditions, and 1 percent have tuberculosis. In Mexico, an IUATLD study implementing asthma control measures was shown to be cost-effective. Control of asthma improved, and the majority of patients experienced a decrease in the severity of asthma. The cost of asthma management decreased because of lower costs for emergency services and hospitalizations (WHO 2003).

FUTURE RESEARCH NEEDS

One of the difficulties in quantifying the burden of respiratory diseases in adults is the inability to apply uniform methods of diagnosis across economies in which sophisticated diagnostic procedures are possible, let alone across less developed economies. The problems relate in part to differences in the language describing the same symptoms, levels of registration of census and disease reporting, availability of diagnostic procedures, and reluctance to make accurate estimates because of the cost of intervention strategies. Furthermore, unless controls on cigarette smoking are initiated, little progress in stemming the increasing burden of chronic respiratory diseases can be expected.

There are still a number of unanswered questions related to COPD, which remains the dominant respiratory disease in adults. The developing world provides some unique opportu-

nities for research that go beyond the primary prevention that would result from better smoking control policies. Because not all smokers are at increased risk, the interaction of smoking with nutritional status (including micronutrient status), with genetic factors that determine susceptibility, and with respiratory infections may act as a precursor of susceptibility to environmental (ambient or occupational) pollution and personal (smoking) pollution. Similarly, the role of immunologic stimulation or immunocompetence needs further exploration as it relates to the development of asthma. Synergies between the conditions discussed in this chapter and other infections (particularly tuberculosis, but possibly others) may be especially important in the developing world. Finally, specific environmental conditions—such as altitude, heat and cold stress, and increased ambient pollution from rapid urbanization—and their effects on asthma and COPD should be explored.

Acute respiratory infections, specifically bacterial pneumonia, have not been addressed nearly as well for adults as they have been for children. For example, simple data on the prevalence of infecting organisms, typical susceptibilities, the ability to train ancillary workers in clinical diagnosis, and the correlation of clinical assessment with verified disease would be helpful in establishing the feasibility of assessment and treatment at home versus at a clinic or hospital, specifically in the developing world. Common etiologic agents in North America are common elsewhere; therefore, treatment of disease would be relatively inexpensive. Most community-acquired acute disease responds relatively well. Certainly, penicillin should be recommended as a first-line drug for community-acquired pneumonia. Educating local healers on the importance of initiating treatment earlier in the course of disease would translate into savings with respect to decreased days of work lost and reduced case-fatality rates. Follow-up monitoring and the development of hospital-based bacteriologic testing should be expanded to identify and control for the emergence of resistant bacterial strains.

Studies of asthma in the developed world have been extensive and of extremely high quality but are directed specifically toward the health care structures in which they are tested. Specific cost-effectiveness studies in the developing world should be done to see, for example, whether a focus on disease education and modification of risk factors in addition to medications outweighs simple administration of medications (with instructions on use). In the developed world, there is no question that an approach that is multitiered and involves multiple health care providers is the best, but we still do not have concrete evidence of where monies are best spent in the developing world. Another possible fruitful area of research is on education programs. Most of the literature relates to education programs for specific entities (for example, “asthma triggers”) and their costs in developed countries. Education programs in developing countries that are multidimensional (smoking

cessation, indoor air quality, vaccination) are likely to be relatively inexpensive and cost-effective. Better methods of educating local healers through the use of demonstration projects should be tested, as should more efficient distribution systems to make relatively inexpensive medication available. General increased awareness of the impact of symptoms on adults and of the potential for earlier intervention in a disease should also be explored and tested for their effects on reducing respiratory disease burdens.

NOTES

1. The survey of the cost-effectiveness of interventions below is based on a review of the University of York database (<http://www.york.ac.uk/inst/crd>), combined with a Medline search (focusing mainly on data after 1996).

2. According to Hay and Robin (1991), cited in Ruchlin and Dasbach (2001). Akins and O'Malley (2000) have a much lower estimate, which probably does not include all the costs of screening and the like.

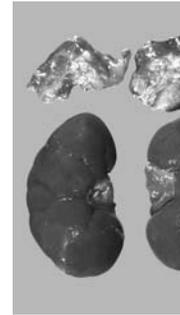

3. This estimate was calculated as follows: the MRC (1981) trials suggest that over five years the mortality in a randomized trial for patients with severe hypoxemia is 667 per 100,000 for those not treated with long-term oxygen, compared with 548 per 100,000 for those treated with long-term oxygen (reviewed in Crockett and others 2001). The cost per month of home oxygen is taken as US\$400 (based on U.S. Medicare reimbursements in the early 1990s).

Diseases of the Kidney and the Urinary System

John Dirks, Giuseppe Remuzzi, Susan Horton, Arrigo Schieppati, and S. Adibul Hasan Rizvi

CAUSES AND CHARACTERISTICS OF THE BURDEN OF DISEASES

Estimates of the global burden of disease indicate that diseases of the kidney and urinary tract account for approximately 830,000 deaths and 18,467,000 disability-adjusted life years annually, ranking them 12th among causes of death (1.4 percent of all deaths) and 17th among causes of disability (1.0 percent of all disability-adjusted life years). This ranking is similar across World Bank regions (table 36.1).

Recent research suggests that the data shown in table 36.1 underestimate the global prevalence of kidney disease. Chronic kidney disease (CKD) patients often suffer from cardiovascular or cerebrovascular disease, and their deaths may be attributed to either complication (Hostetter 2004). Altered kidney function is often found in patients with hypertensive and ischemic heart disease, both of which are associated with increased cardiovascular morbidity and mortality. Approximately 30 percent of patients with diabetes have diabetic nephropathy, with higher rates found in some ethnic groups (King, Aubert, and Herman 1998). Table 36.2 shows that both genders are similarly affected by kidney disease (Coresh and others 2003).

Generally, renal diseases progress to a final stage as end-stage renal disease (ESRD) and function is substituted by renal replacement therapy (RRT), hemodialysis, peritoneal dialysis, or transplantation. National and international registries of patients on RRT are useful for providing information on the prevalence of renal diseases in a given country. Data combined from different sources show that more than 1.5 million people

worldwide are on RRT, 80 percent of whom live in Japan, Europe, and North America (Weening 2004).

The percentage of patients on regular dialysis varies across countries as a consequence of the capacity of health care systems to provide treatment. Europe is an example. Whereas in the 15 countries of the European Union (before 2004) the prevalence rate of RRT was approximately 650 patients per 1 million people, in Central and Eastern Europe it was only 160 patients per 1 million people, reflecting differences in gross national product.

Much less is known about the prevalence of earlier stages of CKD, when symptoms may be mild, ignored, or undiagnosed. A lack of standardization of the stages of CKD has hampered assessments of the burden of CKD. In an attempt to carry out such an assessment, the National Center for Health Statistics of the Centers for Disease Control and Prevention in the United States conducted a survey from 1988 to 1994. The center analyzed a sample of 15,625 noninstitutionalized individuals age 20 and older and defined five stages of renal dysfunction according to estimates of renal function and urine albumin level. Coresh and others (2003) found that the estimated prevalence of CKD in the United States is 11 percent of the adult population, or 19.8 million people. Nationally representative data on U.S. adults older than 20 show that 6.3 percent, or 11 million people, have stage 1 CKD, or kidney damage (proteinuria) with normal kidney function (Glomerular Function Rate (GFR) at least 90 milliliters per minute in 1.73 per meter squared) or stage 2 CKD, that is, mildly reduced kidney function (60 to 89 ml/min/1.73 m²). Furthermore, 4.3 percent, or 7.6 million people, exhibit stage 3 CKD, or moderately

Table 36.1 Contribution of Diseases of the Kidney and Urinary System to the Global Burden of Disease by Gender and Region (thousands)

Gender and region	Population	Deaths	Disability-adjusted life years	Years lived with disability	Years of life lost
Females	3,056,384	397	8,008	2,546	5,450
Males	3,093,849	433	10,459	4,493	5,960
World	6,150,233	830	18,647	7,039	11,415
East Asia and the Pacific	1,850,775	233	5,400	1,858	3,530
Europe and Central Asia	447,180	53	1,417	623	793
Latin America and the Caribbean	526,138	70	1,667	779	888
Middle East and North Africa	309,762	57	1,283	460	823
South Asia	1,387,873	156	3,991	1,373	2,619
Sub-Saharan Africa	667,663	107	2,623	1,046	1,576

Table 36.2 Global Deaths Caused by Diseases of the Genitourinary System by Gender and Age

Gender	Age (years)							
	Birth–4	5–14	15–29	30–44	45–59	60–69	70–79	80+
<i>Male deaths</i>								
Number (thousands)	11	7	24	43	80	86	110	88
Percent	3	2	5	10	18	19	24	20
<i>Female deaths</i>								
Number (thousands)	10	6	21	29	61	66	85	98
Percent	3	2	5	8	16	18	23	24

Source: WHO 2002.

reduced kidney function (30 to 59 ml/min/1.73 m²), and 0.2 percent, or 400,000, have stage 4 CKD, or severely reduced kidney function (15 to 29 ml/min/1.73 m²) (Coresh and others 2003; Coresh, Astor, and Sarnak 2004; National Kidney Foundation 2002). A sizable proportion (360,000) of these patients eventually progress toward ESRD (stage 5, or less than 15 ml/min/1.73 m²) and require RRT. Early detection of CKD is, therefore, important to retard or arrest the loss of renal function. Late detection of CKD is a lost opportunity for making lifestyle changes and initiating therapeutic measures.

CAUSES OF DISEASES OF THE KIDNEY AND URINARY SYSTEM

Kidney disease leading to ESRD has many causes. The prevalence varies by country, region, ethnicity, gender, and age.

Genetic Diseases

Knowledge of inherited kidney disease has changed radically with advances in molecular biology and gene-sequencing

technology. The characterization of inherited kidney diseases has improved, and novel mutations leading to selective renal defects have been described. Inherited kidney diseases are rare, with the exception of autosomal dominant polycystic kidney disease, the fourth most common cause of ESRD in developed countries. This disease has a prevalence of 1 in 1,000 people and affects approximately 10 million people worldwide (Grantham 1997). Autosomal recessive polycystic kidney disease is less frequent, with an incidence of 1 in 40,000, but is an important hereditary disease of childhood (Guay-Woodford, Jafri, and Bernstein 2000). Many other inherited diseases can lead to ESRD, but together they account for only a small percentage of all people with ESRD.

Glomerulonephritis

Glomerulonephritides are a group of kidney diseases that affect the glomeruli. They fall into two major categories: *glomerulonephritis* refers to an inflammation of the glomeruli and can be primary or secondary, and *glomerulosclerosis* refers to scarring of the glomeruli. Even though glomerulonephritis and

glomerulosclerosis have different causes, both can lead to ESRD. Glomerulonephritis ranks second after diabetes as the foremost cause of ESRD in Europe. (Stengel and others 2003) and is the second leading cause of ESRD in the United States, according to the United States Renal Data System (<http://www.USRDS.org/>). Approximately 20 to 35 percent of patients requiring RRT have a glomerular disease.

Glomerular diseases are more prevalent and severe in tropical regions and low-income countries (Seedat 2003). A common mode of presentation is the nephrotic syndrome, with the age of onset at five to eight years. Estimates indicate that 2 to 3 percent of medical admissions in tropical countries are caused by renal-related complaints, most resulting from glomerulonephritis.

A number of kidney diseases that result from infectious diseases, such as malaria, schistosomiasis, leprosy, filariasis, and hepatitis B virus, are exclusive to the tropics. HIV/AIDS can be complicated by several forms of kidney disease; however, patient data are sparse (Seedat 2003).

Acute poststreptococcal nephritis following a throat or skin infection caused by Group A streptococcus has almost disappeared in high-income countries because of improved hygiene and treatment but remains an important glomerular disease in India and Africa, where epidemics have been reported (Seedat 2003).

The eradication of endemic infections, along with improvements in socioeconomic status, education, sanitation, and access to treatment, is a crucial step toward decreasing the incidence of glomerular diseases in developing countries.

Infections, Stones, and Obstructive Uropathy

Infections of the urinary tract are a common health problem worldwide and can be categorized as either uncomplicated or complicated. Uncomplicated infections include bladder infections such as cystitis, seen almost exclusively in young women (Hooton 2000). Among sexually active women, the incidence of cystitis is 0.5 episodes per person annually, and recurrence develops in 27 to 44 percent of cases. Acute, uncomplicated pyelonephritis, involving the kidney, is less frequent in women than is cystitis. Males are less susceptible to acute, uncomplicated infections of the bladder or the kidney, with an incidence of five to eight episodes per 10,000 men annually. Even though uncomplicated urinary tract infections are considered benign, they have significant medical and financial implications estimated at approximately US\$1.6 billion per year (Foxman 2003).

As for complicated urinary tract infections, hospitalization results in almost 1 million such infections per year in the United States. Bladder catheterization is the most important cause.

Developing countries exhibit a different pattern of urinary tract infection. Obstructive or reflux nephropathy is often attributed to urinary schistosomiasis (Barsoum 2003). Worldwide, 200 million people are affected and an estimated

300 million are at risk. The disease causes lesions in the bladder and predisposes those with the condition to secondary infections, bladder cancers, and chronic pyelonephritis.

Some 15 to 20 million people have tuberculosis (TB) worldwide, of whom 8 million to 10 million are infectious. Genitourinary TB is a common form of extrapulmonary TB and is always secondary to the primary lesion, which usually occurs in the lung (Pasternak and Rubin 1997). Lesions referred to as *ulcero-cavernous* or *miliary* affect the kidneys. If left untreated, such lesions may progress to kidney destruction. Early recognition of and effective therapy for TB substantially decrease the consequences in relation to kidney function.

In the industrial countries, kidney stones are a common problem (Morton, Iliescu, and Wilson 2002), affecting 1 person in 1,000 annually, and the incidence is increasing in tropical developing countries (Robertson 2003). Factors such as age, sex, and ethnic and geographic distribution determine prevalence. The peak age of onset is in the third decade, and prevalence increases with age until 70.

Although largely idiopathic, the following risk factors are associated with stone disease: low urine volume, hyperuricosuria, hyperoxaluria, hypomagnesuria, and hypocitraturia. Diarrhea, malabsorption, low protein, low calcium, increased consumption of oxalate-rich foods, and low fluid intake may play a role in the genesis of stone disease. In developing countries, 30 percent of all pediatric urolithiasis cases occur as bladder stones in children. The formation of bladder stones in children is caused by a poor diet high in cereal content and low in animal protein, calcium, and phosphates.

Kidney stones can have different clinical presentations, ranging from asymptomatic to large obstructing calculi in the upper urinary tract that can severely impair renal function and lead to ESRD. Although specific causes of kidney stones should be treated appropriately, general treatment includes increased fluid intake, limited daily salt intake, moderate animal protein intake, and medical treatment with alkali and thiazides.

The Afro-Asian stone-forming belt stretches from Sudan, the Arab Republic of Egypt, Saudi Arabia, the United Arab Emirates, the Islamic Republic of Iran, Pakistan, India, Myanmar, Thailand, and Indonesia to the Philippines. The disease affects all age groups from less than 1 year old to more than 70, with a male to female ratio of 2 to 1. The prevalence of calculi ranges from 4 to 20 percent (Hussain and others 1996). Urolithiasis accounts for some 50 percent of the urological workload and the bulk of urological emergencies. Patients may present with major complications leading to eventual ESRD and resulting in significant morbidity and mortality. In developed countries, only about 1 percent of patients are on dialysis because of obstructive uropathy, whereas in developing countries such as Indonesia and Thailand, obstructive uropathy is often the leading cause of ESRD, accounting for 20 percent or more of patients on dialysis. The availability of appropriately

trained medical and surgical personnel and of equipment essential for treating stone disease promptly would reduce the incidence of obstructive uropathy and ESRD. Cost analyses indicate that the medical prevention of stones saves more than US\$2,000 per person annually (Parks and Coe 1996).

Benign Prostatic Hypertrophy

Benign prostatic hypertrophy is a major cause of lower urinary tract symptoms and leads to obstructive renal failure and ESRD. By age 80, 80 percent of men have benign prostatic hypertrophy. The World Health Organization quotes a mortality rate of 0.5 to 1.5 per 100,000 (La Vecchia, Levi, and Lucchini 1995). The actual incidence of benign prostatic hypertrophy is difficult to assess because of the lack of epidemiological data. In the developed world, the incidence varies between 0.24 and 10.90 per 1,000 annually from age 50 to 80, and the probability of prostate surgery for benign prostatic hypertrophy ranges from 1.4 to 6.0 percent (Oishi and others 1998).

Acute Renal Failure

Acute renal failure refers to a sudden and usually temporary loss of kidney function that may be so severe that RRT is needed until kidney function recovers. Even though acute renal failure can be a reversible condition, it carries a high mortality rate. Acute renal failure is a prominent feature of major earthquakes, where many suffer from crush syndrome accompanied by severe dehydration and rapid release of muscle cell contents, including potassium. Kidney function shuts down unless body fluid and blood pressure are rapidly corrected and frequent hemodialysis is available. Recent earthquake rescues in the Islamic Republic of Iran and Turkey have demonstrated the benefits of rapid hydration and dialysis (Sever and others 2001).

Diabetes

Diabetes is one of the most common noncommunicable diseases (see chapter 30). With the serious complication of nephropathy, diabetes has become the single most important cause of ESRD in the United States and Europe, according to Stengel and others (2003) and the United States Renal Data System (<http://www.ifrr.net/>). Diabetes may account for one-third of all ESRD cases.

Family-based studies and segregation analyses suggest that inherited factors play a major role in people's susceptibility to diabetic renal complications (Seaquist and others 1989). In the United States, the burden of ESRD is threefold to fivefold greater among African Americans, Mexican Americans, and Native Americans than other Americans, and Imperatore and others (2000) find a 200 percent greater possibility of the occurrence of inherited diabetic nephropathy. A family history of

hypertension has also been associated with an increased risk of diabetic nephropathy. When specific markers of risk are found, high-risk individuals can be identified early and monitored for the development of proteinuria and kidney dysfunction.

The earliest sign of diabetic nephropathy is the appearance of small amounts of protein in the urine (*proteinuria*). As proteinuria increases and blood pressure rises, kidney function declines. The complete loss of kidney function occurs at different rates among type 2 diabetes patients, but it eventually occurs in 30 percent of proteinuria cases. The latter have a 10-fold increased risk of dying from associated coronary artery disease, which may obviate the progression of diabetic nephropathy to ESRD. As therapies and interventions for coronary artery disease improve, patients with type 2 diabetes may survive long enough to develop kidney failure.

Hypertension

Hypertension and kidney disease are closely related. Most primary renal diseases eventually produce hypertension. Arterial hypertension accelerates many forms of renal disease and hastens the progression to ESRD (Luke 1999). Recent studies have firmly established the importance of continuous blood pressure reduction to slow the progression of many forms of renal injury, particularly glomerular disease (Agodoa and others 2001; Peterson and others 1995). Over the long term, damage to the heart and cardiovascular system resulting from hypertension represents the major cause of morbidity and mortality among ESRD patients (Martinez-Maldonado 1998).

Before the development of effective antihypertensive agents, 40 percent of hypertensive patients developed kidney damage and 18 percent developed renal insufficiency over time (Johnson and Feehally 2000). Elevated serum creatinine develops in 10 to 20 percent of hypertensive patients, with African Americans and Africans at particularly high risk. In 2 to 5 percent of hypertensive patients, progression toward ESRD will occur in 10 to 15 years. Despite the relatively low rate of progression, hypertension remains the most common cause of ESRD after diabetes in the United States, is the foremost cause of death in all developed countries, and is a likely primary cause in developing countries given its high global prevalence rate. Native Americans and Hispanic Americans are disproportionately affected relative to Caucasian Americans.

GLOBAL PERSPECTIVES IN RELATION TO RRT

Despite the lack of uniform data worldwide, the medical community is aware that the total number of patients requiring RRT is growing in all high- and middle-income countries. In the United States, for example, 360,000 people with ESRD were on RRT in 2003, compared with 150,000 in 1994, and

according to a recent forecast, by 2014 the figure will have increased to 650,000 (Xue and others 2001). This increase represents a linear growth in new cases combined with longer survival by existing patients.

Levels in middle-income countries are lower, but rising. In Eastern Europe between 1990 and 1996, following economic changes, the number of hemodialysis and peritoneal dialysis centers increased by 56 and 296 percent, respectively (Rutkowski 2002), and the number of patients rose by 78 and 306 percent, respectively.

Overall, the incidence of ESRD is increasing worldwide at an annual growth rate of 8.0 percent, far in excess of the annual population growth rate of 1.3 percent. Nearly 1.6 million people, or only 15 percent of those affected, are receiving RRT, 80 percent of them in developed countries. The remaining 20 percent are treated in more than 100 developing countries, whose populations account for more than 50 percent of the world's population. A large proportion of people living in the poorest countries die of uremia because of a complete lack of RRT.

Risk Factors for Kidney Disease

The identification of risk factors can prevent or limit disease through lifestyle modifications or specific therapeutic interventions (Appel 2003; McClellan and Flanders 2003). For example, familial predisposition for a disease, which is not amenable to modification, can be used to identify high-risk populations for future monitoring.

Low socioeconomic status and limited access to health care are strong risk factors for kidney failure but account for only part of the excess of ESRD among African Americans (Perneger, Whelton, and Klag 1995), whereas racial and social factors account for most ESRD incidence (Pugh and others 1988; Rostand 1992). Factors associated with the progression of CKD include the following:

- unmodifiable variables
 - old age
 - gender
 - genetics
 - ethnicity
- risk factors susceptible to social and educational interventions
 - low birthweight
 - smoking
 - alcohol abuse
 - illicit drug abuse
 - analgesic abuse and exposure to toxic substance such as lead
 - sedentary lifestyle
- risk factors susceptible to pharmacological interventions
 - hypertension

- dyslipidemia

 - insulin-resistant syndrome
 - proteinuria
 - serum creatinine.

Growing evidence suggests that fetal exposure to an abnormal intrauterine environment leads to an increased risk of chronic disease later in life. For example, children of diabetic mothers are prone to obesity and diabetes at a young age, and intrauterine growth retardation can lead to ischemic heart disease, diabetes, hypertension, and kidney disease. Disadvantaged racial minorities in developed countries and the impoverished in developing countries are at risk of intrauterine growth retardation caused by malnutrition (Nelson 2001; Nelson, Morgenstern, and Bennett 1998). Attention to maternal nutrition and other factors that would reduce low birthweight and impaired nephron development may have long-term implications for the development of CKD.

In low-income countries, poverty is associated with increased exposure to infectious diseases that increase susceptibility to CKD, including glomerulonephritis and parasitic diseases. Obesity caused by a diet rich in saturated fats and high in salt are risk factors for diabetic nephropathy and hypertensive kidney disease. Change in dietary habits and physical activity can reduce the overall incidence of diabetes (see chapter 44). Smoking and excessive alcohol consumption increase the risk of ESRD (McClellan and Flanders 2003), and analgesic abuse and exposure to toxic substances such as lead may affect progressive renal insufficiency (Lin and others 2001).

Interventions to Delay CKD

During the past 20 years, human and animal research has developed our understanding of CKD and led to preventive measures. The notion of renoprotection has resulted in a dual approach to renal diseases based on effective and sustained pharmacological control of blood pressure and reduction of proteinuria. Lowering blood lipids, stopping smoking, and maintaining tight glucose control for diabetes form part of the multimodal protocol for managing renal patients monitored by specific biological markers (Ruggenenti, Schieppati, and Remuzzi 2001).

Abnormal urinary excretion of protein is strongly associated with the progression of CKD in both diabetic and nondiabetic renal diseases. Clinical studies have established that a reduction in proteinuria is associated with a decreased rate of kidney function loss. A specific category of drugs that lower blood pressure, the angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers, appear to be more effective than

other antihypertensive drugs in slowing the progression of both diabetic and nondiabetic CKDs (Brenner and Zagrobelny 2003). The administration of an ACE inhibitor (or of an angiotensin receptor blocker) is an important treatment for controlling blood pressure and slowing the rate of progression of chronic kidney failure. Other drugs to lower blood pressure are added as necessary to achieve current targets of 120/80 to 130/80 millimeters of mercury. Concurrent diuretic therapy is often necessary in patients with renal insufficiency, because fluid overload is an important determinant of hypertension in such cases.

Dyslipidemia accelerates atherosclerosis and may promote the progression of renal disease. Careful control of the blood glucose level in diabetic patients can be beneficial and may limit other complications. Obesity has not been directly linked to the progression of CKD but is an important risk factor for diabetes and cardiovascular morbidity and mortality. Many patients and health care professionals do not appreciate the benefits of smoking cessation, an important measure in protecting the kidneys from progressive disease resulting from cardiovascular disease (CVD). Additional elements of secondary prevention measures include the treatment of anemia and of abnormal calcium and phosphorus metabolism.

The International Society of Nephrology is developing a program that can be implemented according to the specific needs of a given developing country. The program has two objectives: (a) to identify the prevalence of renal disease among seemingly healthy subjects using a communitywide screening program, especially among populations at risk, and (b) to initiate interventions to prevent the progression of renal disease and affect both renal and CVD outcomes in subjects with or at risk of developing renal disease based on the screening program (Weening 2004). The Kidney Help Trust of Chennai, India, has undertaken a screening program for a population of 25,000. All those who tested positive for high blood pressure, diabetes, or both (about 15 percent) were further studied and then treated with inexpensive antihypertensive and antidiabetic drugs. The cost of the one-year program was Rs 300,000 (US\$7,500) or a per capita cost of US\$0.27, well within the limits of the Indian government's per capita annual health expenditure of US\$7.67 (Mani 2003). A similar program in Bolivia examined a population of 14,000 and also found that 15 percent were hypertensive, diabetic, or both.

An extremely successful program of detection and treatment of renal and cardiovascular diseases among Australian Aborigines was conducted from 1995 to 2000. The ESRD rate among Aborigines is 3 to 10 times that in developed countries. Treatment consisted of long-acting ACE inhibitors to lower blood pressure. After an average of 3.4 years of follow-up, the incidence of ESRD was reduced by 63 percent and nonrenal deaths were reduced by 50 percent. Hoy and others (2003) estimate that this two-year program may have saved US\$500,000 to US\$2.7 million in avoided or delayed dialysis costs.

Trained staff members can carry out screening programs inexpensively. Economic analysis, however, suggests that large-scale programs should be restricted to screening and treating only specific high-risk populations. Screening programs can be implemented using simple, cheap, and reliable tests consisting of measurements of bodyweight, blood pressure, blood glucose, and creatinine. Screening includes testing urine for hemoglobin, glucose, leukocytes, and protein (repeat tests may be necessary on a spot urine sample); calculating albumin to creatinine ratios; testing positive results for increased serum creatinine and fasting glucose (or glycosylated hemoglobin A1c test); and reassessing the urine protein excretion rate, a cornerstone of kidney assessment. Resulting albumin to creatinine ratio categories would indicate a scale of severity of glomerular disease, with a cardiovascular risk score based on body mass index, hypertension, fasting glucose level, microalbuminuria or gross albuminuria, and serum creatinine. Patients with positive markers for kidney disease would receive the best treatment available at the screening center. Incorporating screening for kidney disease within screening programs developed for CVD and diabetes is important because proteinuria and renal dysfunction are early sensitive markers of vascular dysfunction and CVD patients are at significantly higher risk of kidney disease than the general population.

Resultant medical treatment would focus on the use of ACE inhibitors or angiotensin receptor blockers with a target blood pressure of 120/80 to 130/80 millimeters of mercury. The greater the level of proteinuria, the more treatment is required; thus, the ACE inhibitor dose would be titrated up as proteinuria levels increased. Diuretics and other antihypertensives would be added to meet blood pressure targets. Efforts should be made to obtain low-cost (off-patent) ACE inhibitors or other low-cost antihypertensives. Such treatment should delay or stop the progression of kidney disease and reduce the risk of CVD. Other preventive measures include serum glucose and lipid control and low-dose aspirin if a risk of CVD exists (see chapter 44).

ECONOMIC BENEFITS OF INTERVENTION

An abundance of literature is available on the economics of ESRD. In the industrial world, treatment is usually readily available and is covered by government or private health insurance. Previous restrictions—for example, treatment being limited to certain age groups—have been removed (Chugh and Jha 1995). Dialysis treatment accounts for 0.7 to 1.8 percent of health care budgets in European countries, even though dialysis patients account for only 0.02 to 0.05 percent of the population (Schiepatti, Perico, and Remuzzi 2003).

The most cost-effective option is prevention. Population screening is not particularly cost-effective, given the low incidence of ESRD—namely, 100 to 200 per million population

worldwide (Kher 2002)—and given that testing is not highly accurate. According to Kiberd and Jindal (1998), screening costs around US\$20 per test, but the positive predictive value for a single test is only 0.3. Even repeat testing does not improve predictive value dramatically. Screening strategies have, therefore, focused on specific populations at higher risk of ESRD than the general population. Whereas only 2 to 5 percent of more than 1 billion hypertensive patients will ultimately develop nephropathy, approximately 30 percent of type 1 and type 2 diabetic patients will develop overt nephropathy (Satko and Freedman 2001). The conclusion is that treating all diabetics in developed countries with ACE inhibitors is a cost-saving strategy. The modest outlay for ACE inhibitors, which amounts to US\$320 per year in the United States and is likely to come down as more ACE inhibitor treatments come off patent, offsets the much larger future costs of dialysis and transplant (Golan, Birkmeyer, and Welch 1999; Kiberd and Jindal 1998).

We undertook a crude cost-effectiveness calculation for treating diabetics in developing countries with ACE inhibitors in those cases in which no treatment of ESRD is undertaken. If we use Clark and others' (2000) assumptions, 82 percent of diabetic patients not using ACE inhibitors would survive for 11 years from the onset of macroproteinuria to ESRD, whereas 72 percent of those using ACE inhibitors would survive for 18 years from the onset of macroproteinuria to ESRD (the annualized death rate for both groups is 1.8 percent). If we make the gross assumption that all patients with ESRD in poor developing countries die, this assumption suggests that, at a discount rate of 3 percent and an annual cost for ACE inhibitors of US\$320, the cost per quality-adjusted life year (QALY) saved would be about US\$1,100 for treating diabetic patients with macroproteinuria. Because of the lack of data, these calculations apply survival rates in developed countries to developing countries; thus, the rates are likely too high. Using survival rates in developing countries would probably increase the cost per QALY saved, but treatment with ACE inhibitors is nevertheless likely to be an attractive investment (table 36.3).

Satko and Freedman (2001) suggest that screening first- and second-degree relatives of ESRD patients may be cost-effective. They cite one study that found 38 percent of first-degree relatives of African-American patients with hypertensive ESRD had some form of renal disease (Bergman and others 1996). Satko and Freedman also cite a study by Freedman, Soucie and McClellan (1997) revealing that in 4,365 incident ESRD patients in the southeastern United States, 14 percent of white patients and 23 percent of black patients had first- or second-degree relatives with ESRD (the rates would probably have been higher if subclinical nephropathy had been included). Satko and Freedman (2001) recommend annual screening for blood pressure, urinalysis, measurement of serum creatinine and blood urea nitrogen concentration, and testing for diabetes mellitus, when appropriate, for first- and second-degree

Table 36.3 Cost-Effectiveness of Selected Interventions for Kidney Disease

Intervention	Alternative	Outcome (2000 US\$)
Center hemodialysis ^a	No RRT	55,000–80,000/life year 79,000–114,000/QALY
Home hemodialysis ^a	No RRT	33,000–50,000/life year 47,000–71,000/QALY
Kidney transplant ^a	No RRT	10,000/life year 11,000/QALY
ACE inhibitors for all type 1 diabetics with macroproteinuria ^b	No RRT	1,100/QALY
Screening diabetic relatives of nephropathy patients ^c	No screening	Screening potentially cost saving
Treat all type 2 diabetics with ACE inhibitors ^d	Screening for microalbuminuria and treating those who test positive	Incremental cost-effectiveness ratio is 7,500/QALY for treating all type 2 diabetics
Treat all insulin-dependent diabetics with ACE inhibitors ^e	Screening for microalbuminuria or macroproteinuria and treating those who test positive	Treating all insulin-dependent diabetics dominates under a plausible range of parameters

relatives of ESRD patients. They did not calculate any formal cost-effectiveness results (table 36.3).

Kidney transplants are the most cost-effective intervention for ESRD. Transplant costs in developed countries have declined steadily from about US\$60,000 in 1970 to about US\$10,000 currently (Winkelmayer and others 2002). In addition to facing transplant costs, patients face ongoing costs for immunosuppressive drugs, which start at about US\$3,000 per year initially but can decline thereafter to US\$300 per year (Kher 2002). Kidney transplants are cheaper in India than in the United States, ranging from US\$1,500 in government hospitals to as much as US\$7,000 in private hospitals. Such costs, combined with a higher quality of life than obtained with dialysis, make renal transplantation the most cost-effective option (table 36.3). However, the availability of kidneys is a major limiting factor. Developed countries tend to have well-organized organ retrieval programs, and cadaveric donor transplants are more common than they are in developing countries. Japan, with its extremely low transplant rates, is an exception, perhaps because of difficulties in obtaining permission for organ donation.

Developing countries have limited access to cadaveric donor programs but better living donor programs. Unrelated living donors are more common than in developed countries because poverty increases the willingness of donors to offer kidneys in

exchange for payment. The Philippines recently restricted donations to “emotionally related” donors, but that limitation does not prevent abuses, such as men marrying women of the appropriate blood type in the hope of obtaining a kidney. Developing countries face particular transplantation problems, such as patients’ inability to continue paying for immunosuppressive drugs and the transmission of hepatitis B and C, malaria, and TB through organ transplant (Kher 2002).

Long-term hemodialysis was introduced in 1960 and is the most costly treatment option at approximately US\$60,000 per year at a center and US\$40,000 at home in developed countries. It is most cost-effective if used as an interim measure before kidney transplant. Peritoneal dialysis—for example, continuous ambulatory peritoneal dialysis—was developed in the late 1970s and is less expensive—approximately US\$20,000 per year (Winkelmayer and others 2002). Most economies continue to rely on hemodialysis for dialysis patients, except for those mandating that continuous ambulatory peritoneal dialysis be the first choice—that is, Hong Kong (China), Mexico, New Zealand, and the United Kingdom. Switching to continuous ambulatory peritoneal dialysis has the potential of reducing costs for developing countries, especially if they manufacture the consumables domestically rather than importing them. Nevertheless, dialysis remains costly and is not a viable long-term solution in places where health budgets are limited.

More than 120 countries have dialysis programs (Moeller, Gioberge, and Brown 2002). The following data from India highlight the stark economics of dialysis (Kher 2002). Government hospitals will provide hemodialysis only for acute renal failure or pretransplant stabilization (Li and Chow 2001), and with an incidence of 100 per million population, approximately 100,000 patients develop ESRD each year. Of the 10,000 who consult a nephrologist, RRT is initiated for 9,000. Of the 8,500 who begin hemodialysis, about 60 percent are lost to follow-up within three months, probably because of the costs involved. Few remain on dialysis after 24 months. Between 17 and 23 percent of those on dialysis for two to three months receive transplants.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS OF EXPERIENCE

Measures for primary and secondary prevention of CKD are now well documented and will eventually reduce the number of patients requiring dialysis. Until recently, the focus has been on RRT to save lives, and considerable efforts are being made to improve the quality of dialysis. In the United States, guidelines derived from the Kidney Disease Outcomes Quality Initiative have added greatly to the quality of dialysis in terms of access (graft or fistula), adequacy, treatment of anemia, treatment of secondary hyperparathyroidism, and—more recently—greater

emphasis on CVD, all of which contribute to quality-of-life outcomes, but at an increased cost (National Kidney Foundation 2002).

The high mortality rate of dialysis approximates 10 percent per year and has changed little over the past decade; however, new approaches are emerging for dealing with CVD in RRT facilities. More patients with kidney disease die before they get to the point at which they need treatment for renal failure, because early kidney disease is a major marker for CVD and reinfarction, congestive heart failure, and stroke.

In middle-income countries such as Thailand and Turkey and in middle-income countries in Latin America (Zatz, Romão, and Noronha 2003), extensive dialysis facilities are available, as they are in some low-income countries. For example, in 2003, Pakistan had 110 centers with 2,400 patients on hemodialysis; India had 100 centers with 6,000 patients mostly on hemodialysis; and China had 75,000 patients on dialysis. Those figures show that needs and markets for dialysis are expanding. However, in poorer countries, such as Nicaragua and Tanzania, options for RRT are limited because of the lack of equipment, trained staff, and costly consumables. In addition, many low-income countries lack health insurance to defray treatment expenditures, keeping dialysis out of reach. In such countries—for example, Nigeria—dialysis directed at preparation for renal transplantation is the best policy. Recent findings concerning primary prevention through lifestyle changes and secondary prevention by means of pharmaceutical treatment should eventually reduce, but not eliminate, the burden of ESRD.

The acknowledgment by the World Bank and the World Health Organization that chronic conditions, particularly those resulting from diabetes and hypertension, will increase to become a leading cause of death by 2028 has intensified the need for prevention and RRT programs. The need to increase awareness, launch targeted screening and intervention studies, provide training for staff, maintain education for physicians in kidney and urological disease, and assist centers for RRT is urgent.

Developed nations have well-established nephrology and urology centers attached to academic medical institutions and regional public and private secondary and tertiary referral hospitals. They have training programs to meet national requirements for health professionals—including renal physicians, primary care physicians, and nurses—specializing in kidney and urological disorders. Their centers incorporate the results of up-to-date research developments pertaining to kidney disease and clinical applications of the latest advances in care and technology. Numerous publications arise from academic endeavors, and a close association exists between health care delivery and pharmaceutical industries. Each country and region has societies of nephrology and urology for adults and children.

Middle-income countries may have both public academic centers and private hospitals that offer specialized equipment,

such as lithotripters and imaging technology, and dialysis and transplant programs. Although facilities and trained staff for RRT are more limited than in developed countries, some developing countries, such as Turkey, have excellent facilities.

In lower-income countries, facilities and staff are in short supply, and assistance is needed. Large countries, such as China, India, and Pakistan, have kidney centers available but have considerable unevenness in development of kidney centers and health care in general. Some lower-income countries possess remarkable institutions; for instance, the Sindh Institute of Urology and Transplantation in Karachi, Pakistan, which is supported mainly by charitable donations, provides every patient who presents with ESRD an opportunity for accessing RRT. Overall, however, centers of excellence are urgently needed in developing countries. All the “players,” from governments and international organizations to societies and foundations, need to be congregated in conjunction with national institutions to focus on the continued advantages—through treatment—that can be delivered to those developing cardiovascular, diabetic, and kidney disease.

RESEARCH AND DEVELOPMENT AGENDA

Significant progress in knowledge about the geographic burden of kidney and urological diseases has taken place during the past three or four decades as a result of more accurate registries. An international kidney disease data center, in partnership with the World Bank and the World Health Organization, is now required to progressively increase the amount and quality of data collected worldwide.

Basic Knowledge of Kidney Disease

Recent research findings have advanced the understanding and treatment of kidney disease. A continuing emphasis on understanding the basic mechanisms of glomerulonephritic, vasculitic, and autoimmune disease and the detailed mechanisms of the progression of kidney disease to kidney failure is required, as well as research into improved therapies. Well-developed research centers are best equipped to deal with these requirements, aided by national governments, charitable organizations and foundations, international organizations, and centers in the developing world.

Prevention of Kidney Failure

Prevention of acute and chronic kidney disease should be a global priority. During the past decade, an array of clinical trials has been directed at assessing the benefits of interventional therapy, particularly the success of ACE inhibitors. Such trials can play an important role in increasing knowledge and improving the implementation of prevention of kidney disease

in developing countries. Training epidemiologists and physicians to execute screening strategies and clinical trials in their own settings is urgently needed. The cooperation of global funding agencies and training centers; the consistent availability of effective, inexpensive pharmaceuticals; and the assessment of the efficacy and side effects of multiple drug therapy must be coordinated. The priority is to make low-cost drugs available, using as a model the recent process that allowed universal access to inexpensive antiretrovirals for HIV infection.

Renal Replacement Therapy

Successful RRT outcomes depend on reducing morbidity and mortality among dialysis patients. RRT costs escalate in concert with the rising costs of pharmaceuticals—for example, erythropoietin compounds to treat anemia and vitamin D metabolites and calcimimetics to treat secondary hyperparathyroidism and bone disease. Strategies that will result in less expensive dialysis systems and pharmaceuticals are needed (Schieppati, Perico, and Remuzzi 2003). Costs relating to renal transplantation have reached a steady state, but the lack of availability of donor kidneys is a serious—and perhaps irresolvable—limitation.

Establishment of Teaching and Research Centers

Most high-quality training and research centers for kidney and urinary diseases are in the developed world, where training is expensive. Important centers of clinical care have emerged in countries such as Argentina, China, Mexico, South Africa, Thailand, and Turkey. The ability to obtain high-quality training at the local level would be advantageous to developing countries. For example, the International Society of Nephrology has identified and supported a major clinical training center in South Africa that plays a leading role in training nephrologists and urologists for South Africa and other Sub-Saharan African countries to world standards at lower costs than in developed countries and with increased retention of local physicians. Such local centers should be a national priority in developing countries and should be closely linked to international centers for cardiovascular and diabetic disease, meeting approved international standards for training while recognizing national differences in the pattern of kidney disease. Financial assistance is required to enhance the education and training of health professionals, improve baseline infrastructure, and initiate research studies directed at critical clinical questions and at current and new knowledge relating to the prevention of kidney disease. The centers should have excellent data collection methods and a computer infrastructure that would connect them to current knowledge and allow them to communicate freely on a global scale. Major priority should be given to developing leading centers in selected regions.

Cost-Effectiveness of Treatment

More work is needed in the area of screening and treatment in both developed and developing countries. Work on the cost-effectiveness of screening and treating particular subpopulations would be useful, as would the development of better predictive tests for microalbuminuria. In addition, cohort studies of hypertensive and diabetic populations might help develop better indicators that predict susceptibility to progression toward nephropathy.

CONCLUSIONS: PROMISES AND PITFALLS

Kidney disease and kidney failure, especially as a complication of type 2 diabetes mellitus and hypertension, are rising globally and are rising faster in developing countries. Kidney failure patients account for a small fraction of the disease burden but a disproportionately high cost. CKD, along with all chronic diseases, is placing long-term demands on health care. On a global scale, RRT is rising sharply in terms of costs and is usually unavailable in developing countries. Hemodialysis and peritoneal dialysis are life saving, but in the long term they require coupling with newer, proven, interventional pharmacological treatments that frequently delay or stop continuing progression to ESRD. Advances in the past decade have proven that primary and secondary prevention measures can now reduce the burden of ESRD, and if they are not widely disseminated, the need for RRT will increase along with the certainty that the requirements of kidney disease patients cannot be met.

The following guidelines for diseases of the kidney and urinary system are recommended:

- Expand surveillance of the prevalence of various kidney and urological diseases in developing countries. Provide support for further epidemiological studies in selected countries for assessing the prevalence of kidney disease and interventions to address it and for establishing an international kidney disease data center.
- Promote public awareness in developing countries about the nature and early signs of kidney disease along with knowledge of prevention measures and therapies.
- Focus more attention on the increasing prevalence of diabetes and hypertension, and develop kidney disease programs in that context. Measures of kidney function and protein excretion should be taken. The implementation of primary and secondary prevention to reduce the prevalence of ESRD should be expanded.
- Increase coordination and resources for efficient and timely distribution of supplies and equipment, assessment of patients, and frequent dialysis for acute renal failure patients caused by crush injuries during such major disasters as earthquakes. Countries in earthquake-prone regions should

develop emergency policies and practices and be linked with the appropriate international agencies.

- Have the World Bank and the World Health Organization establish a policy advisory group with relevant international groups, such as the International Society of Nephrology, to address and advise national and regional health ministries on kidney and urological strategies as requested.
- Make major health and medical education programs available on an annual basis through existing societies and agencies to train and update physicians, nurses, technicians, and other relevant health professionals.
- Develop selected centers of excellence for education, training, clinical care, and prevention of kidney and urological disease and clinical care of renal failure. At least 10 such centers should be developed in the next decade and located in the countries of the former Soviet Union, Africa, Asia, Eastern Europe, and Latin America. Funds should be provided by international and national agencies and national government organizations and be sustained for up to 10 years.

Chapter 37

Skin Diseases

Roderick Hay, Sandra E. Bendeck, Suephy Chen, Roberto Estrada, Anne Haddix, Tonya McLeod, and Antoine Mahé

In assigning health priorities, skin diseases are sometimes thought of, in planning terms, as small-time players in the global league of illness compared with diseases that cause significant mortality, such as HIV/AIDS, community-acquired pneumonias, and tuberculosis. However, skin problems are generally among the most common diseases seen in primary care settings in tropical areas, and in some regions where transmissible diseases such as tinea imbricata or onchocerciasis are endemic, they become the dominant presentation. For instance, the World Health Organization's 2001 report (Mathers 2006) on the global burden of disease indicated that skin diseases were associated with mortality rates of 20,000 in Sub-Saharan Africa in 2001. This burden was comparable to mortality rates attributed to meningitis, hepatitis B, obstructed labor, and rheumatic heart disease in the same region. Using a comparative assessment of disability-adjusted life years (DALYs) from the same report, the World Health Organization recorded an estimated total of 896,000 DALYs for the region in the same year, similar to that attributed to gout, endocrine disease, panic disorders, and war-related injuries. As noted later, those figures require confirmation by more detailed studies, and their practical application to health interventions needs to be tested.

Assessing the impact of skin disease on the quality of life in comparison with that of chronic nondermatological diseases is difficult; however, the study by Mallon and others (1999), which was not carried out in a developing country, compares the common skin disease acne with chronic disorders such as asthma, diabetes, and arthritis and finds comparable deficits in objective measurements of life quality. Skin disease related to HIV, which may constitute an important component of the skin disease burden in developing countries, particularly in

Sub-Saharan Africa, leads to a similar impact on life quality compared with non-HIV-related skin problems, although the use of antiretroviral therapy significantly improves quality of life (Mirmirani and others 2002). Those findings indicate that skin diseases have a significant impact on quality of life.

Although mortality rates are generally lower than for other conditions, people's needs for effective remedies for skin conditions should be met for a number of important reasons.

- First, skin diseases are so common and patients present in such large numbers in primary care settings that ignoring them is not a viable option. Children, in particular, tend to be affected, adding to the burden of disease among an already vulnerable group.
- Second, morbidity is significant through disfigurement, disability, or symptoms such as intractable itch, as is the reduction in quality of life. For instance, the morbidity from secondary cellulitis in lymphatic filariasis, which may lead to progressive limb enlargement, is severe, and subsequent immobility contributes to social isolation.
- Third, the relative economic cost to families of treating even trivial skin complaints limits the uptake of therapies. Generally, families must meet such costs from an overstretched household budget, and such expenses in turn reduce the capacity to purchase such items as essential foods (Hay and others 1994).
- Fourth, screening the skin for signs of disease is an important strategy for a wide range of illnesses, such as leprosy, yet a basic knowledge of the simple features of disease whose presenting signs occur in the skin is often lacking at the primary care level.

A shortage of elementary skills in the management of skin diseases is a further confounding problem. A number of studies assessing success in the management of skin diseases in primary care settings in the developing world find that treatment failure rates of more than 80 percent are common (Figueroa and others 1998; Hilete-work 1998). An additional point, often overlooked, is that skin diseases in the developing world are often transmissible and contagious but are readily treatable (Mahé, Thiam N'Diaye, and Bobin 1997).

A number of common diseases account for the vast majority of the skin disease burden; therefore implementing effective treatments targeted at those conditions results in significant gains for both personal and public health. Even where eradication is impossible, control measures may be important in reducing the burden of illness; yet few systematic attempts have been made to validate control programs for skin diseases as public health interventions.

PREVALENCE OF SKIN DISEASES

Few studies aimed at estimating the prevalence of skin diseases have been carried out in Western societies. However, Rea, Newhouse, and Halil's (1976) study in Lambeth, south London, which used a questionnaire-based, population-centered approach backed by random examination, reveals an overall 52 percent prevalence of skin disease, of which the investigators judged that just over half the cases required treatment. Studies from developing countries have generally adopted a more inclusive approach that uses systematic, community-based surveys backed by examination. Published figures for the prevalence of skin diseases in developing countries range from 20 to 80 percent.

In a study in western Ethiopia, between 47 and 53 percent of the members of two rural communities claimed to have a skin disease (Figueroa and others 1998), but when they were examined, 67 percent of those who denied having skin problems were found to have treatable skin conditions, most of which were infections. However, prevalence alone does not equate with disease burden. For instance, most communities recognize scabies as a problem because of its intractable itching and secondary infection, whereas they may ignore tinea capitis, which is equally common among the same populations, because they are aware that it follows a benign and asymptomatic course in many patients.

Researchers agree about the main risk factors associated with skin disease in developing countries, the most important of which appears to be household overcrowding. In primary schools in western Ethiopia, more than 80 percent of randomly examined schoolchildren had at least one skin disease, which was usually caused by one of four conditions: scabies,

pediculosis capitis, tinea capitis, or pyoderma (Figueroa and others 1996). Those figures mirror work carried out elsewhere. For instance, in Tanzania, in a survey of two village communities, Gibbs (1996) found that 27 percent of patients had a treatable skin disease, and once again, infections were the most common diseases. Overcrowding was a major risk factor in that survey. A similar community-based survey in Sumatra, Indonesia, showed a 28 percent prevalence of skin disease (Saw and others 2001). What seems to influence the overall prevalence and pattern of skin conditions in certain areas is the existence of a number of common contagious diseases, notably, scabies and tinea capitis. Hot and humid climatic conditions may also predispose populations to pyoderma, thereby affecting the distribution of disease.

PATTERNS OF SKIN DISEASES AT THE COMMUNITY LEVEL

A recent (unpublished) survey by the International Foundation of Dermatology designed to provide information about community patterns of skin disease in nine different countries across the world—Australia (Northwest Territory), Ethiopia, Indonesia, Mali, Mexico, Mozambique, Senegal, Tanzania, and Thailand)—and poor regions in other tropical environments from Mexico to Madagascar indicates that the following were the main skin conditions at community level:

- *Scabies*. Although scabies was often the commonest skin disease, it was completely absent in some regions.
- *Superficial mycoses*. This group of infections was usually reported as one of the three commonest diseases.
- *Pyoderma*. This disease was often, but not invariably, associated with scabies.
- *Pediculosis*. This disease was the subject of much variation but is often overlooked in surveys. Firm, community-level data on the prevalence of pediculosis are deficient; thus, this disease is not discussed further in this chapter.
- *Eczema or dermatitis*. Although this disease was usually unclassified, irritant dermatitis and chronic lichen simplex were often cited.
- *HIV-related skin disease*. This disease was reported mainly in Africa. The pruritic papular dermatitis of AIDS is a specific problem.
- *Pigmentary anomalies*. Three different problems were cited: hypopigmentation, often diagnosed as pityriasis alba, a form of eczema; melasma; and dermatitis caused by cosmetic bleaching agents (Mahé and others 2003).
- *Acne*. This disease was reported as an emerging and common problem.

These diseases are the same as those recorded in the literature described previously. Other skin conditions cited by different members of the group surveyed follow:

- *Tropical ulcer*. The incidence was highly variable, but tropical ulcer can account for a huge workload in primary care centers in endemic areas.
- *Nonfilarial lymphoedema*. This condition was mainly confined to Ethiopia.
- *Onchodermatitis, filarial lymphoedema, endemic treponematoses, Buruli ulcers, and leprosy*. These conditions are discussed in detail elsewhere in this book, but note that they often present with skin changes and symptoms.

According to World Bank (2002) figures for low-income populations in 2000, the estimated numbers of individuals infected with pyoderma and scabies, based on the highest prevalence figures from community surveys in the developing world, are 400 million and 600 million, respectively. Based on the lowest prevalence figures, these estimated numbers are 40 million and 50 million, respectively. For tinea capitis, the estimated number of cases based on the highest estimates of prevalence for Sub-Saharan Africa alone is 78 million.

Overall, these data suggest that significant changes could be made in reducing the burden of skin diseases by focusing on the small group of conditions, particularly infections, that account for the bulk of the community case load. This chapter concentrates on those conditions for which such a strategy could be implemented—namely, scabies, pyoderma, fungal infections, tropical ulcers, HIV/AIDS-related dermatoses, and pigmentary disorders.

EFFECTIVE THERAPIES

In considering the evidence for effective treatment, a subgroup of the team (Bendeck, Chen, and McLeod) undertook a data search to establish the evidence base for treatment of the common conditions. They carried out comprehensive searches of the MEDLINE (1966–April 2003) and EMBASE (1980–April 2003) databases to identify therapeutic studies on scabies, pyodermas, and superficial mycoses (but note that many of the studies were performed in industrial countries). They used foreign-language articles if an English abstract was provided. Table 37.1 shows search terms for each of the skin diseases common in the developing world and for treatment.

The team members reviewed study titles and abstracts to select relevant articles and scrutinized the bibliographies of selected articles to identify pertinent studies not captured in the initial literature search. They defined admissible evidence as primary therapeutic studies, based on clinical evaluation, of the treatment of each disease.

Table 37.1 Search Strategy for Therapies

Disease	Search term for disease	Search term for treatment
Scabies	["scabies"]	["treatment of" or "ivermectin" or "permethrin" or "Lindane" or "malathion" or "benzoyl benzoate" or "crotamiton" or "sulfur"]
Pyoderma or bacterial skin infections	["skin diseases, bacterial" or "ecthyma" or "staphylococcal skin infections" or "impetigo" or "pyoderma" or "folliculitis"]	["drug therapy" or "prevention & control" or "therapy"]
Tinea capitis:	["tinea capitis"]	["drug therapy" or "therapy" or "prevention & control"]
Tinea imbricata:	["tinea imbricata.mp"]	
Tropical ulcer	["tropical ulcer\$.ti"] or ["skin ulcer(explode)" and "tropic\$.mp"]

Note: Terms in brackets are medical subject heading terms. If no standard medical subject heading terms were available, databases were searched either using the title option (denoted as ".ti") or the keyword option (denoted as ".mp").

SKIN DISEASES

Scabies

Scabies is a common ectoparasitic infestation caused by *Sarcoptes scabiei*, a human-specific mite that is highly prevalent in some areas of the developing world. Scabies is transmitted by direct contact. In industrial societies, it is usually seen in sexually active adults, although it may also appear in the form of clusters of cases among the elderly in residential homes. Peaks of infection in communities may be cyclical. The ease of transmission appears to depend, in part, on the parasitic load, and some patients, including the elderly, may have large numbers of parasites present. By contrast, in healthy adults, the total parasite load may be low, but they, nonetheless, may suffer from highly itchy lesions. The organisms can also reach high densities in patients suffering from a severe depression of immunological responses, as in HIV infection. In this crusted or Norwegian form of scabies, lesions may present with atypical crusted lesions that itch little.

In developing countries, transmission commonly occurs in young children and infants and their mothers and is related to close contact, overcrowding, and shared sleeping areas. Sexual contact is less important as a means of transmission. Scabies is also a scourge of prisons in developing countries, where it is

associated with overcrowding (Leppard and Naburi 2000). No evidence exists that transfer is related to inadequate hygiene.

The most important complication of scabies is secondary bacterial infection, usually caused by Group A streptococci. Evidence from studies among the indigenous population of northern Australia indicates that this infection is not always benign and that persistent proteinuria is associated with past scabies infestation, suggesting that nephritis related to secondary infection of scabies may cause long-lasting renal damage (White, Hoy, and McCredie 2001).

The disease presents with itchy papules and sinuous linear tracks in the skin that can be highly pruritic and particularly troublesome at night. Often more than one member of a household has the disease.

Treatment. The treatments used for scabies are mainly applied topically. Treatment is not based on treating just affected individuals, both because of the ease with which scabies spreads and because symptoms may develop days or weeks after infection. The advice given to patients always includes a recommendation to treat the entire household with a similar medication, a difficult problem when many people live in the same dwelling. The treatments commonly available include the following:

- *Sulfur ointments.* There are no controlled clinical studies of the use of this cheap medication, which is usually made up in an ointment base. Soap containing sulfur is available in some areas. Anecdotally, sulfur ointment needs to be applied for at least one week to the entire body. Irritation is a common side effect, and lower concentrations, such as 2.5 percent, are applied to infants.
- *Benzyl benzoate.* A 10 to 25 percent benzyl benzoate emulsion is applied over the entire body and left on the skin for up to 24 hours before washing off. Current recommendations suggest that one to three applications may be sufficient, but consensus on the optimal treatment regimen would be useful. Benzyl benzoate emulsion is an irritant and can lead to secondary eczema in some patients.
- *Gamma benzene hexachloride (Lindane).* This product is widely available and is used as a single application washed off after 12 to 24 hours. Concerns have arisen about the increasing risk of drug resistance and the absorption of the drug through the skin. It is also not used in children because of reports of neurotoxicity and fits. This product is not available in many countries.
- *Malathion (0.5 percent) in an aqueous base.* The highly purified commercial forms are effective after a single application, although a second is advised. No data are available on the use of this preparation in developing countries.
- *Crotamiton cream or monosulfiram 25 percent.* These alternative therapies have highly variable efficacy rates.

- *Permethrin 5 percent cream.* This effective, nonirritant treatment is usually administered as a cream applied all over the body. A single application washed off after 8 to 12 hours is used. The tubes are small, and adequate quantities should be prescribed. This treatment is also the most costly of the topical therapies.

Treatment failures in developing countries may be related to the lack of a suitable place in many communities where patients can apply treatment effectively over the entire body from the neck down in privacy.

Oral ivermectin, which is an important drug in the treatment of onchocerciasis, has also been used in patients with scabies, particularly those with the crusted form or in places such as prisons, where large numbers of infected individuals live in close proximity. It has also been applied as a community-based treatment and is reported to be effective as such (Hegazy and others 1999). It is not licensed for the treatment of scabies, and the lack of safety data on the use of ivermectin in infants limits its use. In addition, insufficient evaluations of its efficacy and cost-effectiveness in developing countries have been carried out.

Evidence for Effective Therapies. The team identified 56 articles on therapies for scabies and found the following to be the viable ones: oral and topical ivermectin, permethrin, gamma benzene hexachloride, benzyl benzoate, crotamiton, malathion, and topical sulfur. Table 37.2 summarizes the evidence for ivermectin versus a placebo or permethrin and for topical ivermectin, as well as for the less expensive topical sulfur.

Community-Based Treatments for Scabies. Few studies have addressed the problem of community-administered treatments for scabies, despite the argument that without a community approach to therapy in many developing countries, the successful management of scabies in areas where it affects more than 5 to 6 percent of the population is doomed to failure. Taplin and others' (1991) study of the use of 5 percent permethrin cream in the San Blas Islands, Panama, confirms this view. A three-year program of treatments backed by surveillance reduced the prevalence of scabies from 33 percent to less than 1 percent; however, a three-week break in regular treatment was followed by a rapid increase in prevalence to 3 percent. The results of treatments involving the application of similar protocols, but using other topical agents, are not available. Oral ivermectin lends itself to a community-based treatment approach and has been used in this way (Hegazy and others 1999; Usha and Gopalakrishnan Nair 2000), but insufficient follow-up data are currently available to comment further on this approach.

Bacterial Skin Infections or Pyoderma

Bacterial skin infections or pyoderma are common in most developing countries (Mahé, Thiam N'Diaye, and Bobin 1997).

Table 37.2 Evidence of the Efficacy of Treatments for Scabies

Treatment and average wholesale price	Strongest evidence	Number of people in study	Results	Comments
Ivermectin oral US\$5.20 (3 mg), given at 200 µg/kg, one or two doses	Randomized clinical trial (versus placebo) (Hegazy and others 1999)	55	79.3 percent cure with single dose of ivermectin 200 µg/kg versus 16.0 percent cure with placebo ($p < 0.001$)	<ul style="list-style-type: none"> • Will treat concomitant strongyloidiasis and onchocerciasis • Not approved for scabies by the U.S. Food and Drug Administration • Safety not established for children under five and pregnant women
	Randomized clinical trial (versus permethrin) (Taplin and others 1991)	85	Single dose: 70.0 percent cure with ivermectin 200 µg/kg versus 97.8 percent cure with permethrin 5 percent Second dose (two-week interval): 95.0 percent cure with ivermectin 200 µg/kg (statistically equivalent cure rates with ivermectin and permethrin used as single dose/application)	<ul style="list-style-type: none"> • A single application of permethrin is superior to a single dose of ivermectin, which suggests that ivermectin may not be effective at all stages in the life cycle of the parasite
Ivermectin (topical)	Open-label, prospective, single group (Macotella-Ruiz and Ramos 1996)	32	100 percent cure rate with two doses of ivermectin 1 percent solution at six weeks (no statistics reported)	<ul style="list-style-type: none"> • Subjects treated with 1 percent ivermectin in a solution of propylene glycol at 400 µg/kg repeated once after one week • Well tolerated
Sulfur compounds (topical) Ointment (480 grams) US\$2.32	Open-label, nonrandomized, prospective cohort (Usha and Gopalakrishnan Nair 2000)	102	71 percent cure at four weeks using sulfur, 5 percent in children younger than 12 months, and 10 percent in children older than 12 months	<ul style="list-style-type: none"> • Typically used as 5 percent to 10 percent in petrolatum • Messy and smelly • Must be applied repetitively for three nights • Mild local irritation may occur

Source: Authors.

µg = microgram; kg = kilogram; mg = milligram; p = probability.

Generally these infections arise as primary infections of the skin known as impetigo or as secondary infections of other lesions such as scabies or insect bites. The usual bacterial causes are Group A streptococci or *Staphylococcus aureus*. Bacterial infections are common in communities. In many cases, no bacteriological confirmation is available from cultures, but surveys show that Group A streptococci account for a substantial number of cases (Carapetis, Currie, and Kaplan 1999; Taplin and others 1973), which is not often the case in similar infections in temperate climates, where *S. aureus* dominates. This finding carries implications for the selection of treatment options. The reasons for this finding are not clear, although humidity and heat are associated with increased risk of bacterial skin infection. In addition to these superficial infections, *S. aureus* also causes folliculitis, or hair follicle infections and abscesses. Rarer causes of skin infection in developing countries include cutaneous diphtheria and anthrax, as well as necrotizing infection caused by *Vibrio vulnificus*.

Bacterial infection causes irritation and some discomfort. In some cases, the infection penetrates deep down through the

epidermis, causing a necrotic ulcer—a condition known as ecthyma. However, some evidence suggests that streptococcal infection may cause additional long-term damage through the development of prolonged proteinuria, as described earlier in relation to scabies.

Treatment. Treatment with topical antibacterials, such as fusidic acid or mupirocin, is expensive; thus, the use of cheaper agents, such as antiseptics, is an important option but one that has been evaluated in only a few instances. Chlorhexidine and povidone iodine have both been used, but potassium permanganate is also said to be clinically effective. Gentian violet at concentrations of 0.5 to 1.0 percent is a cheap agent that is widely used, with proven in vitro efficacy against agents commonly involved in pyoderma. Most of those compounds have been used to prevent rather than to treat infections. The most extensively evaluated topical preparations are fusidic acid ointment and mupirocin, which are given daily for up to 10 days. Those drugs are effective in eradicating bacterial infections but, as noted, are not cheap options. Group A streptococci are still

sensitive to penicillin, which can be used for treatment, with alternatives for staphylococcal infections being cloxacillin, flucloxacillin, and erythromycin. Industrial countries largely view methicillin resistance among staphylococci as a nosocomial problem, yet it has now spread to the community, and skin infections provide an ideal medium for the spread of resistance, even in developing countries. *S. aureus* strains isolated from skin sites, even in remote tropical areas, are now resistant to beta-lactam penicillins and tetracyclines through the spread of resistance genes. Tetracycline ointment is still available in many rural pharmacies and is widely used to treat superficial skin lesions, even though some bacterial infections will be unresponsive. Topical neomycin and bacitracin are widely available, are associated with identifiable levels of treatment failure, and also carry a risk of sensitization or adverse effects.

Evidence for Effective Treatment. The team reviewed 727 studies of therapies for pyoderma or bacterial skin infections. These studies could be grouped into either prophylactic regimens or therapeutic trials. For the prevention of pyoderma, the studies surveyed included the following effective therapies: chlorhexidine solution, hexachlorophene scrubbing, and neomycin/polymyxin B-bacitracin (Neosporin) cream. For

the treatment of pyodermas, a number of studies reported effective topical therapies, namely: povidone-iodine solution, hydrogen peroxide cream, electrolyzed strong acid aqueous solution, tea ointment, Soframycin ointment, honey, fusidic acid cream, trimethoprim-polymyxin B sulfate cream, rifaximin cream, sulconazole cream, miconazole cream, neomycin/polymyxin B-bacitracin (Neosporin) cream, terbinafine cream, and mupirocin. Systemic agents cited were cephalixin, erythromycin, penicillin, Augmentin, amoxicillin, sultamicillin, (di)cloxacillin, azithromycin, cefadroxil, cefpodoxime, cefaclor, ceftizoxime, clindamycin, clarithromycin, tetracycline, fluoroquinolones, and fusidic acid.

Table 37.3 presents the evidence for commonly used antiseptics and some of the specific antibacterial agents. In practice, topical treatments such as chlorhexidine, povidone, and in some cases neomycin or mupirocin will provide the most cost-effective control measures. For extensive infection, cloxacillin or erythromycin provides alternatives. However, current evaluations are subject to some weaknesses, such as a lack of large, comparative studies, particularly of the topical therapies, including antiseptics, used in developing countries.

Community-applied measures for managing skin infections have not been evaluated, but measures such as early treatment of scabies or basic wound care of sores might provide

Table 37.3 Evidence of the Efficacy of Topical Treatments for Pyoderma

Treatment, level of evidence, cost (manufacturer, formulation, average wholesale price)	Evidence	Number of people in study	Results	Comments ^a

significant benefits. In this area, carefully designed pilot control programs would provide extremely valuable data.

Fungal Infections

Fungal infections that affect the skin and adjacent structures are common in all environments. They include infections such as ringworm or dermatophytosis; superficial candidosis and infections caused by lipophilic yeasts and *Malassezia* species;

and some other common causes of foot infection, such as *Scytalidium*. The clinical and social impact of fungal infections on individuals varies with local conditions. For instance, tinea pedis is a treatable condition that causes cracking and inflammation with itching between the toes. It is generally viewed as a nuisance that only marginally affects the quality of life; however, under certain conditions its significance is far greater. For example, fungal infections of the web spaces and toenails in diabetics provide a portal of entry for *S. aureus*, an event closely

related to the development of serious foot complications in patients with peripheral vascular disease and neuropathy. Similarly, foot infections originally caused by dermatophytes can develop into more serious disabling infections through secondary Gram-negative bacterial infection among certain occupational groups in the tropics, such as workers in heavy industry, the police, or the armed forces. Wearing heavy footwear is a risk factor for the emergence of this problem.

Other infections, such as oropharyngeal candidosis, are important complications of HIV. This commonest infectious complication of AIDS is a potential early marker. Whereas in many patients it may simply have nuisance value, in others it has a more serious impact and leads to dysphagia and loss of appetite. *Malassezia* infections such as pityriasis versicolor are also common in the developing world and often occur in more than 50 percent of the population; however, they are generally asymptomatic but cause patches of depigmentation, and patients seldom seek treatment.

Some fungal infections are extremely widely distributed or common in defined endemic areas. They include tinea capitis and tinea imbricata.

Tinea Capitis. Tinea capitis is a common, contagious disease of childhood that can spread extensively in schools. It is caused by dermatophyte fungi of the genera *Trichophyton* and *Microsporum* (Elewski 2000). Infections can spread from child to child (*anthropophilic infections*) or from animals to children (*zoophilic infections*). Anthropophilic infections tend to be endemic or epidemic, whereas the zoophilic forms occur sporadically. The commonest sources and causes of zoophilic infections are cats and dogs (*Microsporum canis*), cattle and camels (*Trichophyton verrucosum*), and rodents (*T. mentagrophytes*). The causes of the anthropophilic form of this infection vary in different areas of the world. Although in areas of the developing world this condition is endemic at high levels, in many parts of Africa it is a common condition affecting more than 30 percent of children in primary schools. The main African species are *M. audouinii*, *T. soudanense*, and *T. violaceum*. The last is also found in the Middle East and India. *T. tonsurans*, the form of tinea capitis endemic in the United States (Wilmington, Aly, and Frieden 1996) and in parts of Europe, such as France and the United Kingdom (Hay and others 1996), is extremely resistant to treatment. No evidence indicates that this form has spread to Africa yet, although this possibility exists.

Families of children with tinea capitis seldom present for treatment. However, in a small proportion of individuals, tinea capitis produces a highly inflammatory lesion with suppuration on the scalp along with permanent scarring and local hair loss. The numbers of infected individuals showing this highly symptomatic change are not known with any accuracy, but it is believed to occur in about 5 percent of cases, more

with *T. tonsurans*. This factor poses a dilemma in management, because where the disease is common and endemic, a regular source will always exist for new, severe, inflammatory infections in children. Therefore, addressing this issue by tackling individual cases without addressing the reservoir, albeit illogical, may ultimately be the most practical approach.

The diagnosis of tinea capitis is difficult to make clinically in mild cases because the main presenting signs are localized patches of hair loss with fine scaling. In some children, the hair loss is more diffuse. With the inflammatory forms, circumscribed patches of hair loss with erythema and pustulation also occur, and the whole area is raised into a boggy mass. The only way to confirm the diagnosis accurately is to take hair samples for culture and microscopy, which is not possible in many areas because they lack laboratory diagnostic facilities. One specific form of tinea capitis, favus, is clinically recognizable and distinct, because the scalp is covered with white plaques called *scutula*. The infection is chronic and can develop into permanent, scarring alopecia. Inhabitants of endemic areas often recognize favus as a distinct condition that causes chronic illness, and as a result, the uptake of consultation for treatment is higher.

Highly effective, topically applied treatments for tinea capitis are unavailable, and even though simple remedies such as benzoic acid compound (Whitfield's ointment) may lead to clinical improvements, relapse is almost universal. Nevertheless, the use of topical therapies may limit the spread of tinea capitis. Treatment depends on the use of oral therapies. The most widely available of these is griseofulvin, which is given to children in doses of 10 to 20 milligrams per kilogram daily for a minimum of six weeks. Noncontrolled studies show that a single dose of 1 gram of griseofulvin given under supervision can eradicate infection in more than 70 percent of individuals, but such regimens have not been adequately assessed under trial conditions to determine their effect on community levels of infection, nor are follow-up data available.

Recent years have seen the development of a number of effective, new, oral antifungals, including terbinafine, itraconazole, and fluconazole. Terbinafine is a highly active agent that is effective in the treatment of dermatophyte infections. It is given in doses of 62.5 milligrams for those under 10 kilograms, 125 milligrams for those weighing 10 to 40 kilograms, and 250 milligrams for those over 40 kilograms. Evidence indicates that it is effective after one week of therapy in *T. violaceum* and *T. tonsurans* infections, but the best responses are seen when it is used for four weeks. Unfortunately, at these doses it is less effective for *Microsporum* infections, although some data suggest that responses are significant if the doses are doubled. This drug is, therefore, difficult to administer in standardized protocols when the cause of infection is uncertain. Itraconazole is also effective, but no suitable pediatric formulation is available because it is marketed in a capsule form that is difficult to administer to young children. Fluconazole is also effective,

although comparative studies of its use are not available. All three drugs are costly, and a community-based program that uses them would be difficult to fund and implement.

The team found a total of 432 articles for the treatment of tinea capitis. Table 37.4 presents key references for the oral therapies, the mainstay of therapy. The effective treatments included topical therapies (benzoic acid, bifonazole, selenium sulfide, ketoconazole shampoo, and miconazole shampoo) as well as systemic agents (griseofulvin, terbinafine, itraconazole, fluconazole, and ketoconazole). The results of topical treatments appear inferior to those of oral therapy, although they have not been directly compared, and some of the topical agents were applied to prevent transmission rather than to treat infection.

Attempts at community control of tinea capitis have been devised but have not been monitored adequately. The methods have been based on surveillance through culture and treatment of all infected children. Culture-based diagnosis is difficult to implement regularly in developing countries. The treatment used for community therapy has been griseofulvin in conventional daily or large single doses, but those approaches have not been compared. In addition, control protocols usually advise treating carriers with topically applied agents such as selenium sulfide (which is relatively cheap) or a miconazole shampoo (which is moderately priced). In practice, some “carriers” are really patients with extremely localized and hard-to-detect infections, and such patients will not respond to topical treatment in the long term. A second problem is the absolute reliance on laboratory confirmation of cultures to direct treatment of carriers. Therefore, other strategies need to be evaluated, such as reducing the community load, perhaps by topical therapy or single-dose griseofulvin, to reduce the risk of spread. An alternative would be to continue with the existing practice of treating individual cases while recognizing that this process ignores the community reservoir.

Tinea Imbricata (Tokelau Ringworm). In many parts of the developing world, tinea imbricata is an exotic and unusual infection, with isolated foci occurring in remote areas of Brazil, India, Indonesia, Malaysia, Mexico, and the western Pacific. However, in some specific locations, it is common and endemic, reaching prevalence rates of more than 30 percent in some communities in the western Pacific. For example, extrapolating from a school survey in Goodenough Island, Papua New Guinea, Hay and others (1984) estimate that more than 7,000 people out of a population of about 20,000 were infected.

The disease presents in the form of widespread scaling, often arranged in concentric rings or with large sheets of desquamation. The infection may develop early in life and persist into old age without the development of effective immunity. Tinea imbricata often affects wide areas of the body, sparing only body folds and scalp skin. In those areas where it

is endemic, it can be a significant problem occupying much of the time of health aid post staff.

Individual treatments have depended on the antifungals described earlier, including griseofulvin. Terbinafine and itraconazole are highly effective, but their cost has constrained their use. As table 37.5 shows, the relapse rates after itraconazole are also higher than after terbinafine (Budimulja and others 1994). Topical agents such as benzoic acid compound (Whitfield’s ointment) are helpful, but are seldom curative and are difficult to apply over such large areas. Some patients may be treated with locally derived treatments, such as the sipoma paint used in Papua New Guinea, which contains salicylic acid, brilliant green, and kerosene. Traditional treatments have also been used, but never evaluated. The leaves of *Cassia alata*, for instance, are widely used in the western Pacific.

The team found studies of the use of griseofulvin, terbinafine, and itraconazole for tinea imbricata. Some studies did mention sipoma paint and *Cassia alata*, but no studies evaluating their efficacy have been performed. The team also found case reports supporting the use of griseofulvin.

Different treatments for use on a community basis need to be evaluated because the impact of this condition on local health services in areas of high prevalence is heavy in terms of both time and staff workload.

Tropical Ulcer

Tropical ulcer is a common condition found mainly in children and teenagers in well-defined tropical regions. It usually affects the lower limbs (Bulto, Maskel, and Fisseha 1993), causing the sudden appearance of regular and deep ulceration. It is mainly seen in Africa, India, and the western Pacific and in parts of Indonesia and the Philippines. The disease is caused by a combined infection of a number of different bacteria together with a fusiform bacterium, *Fusobacterium ulcerans*, and an as yet unidentified spirochete. The disease is associated with poor living conditions and exposure to water, particularly flood or stagnant water and mud. In endemic areas, it is a constant drain on resources. Morris and others’ (1989) study of aid posts in East Sepik province, Papua New Guinea, shows that management of tropical ulcer was occupying a third of the posts’ time and almost half their health care budgets.

The lesion usually starts with mild discomfort and overlying hyperpigmentation on the skin that progresses rapidly over a few days until the skin breaks down and sloughs, revealing an underlying ulcer. The lesion is often clean on first presentation and round with smooth edges. It generally starts on the lower leg or ankle, and in about 10 percent of cases, it progresses to become an irregular, enlarged, and chronic ulcer.

The condition heals well in most patients with simple cleansing and treatment with penicillin; however, early grafting

Table 37.4 Evidence of the Efficacy of Different Regimens for Tinea Capitis

Treatment, level of evidence, cost (manufacturer, formulation, average wholesale price)	Evidence	Number of people in study	Results	Comments

may be necessary if healing is delayed. Treatment, therefore, consists of early treatment with penicillin, a strategy that may also fit with a syndromic approach to ulceration, because it will also be effective for yaws. The alternative is oral metronidazole, but no evidence of the comparative efficacy of these two approaches is available.

In searching the literature for effective remedies for tropical ulcer, the team found little evidence. The team did find studies evaluating metronidazole and topical dressings, and several articles mentioned the efficacy of penicillin and split skin grafting, but no randomized controlled trials have been performed. A single case report supports the use of co-trimoxazole. The management strategy thereafter depends on keeping the wound clean to allow appropriate healing using local antisepsis and cleansing, such as potassium permanganate solution, chlorhexidine, or even saline, and protecting the area from further abrasion or secondary infection with sterile dressings. Clinical experience suggests that if this regimen is not followed, the risk of developing chronic leg ulceration is substantial.

No community strategies for preventing tropical ulcer are known, although the process of infection suggests that simple, hygienic measures to disinfect and clean the affected limb, perhaps modified from those used in lymphatic filariasis, might be effective as a simple preventive regimen. The possible use of vaccines has been substantially researched for the animal counterpart, sheep foot rot, which is caused by a similar combination of organisms.

HIV-Related Skin Diseases

A wide range of skin conditions may develop as a consequence of HIV infection, but most are beyond the scope of this chapter. They include conditions that are a significant drain on scarce resources. These include Kaposi's sarcoma and toxic epidermal necrolysis, a potentially life-threatening form of skin failure that is often drug induced and requires the level of care and attention that would be deployed for patients with severe burns.

The commonest skin-related complication of HIV, particularly in Africa, is the itchy papular eruption or papular pruritic eruption of HIV. It presents with fiercely itchy multiple papules on the face and upper trunk. It is of unknown etiology and responds only to symptomatic treatment—for instance, antipruritic preparations such as antihistamines—although simple topical preparations, such as calamine or menthol creams, may alleviate the itching. Recognizing this condition is important, because it is seen only in HIV/AIDS cases and is often mistakenly treated as acne. It does not respond to treatments for acne.

Pigmentary Disorders

The development of pigmentary change is an important source of concern in many communities (Taylor 1999). Disorders associated with pigmentary changes are common and range from hereditary defects such as albinism (Lookingbill,

Lookingbill, and Leppard 1995) to increased pigmentation, or *hyperpigmentation*, associated with inflammatory skin lesions such as acne. Albinism is a significant cause of life-threatening skin cancer in the developing world.

For many of these conditions, no effective remedies are available. For instance, hyperpigmentation secondary to inflammation cannot be removed effectively, although it may fade with time. Similarly, no effective cure exists for vitiligo, a common disease involving loss of pigment, although experimental treatments such as melanocyte grafting do produce localized repigmentation. Therefore, advising patients of the current comparative ineffectiveness of treatments for these conditions is important. Preventing the use of therapies that do not lead to effective outcomes should be an important part of the strategy for treating skin diseases.

Some forms of increased pigmentation, such as melasma, which is hyperpigmentation of the cheek and forehead areas and is seen mainly in women, respond to the application of hydroquinone derivatives. However, because such treatments are often misused, they would not be used at the community level and would be used only with advice from a trained practitioner. Depigmenting creams, lotions, and emulsions are widely available as cosmetic preparations in many local markets and shops, and in a study in Dakar, Senegal, more than 50 percent of women questioned stated that they were regularly using bleaching creams ranging from hydroquinones to corticosteroids (Mahé and others 2003). Hydroquinones are potentially damaging to the skin and with continuous use cause patchy increased pigmentation and scarring of the facial skin. Similarly, misuse of corticosteroids is associated with a range of secondary effects from skin thinning to increased infection rates. Warning people about the potential risks of depigmenting creams would be a useful health promotion strategy in many communities.

Skin depigmentation is also a feature of leprosy. Thus, teaching health care workers responsible for leprosy surveillance to recognize skin patterns is a practical strategy of great potential value in continuing progress toward eliminating this disease.

ECONOMIC ASSESSMENTS AND SKIN DISEASES IN DEVELOPING COUNTRIES

Apart from the studies mentioned here in relation to families' costs for treating community-acquired skin diseases in Mexico (Hay and others 1994) and costs to health posts of managing tropical ulcer in Papua New Guinea (Morris and others 1989), no published studies are available of the economic burden of skin disease. An extensive literature search did reveal some studies related to diseases that affect the skin but discussed elsewhere in this work (Buruli ulcer and

onchocercal skin disease), as well as a paper on the direct costs of treating scabies in Italy. These studies are shown in table 37.6.

Examples of drug costs (tables 37.2 to 37.4) for tinea capitis, scabies, and pyoderma can be estimated as follows:

- Treatment of a single case of scalp ringworm using griseofulvin purchased from two differently priced U.S. sources to achieve the published efficacy rates (table 37.4) with a conventional therapeutic course of six weeks, assuming a daily dose of 250 milligrams, would provide between 61 and 92 percent efficacy at a drug cost per individual of US\$29 or US\$53, depending on the drug source. Alternatively, a single supervised dose of 1 gram would cost US\$1.40 or US\$2.50. With supervision of treatment, the total cost per cure using daily treatment ranges from US\$35 to US\$88 per patient.
- Treatment of 100 people with scabies using sulfur ointment, assuming 500 grams per individual, would cost US\$58 or US\$0.58 per person. This regimen would provide a 71 percent cure rate at three months and a cost per cure of \$1.30 per patient.
- Treatment with povidone of an individual with pyoderma would cost US\$0.68, assuming that 400 milliliters would treat eight people. This regimen would provide a cure rate of 88 percent at three months and a cost per cure of US\$1.10 per patient.

These calculations have taken into account ideal community treatment conditions, where the recurrence rate is negligible. However, if such a community-based scheme is not effectively developed, more than 50 percent of those with scabies are likely to be reinfected. The figures are lower for tinea capitis (15 percent) and pyoderma (10 percent). Table 37.7 shows the costs of treating large populations.

Although little information is currently available, in particular about the effect of local pricing of medications on overall effective treatment costs, the studies cited in this chapter indicate that the financial burden of skin diseases within families may well be significant and that producing a series of robust analyses of the cost implications of both treatment and failure to provide adequate management strategies for these common conditions is critical.

The 1990 global burden of disease study estimated that the disability weighting associated with skin disease was at least 0.02. However, the disability weighting for severe scabies (25 percent of cases) and patients with ecthyma (10 percent of pyoderma cases) is 0.10. If we take skin cases with the lower disability estimates—for example, mild to moderate scabies and pyoderma—the cost per DALY gained would be about US\$1.00 to US\$1.50 (table 37.7). For tinea capitis, the cost per DALY gained using daily treatment would be considerably higher, US\$175 at the lower drug cost.

Table 37.6 Literature Review on the Economic Impact of Skin Diseases

The benefits of devising control measures for treatable skin disease are also affected by the high prevalence figures for skin diseases in low-income countries with total populations of between 40 million and 600 million affected, depending on variations in disease prevalence.

CURRENT STATUS OF COMMUNITY CONTROL MEASURES IN DERMATOLOGY

Despite the logic of developing community-focused services for dermatology, such services have seldom been achieved (Hay, Andersson, and Estrada 1991). Perhaps the best current example of a concerted, community-based approach is the Regional Training Center for Dermatology in Moshi, Tanzania, which focuses on developing a primary care skills base in African countries for the care of patients with skin and sexually transmitted diseases (Kopf 1993). The program has now trained more than 100 medical assistants and nurses, who were placed in 15 different countries at the primary care level and who, in many cases, play key roles in developing local health programs. A key issue is that action proportional to the severity of the problem is needed. For instance, one option would be to help nonspecialized health workers significantly improve their skills in managing common skin diseases. That option would present a new challenge for the teaching of dermatology. Along those lines, a recent initiative to effect change through a control and education program in Mali targeted at pyoderma, scabies, and tinea capitis is currently being evaluated. Early assessments indicate that the teaching methods have been effective in instilling recognition skills among primary care health workers. The effect on community levels of skin diseases is not yet known.

Skin diseases remain a low priority for many health authorities, despite the large demand for services. Addressing the potential for controlling skin problems by means of simple and effective public health measures should be a realistic target for alleviating a common and solvable source of ill health. An effective plan, team, and basic dermatological formulary can do much to improve matters (Estrada and others 2000). This chapter outlines some of the challenges for such programs and some of the deficiencies of current provision.

Chapter 38

Oral and Craniofacial Diseases and Disorders

Douglas Bratthall, Poul Erik Petersen, Jayanthi Ramanathan Stjernswärd, and L. Jackson Brown

The oral cavity is an essential part of the body and contributes to total health and well-being. Recent research indicates that poor oral health affects general health and that some systemic diseases can affect oral health. A variety of diseases involve the oral cavity; the two main oral diseases present worldwide and lead to tooth destruction or tooth loss:

- dental caries, the disease that leads to cavities in the teeth
- periodontal disease, which leads to loosening of teeth.

Both diseases are preventable, and strong efforts have been made to control them. Other diseases and conditions are much less prevalent, yet serious, and sometimes even life threatening: oral precancer and cancer, oral manifestations of HIV and AIDS, noma, developmental disorders, and fluorosis of teeth.

DENTAL CARIES

Dental caries develops by the localized dissolution of the tooth hard tissues, caused by acids that are produced by bacteria in the biofilms (dental plaque) on the teeth and eventually lead to “cavities.” The biofilm consists of microorganisms, including the highly cariogenic mutans streptococci, and a matrix made up mainly of extracellular polysaccharides. The destructive acids are produced when fermentable carbohydrates (sugars) reach these biofilms, each episode resulting in tooth damage (attack). If this process does not occur frequently, then the natural capacity of the body (through saliva) to remineralize will

prevent formation of a cavity. Thus, the main risk factors include presence of cariogenic biofilms and frequent consumption of fermentable carbohydrates. Exposure to fluorides in optimum concentrations reduces the risk, and normal saliva flow and saliva protective systems are also important to counteract the cariogenic factors.

Untreated caries can give rise to infection of the tooth pulp, which can spread to the supporting tissues and the jaws, culminating in advanced disease conditions that are often painful. For example, in Thailand, recent surveys of a sample of 12-year-old children revealed that 53 percent had suffered from pain or discomfort from teeth over the past year (Petersen and others 2001). The corresponding figures in China were 34 percent for 12-year-olds (Peng, Petersen, Fan, and others 1997) and 74 percent for adults (Petersen, Peng, and Tai 1997).

Tooth decay is a public health problem worldwide. According to the U.S. Surgeon General’s report (U.S. Public Health Service 2000), dental caries is the single most common chronic childhood disease in the United States. Epidemiological data for almost 200 countries are available in the World Health Organization (WHO) Country/Area Profile Programme (CAPP) oral health database (<http://www.whocollab.od.mah.se/index.html>) (see table 38.1 for examples). Caries prevalence of permanent teeth is expressed by the decayed, missing, and filled teeth (DMFT) index (calculated by counting the number of DMFT of individuals and taking the mean for the group examined). One indicator age group used for international comparisons is 12-year-old children. The WHO oral health goal was to achieve three DMFT or fewer among 12-year-olds

Table 38.1 Mean DMFT and SiC Index of 12-Year-Olds for Some Countries, by Ascending Order of DMFT

PAHO = Pan American Health Organization; SiC = Significant caries.

by 2000. According to the CAPP database, 70 percent of the countries had achieved three DMFT or fewer by 2001, representing 85 percent of the world population. Several developing economies, however, have reported a trend toward higher levels of dental caries.

A detailed analysis of caries data for many countries, both industrial and developing, shows skewed distributions of the disease—that is, a proportion of a population of children showing a high or very high number of caries and the rest showing a low number of caries or none. Expressing caries prevalence as mean DMFT may, therefore, not accurately describe the disease

level in populations with skewed distribution. The Significant Caries (SiC) Index was proposed to bring attention to those hidden high caries groups (Bratthall 2000). The SiC Index is calculated by simply taking the mean DMFT of the one-third of the group having the highest DMFT in a population (figure 38.1). Table 38.1 shows several countries having fewer than three mean DMFT but high SiC Index values, thus illustrating the hidden caries burden for children (Nishi and others 2002).

Dental caries is found not only in children and young adults but also in all age groups. The elderly, in particular those with exposed tooth root surfaces, constitute a special risk

Source: Adyatmaka and others 1998.

Note: The mean DMFT is 2.3. The Significant Caries Index is 5.4. Arrow indicates the proportion of individuals who are included in the calculation of the index. West Kalimantan is one of the most caries-affected provinces in Indonesia.

Figure 38.1 DMFT for 331 12-Year-Olds, West Kalimantan, Indonesia

population (Barnes 2000). A Swedish study reported DMFT values of 21.4 and 24.4 for 50- and 70-year-olds, respectively, indicating that nearly all teeth were affected in these age groups (Hugoson and others 1995). Thomson (2004), reviewing longitudinal studies of older adults (age 50+), found an incidence of root surface caries varying from 29 to 59 percent and concluded that older people are a caries-active group, experiencing new caries at a rate comparable to that of adolescents. With increasing numbers of people becoming 50 years of age or older in some developing countries, root surface caries may become a significant problem.

When we consider the global epidemiology of dental caries, the main patterns seem to be the following:

- Countries with low mean sugar consumption (less than 10 to 15 kilograms of sugar per person per year) generally have low mean caries prevalence.
- Countries with high mean sugar consumption (more than 20 to 25 kilograms of sugar per person per year) and without effective preventive programs generally have high mean caries prevalence.
- Countries with high mean sugar consumption (more than 20 to 25 kilograms of sugar per person per year) using effective preventive programs have been able to reduce the caries prevalence.

If we consider the prevalence of caries *within* a population, the main patterns seem to be as follows:

- Disadvantaged or poor population groups have higher dental caries experience than advantaged groups.

- Individuals with poor oral hygiene and frequent sugar intake are at increased risk.
- Individuals not exposed to fluorides—for example, from fluoridated water or toothpastes—are at increased risk of caries.
- Persons with individual risk factors, such as reduced saliva flow or exposed tooth root surfaces, or with certain general diseases are also at increased risk of caries.

Caries Intervention Programs

Since the discovery of the caries-preventive effect of fluorides in the 1930s, different forms of fluoride administration programs have been implemented, often with remarkable caries-reducing effects. Fluoride has been added to different vehicles, such as water, salt, toothpaste, and milk. Fluoride tablets and fluoride mouth rinsing have been used among young children and in schools, and more recently even among adults at high caries risk (Petersen 1989, 1990). For individual use, fluoride in high concentrations has been added to various forms of gels and varnishes to be applied on the teeth. Furthermore, fluoride in chewing gum is available in some countries. When a group of international experts on cariology were asked in a study to identify the main causes of the caries decline seen in several Western countries during recent decades, practically all the experts pointed to fluoride dentifrice as the most significant factor (Bratthall, Hänsel-Petersson, and Sundberg 1996).

According to WHO (1994), community water fluoridation is safe and cost-effective in preventing dental caries in every age group, benefiting all residents served by the community water regardless of their social or economic status (Burt 2002; Petersen and Lennon 2004; White, Antczak-Bouckoms, and Weinstein 1989). Examples of countries with fluoridated water supplies for significant parts of the populations are Argentina, Brazil, Brunei Darussalam, Canada, Chile, Ireland, New Zealand, the United Kingdom, and the United States. In many developing countries, lack of community water supplies makes water fluoridation impossible.

Effective fluoride toothpastes have been available for about 40 years (WHO 1994). They have been tested in numerous studies, in particular in school-based programs. The most commonly used concentrations are 1,000 or 1,500 parts per million (ppm). Because most studies have been conducted in developed countries, WHO launched a program testing a so-called “affordable fluoridated toothpaste” in developing countries. In the West Kalimantan Province of Indonesia, a supervised school-based toothbrushing program was implemented over a period of three years, resulting in a reduction of 12 to 40 percent of caries incidence in the study groups when compared to control groups (Adyatmaka and others 1998).

Domestic salt fluoridation is another method of automatic fluoridation. In the early 1950s, Switzerland and Austria

introduced this approach by offering their populations fluoridated salt for the table and for cooking. The fluoride concentration in the salt originally was 90 ppm and was later increased to 250 ppm. Fluoridated salt is now available in several countries in Europe and in South and Central America. A comparison of caries data for Jamaica in 1984 (before salt fluoridation) and 1995 (after salt fluoridation) showed a reduction of caries experience of 69 percent, 84 percent, and 87 percent among 15-, 12-, and 6-year-olds, respectively (Estupinan-Day and others 2001).

Milk fluoridation projects are being conducted in several countries, including Bulgaria, China, the Russian Federation, Thailand, and the United Kingdom. In Bulgaria, a milk fluoridation project resulted in a 79 percent lower DMFT in those children who had participated in the full five years of the program than in the control children (Pakhomov and others 1995).

Fluoride tablets and fluoride mouth-rinsing programs under supervision in schools have been implemented in several countries, including the Scandinavian countries, the United Kingdom, and the United States. The requirement that teachers and students be motivated has limited such approaches. In recent years, many national fluoride programs have been adjusted as the additional caries-reducing effects of topical applications with daily use of fluoridated toothpaste have been questioned (Petersen and Torres 1999).

Oral Health Education and Promotion Programs

The WHO Global Oral Health Programme has developed a manual for integration of oral health with school health programs (WHO 2003). In many industrial countries, school health education programs have included oral health, and researchers have shown that children's self-care capacity improved in regard to regular toothbrushing with the use of fluoridated toothpaste (Flanders 1987; Honkala, Kannas, and Rise 1990; Petersen and Torres 1999; Sogaard and Holst 1988; Wang and others 1998). Examples also exist from school oral health education in developing countries. Some programs have been organized within the context of the WHO Health Promoting Schools Initiative. In Madagascar, the evaluation of program outcomes has shown remarkably good results in reducing dental caries risk, improving self-care capacity of children and mothers, and introducing higher levels of dental knowledge and attitudes (Razanamihaja and Petersen 1999). Other successful examples are available from Tanzania (Petersen and others 2002; van Palenstein Helderman and others 1997), Zimbabwe (Frencken and others 2001), and Namibia (Priwe 1998).

In China, principles from the WHO Health Promoting Schools Initiative have been applied in certain provinces; positive effects of programs were obtained regarding health-related knowledge and behavior, but the clinical outcome measures were less evident (Petersen and others 2004; Tai and others

2001). The Chinese health authorities have emphasized preventive oral care and oral health education since the late 1980s. The nationwide mass campaign "Love Teeth Day" has been conducted annually since 1989, and the effective transmission of oral health messages to the public has shown improved oral health knowledge and behavior in children as well as in adults (Peng, Petersen, Tai, and others 1997).

In addition, various dental organizations (Cohen 1990) and private companies have developed and carried out successful oral health programs worldwide. For example, toothpaste manufacturers have donated toothpastes, toothbrushes, and educational material promoting oral health in several countries.

Effectiveness of the Oral Health Programs

In countries with systematic national oral disease prevention programs, the total cumulative effect of these programs is reflected in the epidemiological figures demonstrating caries decline (table 38.2) and in the growing proportions of caries-free individuals. However, singling out the effects of specific activities or methods of programs is difficult because several program components often operate simultaneously. For example, in industrial countries, practically all individuals use fluoridated toothpaste, and removing this preventive measure from a group of individuals just to evaluate the effect of another fluoride program would be unethical. In addition, other factors affect caries reduction, such as changing lifestyles, changing patterns of sugar consumption, and improving living conditions.

The current trend in clinical health care and public health is to base recommendations on evidence derived from systematic reviews of the literature and critical assessment of the quality of results (U.S. Public Health Service 2000). The office of the U.S. Surgeon General (U.S. Public Health Service 2000) and the Swedish Council on Technology Assessment in Health Care (SBU 2002) are examples of entities that have attempted to determine the effectiveness in public health of evidence-based approaches and technologies.

Oral Health in America, the U.S. Surgeon General's report (U.S. Public Health Service 2000), reviewed experiences from the administration of fluorides. Primarily based on U.S. studies, the report had these conclusions:

- Strong evidence exists supporting the effectiveness of water fluoridation in preventing crown and root caries in children and adults.
- Strong evidence exists of the effectiveness of the school-based fluoride supplement (tablets) program. The program, with motivated supervising personnel, such as teachers, is recommended for children at high risk for caries.
- Evidence supports the effectiveness of school-based fluoride (0.2 percent sodium fluoride) mouth-rinsing programs conducted before 1985 (before the introduction of fluoride

Note: Numbers in italics indicate that the country did not achieve the WHO global goal of fewer than three DMFT by 2000 but shows caries decline.

toothpastes) in preventing caries in children. The cost-effectiveness of this intervention is reduced with the current decline in prevalence of caries. It is recommended for use in high-risk children consistently over a period of time.

- Strong evidence supports the effectiveness of sealants in preventing pits and fissure caries. The report recommends that the programs be limited to high-risk children and high-risk teeth.
- Fluoride varnishes were not approved for use in the United States until 1994; hence, investigations are ongoing of the effectiveness of this intervention.

The Swedish Council on Technology Assessment in Health Care (SBU 2002) applied strict criteria of evidence of effectiveness; that is, the study had to be randomized and have a sample representing the total population. For permanent teeth, a three-year follow-up was necessary. The number of studies meeting all the criteria was not very high. Here are some conclusions of this review:

- Daily use of fluoridated toothpaste is an effective method to reduce caries in permanent teeth among children and adolescents. Daily, weekly, or biweekly fluoride mouth rinsing can reduce caries, but together with daily fluoride toothpaste use, the additional effects are not strong.
- Daily fluoride mouth rinsing can reduce root surface caries in the elderly, and professional application of fluoride varnish twice a year has a caries-reducing effect in permanent teeth among youth, as does the use of fluoridated toothpaste.
- Fissure sealants have a caries-reducing effect.

According to the SBU report, it was difficult to interpret the effect of programs aimed at reducing the intake of sugars or the effect of so-called sugar substitutes. Systematic evaluation of community preventive programs should be carried out in the future, particularly to help identify appropriate alternatives for developing countries.

ASPECTS OF TREATMENT OF CAVITIES AND OF CARIES DISEASE

One has to differentiate between treatment of cavities and treatment of the disease process resulting in cavities. The normal treatment of a tooth with a cavity is a filling or, if the cavity is large, a crown. Large cavities may involve “root-fillings” or even extraction of the tooth. A variety of materials are used globally: composites, amalgam, gold, porcelain, and others. Options for replacing extracted teeth include removable prostheses, fixed bridges, or implants. The more complex treatments are costly, and no country has been able to afford to introduce systems in which all dental costs are covered by

public funds. Moreover, a filling does not affect the disease process causing the cavities. Treatment must be directed against the causative factors (described earlier). For the individual case, several options are available in addition to the various fluoride programs mentioned: dietary counseling, sugar substitutes, antimicrobial agents to reduce plaque and specific bacteria, and the use of saliva-stimulating products.

In many developing countries, the lack of dental manpower means that carious teeth remain untreated. The ratio of dentists to population is particularly unfavorable in the African region compared with Western European countries. For instance, according to CAPP, the ratio is 1 to 1.2 million in Ethiopia, 1 to 225,000 in Mali, and 1 to 166,000 in Zambia, against about 1 to 1,000 in Scandinavian countries and 1 to 2,100 in the United Kingdom (see <http://www.whocollab.od.mah.se/index.html>). In India, the ratio is 1 to 27,000 in the urban areas but 1 to 300,000 in the rural areas (Shah 2001). Such ratios mean that neither dental caries disease nor the cavities will receive proper attention.

After taking into consideration the high costs for dental treatment and the lack of dentists, atraumatic restorative treatment (ART) was introduced. This approach requires only hand instruments rather than sophisticated electric dental drills, and trained dental auxiliaries can deliver ART. The public dental health services in South Africa adopted the approach as an appropriate and economic means of providing basic restorative care in certain communities. A randomized clinical trial conducted in Tanzania showed no statistically significant differences between the retention of occlusal amalgam (74 percent) and ART occlusal restorations (67 percent) after a six-year follow-up (1992–98) (Mandari, Frencken, and Van't Hof 2003). A potentially affordable treatment procedure that could prevent untreated carious teeth from being extracted, ART may have relevance to some middle-income countries, although the method is not realistic for most low-income countries, where sustainability of such programs would be low.

PERIODONTAL DISEASES: CHRONIC GINGIVITIS AND CHRONIC PERIODONTITIS

Gingivitis, the inflammation of gum tissue caused by bacteria accumulating in the plaque along the gingival margin, precedes chronic periodontitis. The more destructive form of periodontal disease, which breaks down the supporting tissues of the teeth, progressively leading to loosening of teeth and tooth loss, affects 10 to 15 percent of most adult populations (Papapanou 1999). Cigarette smoking and diabetes mellitus (with poorly controlled diabetes) are two major risk factors associated with periodontal disease and appear markedly to affect the initiation and progression of the disease (Genco 1996; Papapanou 1999).

In recent years there has been a growing awareness of the association between some systemic diseases and oral disease, especially periodontal diseases. For example, a national study in the United States found that the prevalence of diabetes mellitus in patients with periodontitis was significantly greater (twofold) than in nonperiodontal patients (Soskolne and Klinger 2001). Periodontal disease may be considered one of the complications of diabetes. Effective control of periodontal infection in diabetics appears to reduce the levels of advanced glycogen end-products in the serum.

Proper oral hygiene practices can prevent both gingivitis and advanced periodontal disease. All intervention programs leading to improved oral hygiene are instrumental in the control of periodontal disease and will reduce risk of future tooth loss. The school-based oral health educational programs previously discussed are effective in preventing gingivitis, but no community-based intervention program addresses periodontal disease, especially among adults. Tobacco cessation programs are also important in the prevention of periodontal diseases. Treatment of periodontal diseases consists of plaque removal, scaling, and sometimes surgery, plus motivation and instruction in oral hygiene. Dental hygienists can perform parts of the treatment program.

ORAL PRECANCER AND CANCER

The most frequent form of oral precancerous lesion, leukoplakia, appears as a white patch that cannot be rubbed off, typically in the buccal mucosa, lateral borders of the tongue, and floor of the mouth. The prevalence of leukoplakia among those 15 years old and above ranged from 1.1 percent in Cambodia, to 1.7 percent in Myanmar, to 3.6 percent in Sweden (Axell 1976; Ikeda and others 1995). Malignant transformation varies in different populations; nearly 5 percent of lesions are found to be malignant at first biopsy, and 5 percent develop into malignancy at a later stage. Erythroplakias appear as red patches and are less common but have a higher tendency (90 percent or more) than leukoplakias to transform into malignancies (Sudbo and Reith 2003).

Oral cancers affect about 300,000 people worldwide annually (Ferlay and others 2001) and often develop from oral precancerous lesions (Sudbo and Reith 2003). Early detection of oral precancerous lesions, notably oral leukoplakia and erythroplakia, could easily prevent the development of the disfiguring disease oral cancer and premature death.

Tobacco use in any form (smoking or chewing) and excessive alcohol consumption remain the primary risk factors in the development of these precancerous lesions (“Early Diagnosis and Prevention of Oral Cancer and Precancer” 1995; Reichart 2001). Factors such as local irritation, *Candida albicans* infection, and nutritional deficiencies are also associated with the presence of leukoplakia.

Screening populations and routine examination in dental and medical clinics for oral precancer and early cancer lesions would reduce the mortality, morbidity, and cost of treatment associated with oral cancers. Not all oral premalignancies show malignant transformation, and detection of these oral lesions by biopsies are straightforward, not requiring sophisticated equipment. Tobacco cessation programs aimed at younger and older age groups and control of excessive alcohol intake are definitely beneficial in the prevention of oral cancer.

ORAL MANIFESTATIONS OF HIV/AIDS

The scarce epidemiological data available on oral manifestations of HIV in developing countries are difficult to interpret because these studies are not standardized (Holmes and Stephan 2002). In the study groups, the prevalence of oral lesions in Africa ranged from 15 percent to more than 90 percent of infected individuals; in India the prevalence was 72 percent; and in Thailand it was 82 percent. Reviews are available on the different studies performed on oral manifestations of HIV and AIDS (Naidoo and Chikte 1999; Patton and others 2002).

Candida infections, oral hairy leukoplakia, oral ulcers, and Kaposi’s sarcoma are some of the common oral manifestations of HIV and AIDS. Notably, Kaposi’s sarcomas were never detected in the Asian populations studied in India, Singapore, and Thailand but were seen in South African, Zambian, and Zimbabwean studies (Arendorf and others 1998; Hodgson 1997; Holmes and Stephan 2002; Lim and others 2001; Nittayananta and Chungpanich 1997; Ranganathan and others 2000). The presence of oral candidiasis and hairy leukoplakia alone or at the same time in an apparently healthy individual could be an early indicator of the undetected HIV infection progressing to AIDS. Those signs may be used as indicators during clinical examinations in developing countries where technology for laboratory tests is not available or is too expensive (Greenspan and Greenspan 2002; Holmes and Stephan 2002).

NOMA (CANCERUM ORIS)

Noma usually begins as a small ulcer of the gingiva and develops into a rapidly spreading gangrenous condition of the oral and facial tissues. Seen mainly in debilitated and malnourished children, it is disfiguring and deadly. The condition is reported in developing countries in several regions of the world, particularly in Sub-Saharan Africa (Enwonwu, Falkler, and Idigbe 2000; Naidoo and Chikte 2000; Petersen 2003). Noma disappeared from the industrial world in the 20th century except

during World War II. In contrast, risk factors such as poverty, poor hygiene, and malnutrition, eventually in combination with infectious diseases such as HIV and AIDS, may have recently increased the prevalence of this disease in Sub-Saharan Africa (Enwonwu 1995; Naidoo and Chikte 2000). Most important, 90 percent of infected children die without having received any care.

Although the specific etiologic factors for noma are not known, poverty has been identified as the single most important risk indicator. Accordingly, improving the overall socioeconomic conditions can prevent noma. Public health approaches such as providing a high-protein diet, clean water, and sanitation and preventing communicable diseases such as diphtheria, dysentery, and tuberculosis would be needed for effective prevention of noma in Africa. Prognosis of noma is considerably better with timely administration of antibiotics.

DEVELOPMENTAL DISORDERS

Developmental disorders involve teeth and the craniofacial structures. A few of these disorders are congenital diseases of the enamel or dentin; problems related to the number, size, or shape of teeth; and craniofacial birth defects, such as cleft lip and palate (CL/P). Among the most common congenital malformations seen in humans, cardiovascular malformation is ranked as the first and CL/P as the second. Unilateral CL/P occurs six times more frequently than the bilateral form. Females are more prone to get cleft palates, whereas cleft lip or CL/P is most common in males (U.S. Public Health Service 2000).

The incidence of CL/P differs from 0.18 to 3.74 per 1,000 live births, the highest incidence being seen in Native Americans at 3.74 per 1,000, closely followed by the Japanese at 3.36 per 1,000 live births. A fairly uniform incidence of 1 per 600 to 700 live births is reported among Europeans. Overall, the incidence rates appear high among Asians (0.82 to 3.36 per 1,000 live births), intermediate in Caucasians (0.9 to 2.69 per 1,000 live births), and often very low in black Africans (0.18 to 1.67 per 1,000 live births) (Hewson and McNamara 2000; Vanderas 1987; Wantia and Rettinger 2002).

The causes of CL/P are complex, involving multiple genetic and environmental risk factors. Not all cases of CL/P are inherited. A number of risk factors, such as folic acid deficiencies, maternal smoking, and maternal age, have been implicated in the formation of clefts (Wantia and Rettinger 2002).

Advanced surgery, specific prosthetic appliances, and orthodontic treatment can improve the quality of life for those born with clefts. However, such treatment is not accessible to children of several developing countries. Tobacco cessation programs aimed at pregnant mothers are essential in the prevention of CL/P.

FLUOROSIS OF TEETH

Fluorosis of teeth develops during formation of teeth when children are young. Drinking water having more than 1.5 ppm of fluoride can give rise to enamel defects and discoloration of teeth, leading to endemic fluorosis in the population. These effects may vary from mild to severe. For example, in the Great Rift Valley area of East Africa, the ground water has high levels of fluoride, leading to high rates of dental fluorosis—nearly 90 percent in some parts of Kenya (Chibole 1987). Some individuals in developed countries can acquire fluorosis of teeth as a result of the widespread use of different forms of fluorides in the prevention of caries, though the degree of fluorosis often is mild compared with endemic fluorosis.

Defluoridation of the central water supplies is possible when naturally occurring fluoride is excessive in the drinking water. However, most developing countries do not have central water distribution systems, and the cost of defluoridation equipment and its maintenance can be high. WHO encourages effective and inexpensive methods that are useful for individual households or community defluoridation of drinking water (WHO 1994). Such methods exist, but a number of operational problems have been identified, requiring further initiatives in this field (Kloos and Haimanot 1999).

COMMON-RISK-FACTOR INTERVENTION PROGRAMS

New research is pointing to associations between chronic oral infections—particularly periodontitis—and heart and lung diseases, stroke, osteoporosis, low birthweight, and premature births in addition to diabetes. Such findings strengthen WHO health promotion strategies that are based on the common-risk-factor approach, which controls essential risk factors that contribute to a large number of chronic diseases (Petersen 2003). Risk behaviors such as smoking; alcohol; diets rich in fats and sugars and low in fiber, fruit, and vegetables; stress; poor hygiene; and sedentary lifestyle are factors leading to such major chronic diseases as cardiovascular diseases, cancers, diabetes, obesity, osteoporosis, dental caries, and periodontal disease. These principal risk factors for major chronic diseases are often seen to cluster in the same individuals.

The WHO Global Oral Health Programme recommends the common-risk-factors approach (Petersen 2003), which implies development of integral activities in health promotion and disease prevention, involving health education, community empowerment, and legislative policy development. For example, such programs could aim at reducing the caries levels among preschool children and simultaneously improving general health. Promoting the reduction of sugar consumption would improve not only oral health but also general health

Table 38.3 Prevention Strategies for Oral Health

Disease or condition	Causes	Actions needed and methods
Dental caries	High or frequent sugar consumption, plaque present, highly cariogenic microorganisms, nonuse of fluorides, reduced saliva flow, systemic diseases, and other individual risk factors	Targeted actions against causative factors on community and individual levels Health education toward self-care capacity, fluoride programs, sugar restriction, actions based on risk assessment of individuals and groups
Periodontal diseases	Plaque present, pathogenic bacteria, influence of systemic diseases, tobacco use	Improved oral hygiene, professional cleaning, antibiotics, identification and treatment of systemic diseases Elimination of pockets if present and removal of local dental irritants, such as rough fillings Tobacco cessation
Oral precancer and cancer	Tobacco and alcohol use; see chapter 29	Tobacco cessation; see chapter 29
Oral manifestations of HIV/AIDS	See chapter 18	See chapter 18. Special oral care
Noma (cancrum oris)	Probably bacterial in connection with severe malnourishment	Antibiotics together with nutritional support; surgery sometimes necessary
Developmental disorders	Various genetic or environmental causes such as tobacco use	Tobacco cessation programs aimed at pregnant mothers
Fluorosis of teeth	Too high concentration of fluoride in drinking waters or from other sources	Identification of water sources and reduction of fluoride or recommendation of other water sources

Source: Authors; partly based on Bratthall and Barnes 1993.

Note: This table is by no means complete. Many other oral diseases or conditions are important and need attention. The listed ones are of special relevance for developing countries.

through better quality of children's diet. Some prevention strategies for oral health, suitable for developing countries are outlined in table 38.3.

RESEARCH AND FUTURE ACTIONS

Several promising actions against factors causing the two major oral diseases, caries and periodontal disease, are ongoing: attempts to control the formation of the biofilm with its microflora are of high priority. One research line is to identify pathogenic bacteria and try to replace them with genetically modified, less pathogenic bacteria or to eradicate them by antibiotics or antiseptics. Preventing dental caries by a vaccine is not a new idea, and efforts continue. Among other ideas is the use of plantibodies (plant-derived therapeutic antibodies) or genetically modified bacteria, releasing components targeting pathogens. Functional foods, which include various elements in food, may be another future option to control oral diseases. Although pilot or small-scale studies seem promising, it will be several years before such methods can possibly be of use in populations because large clinical trials have not even started.

Saliva is believed to be usable as a diagnostic tool, providing noninvasive assessment of a number of oral and systemic diseases. Devices are being designed to identify in saliva various bacteria and their virulence factors, drugs, metabolic products,

hormones, biomarkers for oral cancer, inflammatory mediators, and more. Future developments may result in other affordable and effective devices.

Continuous attempts are being made to assess the sociobehavioral factors in oral health and the information on risk factors. Caries risk assessment models are tested also for the individual cases. Through present knowledge, individuals in need of targeted actions can be identified. Another strong trend is to use evidence-based reviews. This type of research is, of course, not restricted to oral health. Several reviews have already been done, and a frequent conclusion is that the number of randomized clinical trials is limited, in particular for common clinical procedures. This trend will change as the quality of future oral health research improves, but not all research problems can be solved by such studies. Community-based participatory research is another approach that may be used to improve oral health studies (O'Fallon and Deary 2002).

Within the management of dental diseases—in particular, caries—is the “minimally invasive dentistry” approach, which promotes the concept that large restorations (crowns, bridges) are not as necessary as believed. Risk assessment, preventive measures, and improved dental materials with good adhesion capacity are some of the several components in this approach.

Research in transfer of knowledge using the Internet or other electronic media is another strongly expanding area, from which developing countries should be able to benefit.

COST-EFFECTIVENESS OF ORAL HEALTH CARE

Using the evidence available, the U.S. Surgeon General's report (U.S. Public Health Service 2000) and the report of the Swedish Council on Technology Assessment in Health Care (SBU 2002; see also Kallestål and others 2003) have attempted to determine the cost-effectiveness of oral health intervention programs from developed countries.

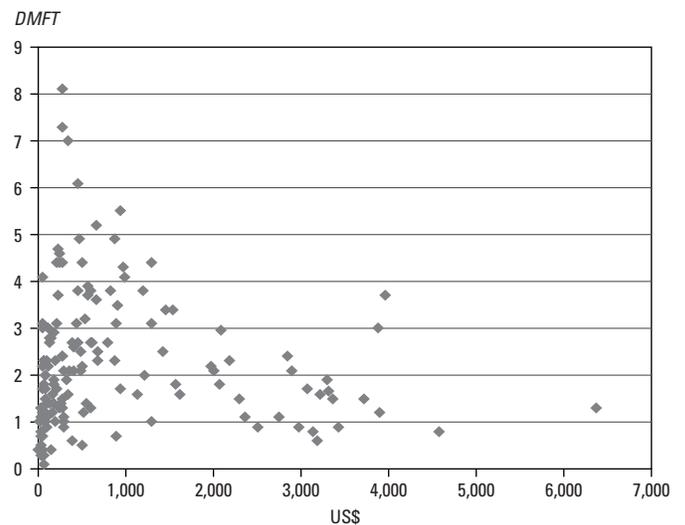

Among the findings in the U.S. report were the following:

- Water fluoridation costs about a dollar per person per year for water serving most individuals in the United States. Community water fluoridation is believed to be an effective and cost-effective caries preventive method.
- Economic analyses of community dental sealant programs suggest that they are cost-effective and may even provide cost savings when used in high-risk populations.

The Swedish report (SBU 2002), reviewing original studies on economic evaluation of caries prevention (a total of 17 selected from 1966 to 2003 MEDLINE and manual Internet searches), commented that no conclusion could be drawn owing to the low evidence values and contradictory results. This comment prompted the group to present its own calculation for cost-effectiveness based on Swedish caries prevalence and charges used in Swedish dental care. The group found that the cost-effectiveness for fluoridated toothpaste is extremely good (cost per prevented DMFT very low), which, of course, is not surprising, given the significant caries-reducing results in combination with low cost for society.

No clear correlation appears to exist between caries experience and health care investment for individual countries. Some countries with the lowest health care expenditures have values for caries experience (DMFT) that are similar to or even lower than those countries having the highest expenditures on health (figure 38.2). Those low-income countries often have low per capita sugar consumption and, therefore, do not need to install expensive measures for treatment or prevention.

It may seem surprising that so few studies are available regarding the cost-effectiveness of caries prevention, or of any other oral disease. In a critical review article, Schwarz (1998) analyzed the issue. He wrote, "Several decades after considerable improvements in the oral disease situation were documented in Scandinavia, doubts are still expressed about whether preventive measures are cost-effective." In addition, he recommended that four elements be considered when a preventive effect was evaluated: the definition of prevention, the practical perception of effective prevention, the appropriateness of traditional cost-effectiveness analysis, and the time factor. He pointed out that "caries prevention is not uniformly defined by the profession, that dental research is casting doubt

Source: For health expenditure: <http://www.who.int/en/>; for DMFT: <http://www.whocollab.od.mah.se/index.html>, both for June 2003.

Note: Original data for health expenditures were in international dollars and were converted to U.S. dollars using the exchange rate of US\$1 = 0.70681 (period average June 2003). Because the exchange rate varies over time, the data should be taken as approximate values.

Figure 38.2 DMFT as Related to Health Care Expenditure per Capita for 12-Year-Olds in 149 Countries

on the effectiveness of traditionally accepted preventive measures, that political pressures on health care are motivated by economic pressures." Finally, he stated that traditional cost-benefit and cost-effectiveness analyses have not been able to help the decision makers choose wisely and that the time perspective for the real effects of prevention lies beyond the interests of decision makers.

However, without proper prevention, the alternative strategy is restorative dentistry—that is, to make fillings, crowns, and dentures. Is this a feasible alternative for developing countries? Yee and Sheiham (2003) give some examples: In Nepal, a simple amalgam filling would cost about US\$4, which does not include the many additional expenses for impoverished rural families, who may have to travel by bus or walk for a day or two to get to the clinic. The total expenses incurred, including dental fees, meals, and lodging but not including lost wages, would amount to US\$12, an enormous sum considering the average Nepalese's earning of US\$0.75 per day, and it is enough to buy food for a month. Yee and Sheiham conclude that treating caries with the traditional method of restorative dentistry is beyond the financial capabilities of most low-income nations because three-quarters of these countries do not even have sufficient resources to finance an essential package of health care services for their children. Yee and Sheiham (2003) estimate that treating dental caries by the traditional amalgam restorative dentistry in the permanent dentition of the child population would cost about US\$2,000 for 1,000 children of mixed ages from 6 to 18 years, which would require financial

resources beyond the capabilities of low-income nations. Hence, they propose a public health and health promotion approach to reduce caries burden instead of the restorative approach.

Although several studies evaluating the effectiveness of intervention and oral health promotion programs in developing countries are becoming available (Estupinan-Day and others 2001; Pakhomov and others 1995; Petersen and others 2004), a definite need exists for further cost-effectiveness analysis on such programs, which should be addressed in the future. It would also be useful if studies were commenced on intervention programs using the common-risk approach suggested by WHO (Petersen 2003).

CONCLUSIONS

Dental caries and periodontal diseases are the most known oral diseases, but other conditions can strongly and negatively influence the quality of life. Effective programs to reduce the burden of oral diseases—in particular, caries—are available in principle, but to run these programs in developing countries, new approaches are needed. The WHO strategy of identifying common risk factors seems promising for health promotion. In broad terms, the most important challenges for oral health in the 21st century relate to the transfer of knowledge and experiences in preventive oral care to the poor and disadvantaged population groups in both developing and developed countries.

ACKNOWLEDGMENTS

We acknowledge with great appreciation comments and suggestions from Dr. Lois Cohen, Dr. Kevin Hardwick, Dr. Jeanne C. Sinkford, and Thomas Wall. Sir George Alleyne, our editor, is to be congratulated for his constructive ideas and patience.

Chapter 39

Unintentional Injuries

Robyn Norton, Adnan A. Hyder, David Bishai, and Margie Peden

This chapter examines the issue of unintentional injuries and focuses on a selected number of cause-specific unintentional injuries. Injuries have traditionally been defined as damage to a person caused by an acute transfer of energy (mechanical, thermal, electrical, chemical, or radiation) or by the sudden absence of heat or oxygen. Unintentional injuries consist of that subset of injuries for which there is no evidence of pre-determined intent. The cause-specific unintentional injuries examined here include those that the World Health Organization (WHO) routinely analyzes and publishes data on and that individually account for the greatest unintentional injury burden in terms of mortality and disability-adjusted life years (DALYs). These include road traffic injuries (RTIs), poisonings, falls, burns, and drowning (figure 39.1).

BURDEN AND CAUSES OF UNINTENTIONAL INJURIES

This section provides a brief outline of the burden of unintentional injuries and then reviews the available evidence about known and potential causes of such injuries.

Burden of Unintentional Injuries

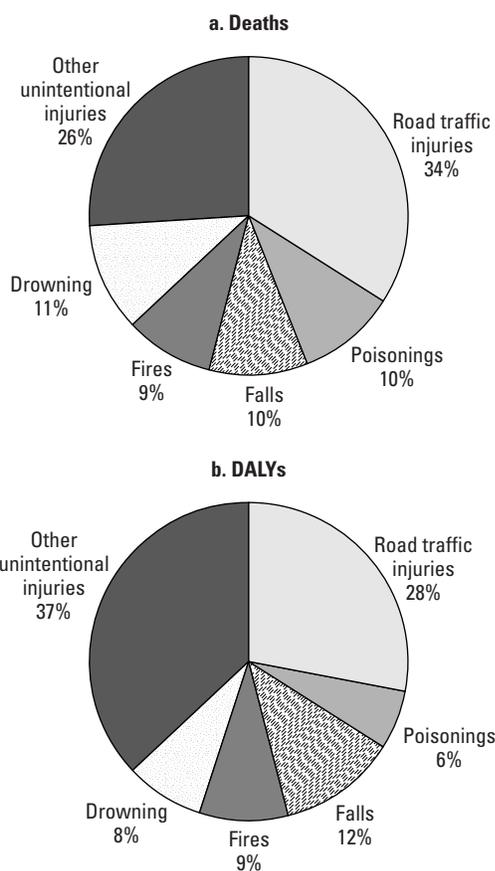

Worldwide, unintentional injuries accounted for more than 3.5 million deaths in 2001, or about 6 percent of all deaths and 66 percent of all injury deaths. Unintentional injuries were also responsible for more than 113 million DALYs in 2001, or about 8 percent of all DALYs and some 70 percent of all injury DALYs. More than 90 percent of unintentional injury deaths occurred in low- and middle-income countries (LMICs),

accounting for around 7 percent of all deaths in those countries. Similarly, more than 90 percent of DALYs that were attributed to unintentional injuries occurred in LMICs, accounting for about 8 percent of all DALYs in those countries. Injury death rates per 100,000 population were higher in LMICs (62 per 100,000) than globally (57 per 100,000).

Males accounted for almost two-thirds of the deaths attributed to unintentional injuries in LMICs in 2001, with rates of both injury death and DALY losses higher among males than females (table 39.1). Compared with other age groups, young people age 15 to 29 accounted for the largest proportion of deaths from unintentional injuries in LMICs (figure 39.2).

RTIs accounted for the greatest burden of deaths from unintentional injuries in LMICs in 2001, or about 34 percent of the total burden, and the greatest burden of DALYs from unintentional injuries in LMICs in 2001, accounting for 28 percent of the burden (figure 39.1). Whereas young people age 15 to 29 years accounted for the highest proportion of all unintentional injuries, those age 45 to 59 accounted for the highest proportion of injuries from poisonings, while those age 70 to 79 accounted for the highest proportion of injuries from falls (figure 39.2).

Economic Burden of Unintentional Injuries. Estimates of the burden of unintentional injuries as measured in terms of economic costs are almost nonexistent. The best estimates available are for RTIs. Using road crash costs from 21 developed and developing countries, the Transport Research Laboratory Ltd. finds that the average annual cost of road crashes was equivalent to about 1.0 percent of gross national product in developing countries, 1.5 percent in transition countries, and 2.0 percent in highly motorized countries. The annual burden

Figure 39.2 Distribution of Unintentional Injuries by Type of Injury and Age Group, LMICs, 2001

of road crash costs is about US\$518 billion globally and about US\$65 billion in LMICs, exceeding the total annual amount these countries receive in development assistance (Jacobs, Aeron-Thomas, and Astrop 2000).

Causes of Unintentional Injuries in LMICs

As in the case of most diseases, unintentional injuries are caused by multiple factors. The traditional epidemiological paradigm of host, vector, and environmental factors that in combination contribute to the incidence of disease has been adapted and applied in determining the causes of unintentional injury. However, this paradigm has been extended to consider each factor in relation to the time of the injury—that is, factors operating before, during, and after the injury that might be associated with both its incidence and its severity (Haddon 1968). Although the matrix, called the *Haddon matrix*, was initially developed to address the problem of RTIs only, it provides a comprehensive framework in which researchers can consider the multitude of factors that may play a role in the causal injury pathway, as outlined in table 39.2.

In the past two decades, the evidence base for the identification of risk factors for unintentional injuries in high-income countries (HICs) has increased dramatically as the number of injury researchers and research institutions has increased. However, because of the paucity of injury researchers and research institutions in LMICs, the evidence base for the identification of risk factors for unintentional injuries in these countries is growing more slowly.

Although knowledge about risk factors for injuries in HICs may also be relevant for LMICs, the material presented in the following section focuses on information that has been obtained from studies in LMICs. However, the section also

considers the extent to which information obtained from studies conducted in HICs may be relevant.

Risk Factors for Road Traffic Injuries. The increasing volume of traffic is one of the main factors contributing to the increase in RTIs in LMICs. Motorization rates rise with income (Kopits and Cropper 2005), and a number of LMICs experiencing growth have seen a corresponding increase in the number of motor vehicles (Ghaffar and others 1999). In some LMICs, this growth has been led by an increase in motorized two-wheeled vehicles, one of the least safe forms of travel, which has resulted in concurrent increases in related injuries (Zhang and others 2004).

The rapid growth in motor vehicles in many LMICs has not been accompanied by improvements in facilities for these road users or by facilities that respond to the continued predominance of nonmotorized traffic (Khayesi 2003). Many of the technical aspects of planning, highway design, traffic engineering, and traffic management that are the hallmarks of transportation systems in many HICs are absent in LMICs, which need to plan for a level of heterogeneity in traffic that HICs do not encounter (Tiwari 2000).

Studies undertaken primarily in HICs show a strong relationship between the increase in vehicle speeds and increased risk of crash and injury, both for motor vehicle occupants and for vulnerable road users, particularly pedestrians (European Road Safety Action Program 2003). This relationship is likely to be true for LMICs, and indeed, data obtained from routinely collected police reports in a number of LMICs show that speed is listed as the leading cause of road traffic crashes, accounting for up to 50 percent of all crashes (Afukaar 2003; Odero, Khayesi, and Heda 2003; Wang and others 2003).

Several case-control studies in HICs have confirmed the role of alcohol in the increasing risk of road crashes (Peden and

Table 39.2 The Haddon Matrix as Applied to Road Traffic Injuries

Phase	Nature of intervention	Factors		
		Human	Vehicles and equipment	Environment
Precrash	Crash prevention	Information	Roadworthiness	Road design
		Attitudes	Lighting	Road layout
		Impairment	Braking	Speed limits
		Police enforcement	Handling	Pedestrian facilities
			Speed management	
Crash	Injury prevention during crash	Use of restraints	Occupant restraints	Forgiving roadside (for example, crash barriers)
		Impairment	Other safety devices	
			Crash-protective design	
Postcrash	Life sustaining	First-aid skill	Ease of access	Rescue facilities
		Access to medical personnel	Fire risk	Congestion

others 2004). Studies conducted in LMICs showed that drivers had consumed alcohol in 33 to 69 percent of crashes in which drivers were fatally injured and in 8 to 29 percent of crashes in which drivers were not fatally injured (Odero and Zwi 1995). Alcohol consumption by pedestrians also increases their risk of injuries in HICs; moreover, in at least some LMICs, more than 50 percent of fatally injured pedestrians had consumed alcohol (Peden and others 1996).

Other factors that increase the risks of road crashes in HICs include fatigue, use of hand-held mobile telephones, and inadequate visibility of vulnerable road users (Peden and others 2004), all of which are equally likely to increase risks in LMICs. Indeed, a recent case-control study from China shows that the risks of a crash doubled with chronic sleepiness on the part of the driver (G. F. Liu and others 2003), and surveys of commercial and public road transport in a number of African countries have shown that drivers often work long hours and go to work exhausted (Mock, Amegashi, and Darteh 1999; Nafukho and Khayesi 2002). Studies in Malaysia clearly show that motorcyclists who use daytime running lights have a crash risk about 10 to 29 percent lower than those who do not because of their greater visibility (Radin Umar, Mackay, and Hills 1996).

Road- and vehicle-related factors may also increase the risk of crash involvement. Specific factors related to road planning include traffic passing through residential areas, conflicts between pedestrians and vehicles, schools located on busy roads, lack of median barriers to prevent dangerous passing on two-lane roads, and lack of barriers to prevent pedestrian access onto high-speed roads, although few studies have specifically examined the risks associated with those factors (Ross and others 1991).

Although the severity of crash injuries is related to in-vehicle crash protection, evidence indicates that many engineering advances found in vehicles in HICs are not present in vehicles in LMICs (Odero, Garner, and Zwi 1997). Perhaps one of the most important factors contributing to injury severity relates to crash protection for vulnerable road users. However, few HICs, let alone LMICs, require the fronts of cars or buses to be designed in a way that would protect vulnerable road users (Mohan 2002).

A significant risk factor for increased severity of injuries of users of motorized two-wheeled vehicles is riders' failure to use motorcycle helmets (B. Liu and others 2004). Studies in a number of Asian countries have shown that failure to use helmets, use of nonstandard helmets, and use of improperly secured helmets are not uncommon, even in countries with mandatory helmet laws (Conrad and others 1996; Kulanthayan and others 2000). Failure to wear helmets is also a risk factor for increased injury severity among bicyclists (Attewell, Glase, and McFadden 2001). Although the failure to use seat belts is a significant risk factor associated with injury severity among vehicle occupants, many LMICs have no requirements for seat belts to be fitted or used (Peden and others 2004).

Studies in HICs suggest that roadside hazards, such as trees, poles, and road signs, may contribute to between 18 and 42 percent of road crashes and increase injury severity (Kloeden and others 1998), although the extent to which this is also true in LMICs has not been determined.

Risk Factors for Poisonings. The literature on poisonings in LMICs includes comprehensive information about intentional poisonings; significant information about occupation-related poisonings, especially pesticide poisonings; and a growing body of information about lead poisoning. Each of these types of poisoning is covered elsewhere in this book. This chapter focuses on risk factors for other types of poisoning in LMICs, and, in particular, focuses on risk factors for poisonings in young children.

The literature's focus on risk factors for childhood poisoning probably reflects the fact that child poisoning victims are seen more often than adults in most hospital settings (Ellis and others 1994; Nhachi and Kasilo 1992). This fact is in stark contrast to the data presented earlier, which clearly show that middle-aged individuals sustain the vast majority of deaths and DALYs from poisonings in LMICs. Those numbers no doubt reflect the importance of work-related poisonings.

Young males consistently appear to be at higher risk of poisonings than females (Ellis and others 1994; Fernando and Fernando 1997; Soori 2001). The most common agents involved in childhood poisonings are paraffin (or kerosene) and other household chemicals; pesticides; and various plants or animals, including snakes (Fernando and Fernando 1997).

Several case-control studies in LMICs indicate the importance of a number of sociodemographic risk factors, including young parents, residential mobility, and limited adult supervision of children (Azizi, Zulkifli, and Kasim 1993; Soori 2001). The studies also suggest that previous poisoning may be a risk factor (Soori 2001). Another important factor seems to be storage, including the number of storage containers used in the residence; the use of nonstandard containers for storage (for example, beverage bottles for storing kerosene); and the storage of poisons at ground level (Azizi, Zulkifli, and Kasim 1993; Chatsantiprapa, Chokkanapitak, and Pinpradit 2001; Soori 2001).

Risk Factors for Fall-Related Injuries. Risk factors for fall-related injuries in older people are generally considered in terms of risk factors for falling, risk factors associated with the severity of the impact following the fall, and risks factors associated with low levels of bone mineral density—insofar as almost all fall-related injuries in older people involve broken bones. The risk factors associated with the latter two categories are generally related to aspects of the aging process and, as a consequence, are considered in more detail in chapter 51.

Analytical studies conducted in a variety of LMICs have tended to show that risk factors for fall-related injuries, especially hip fractures, are consistent with the risk factors identified in HICs. Those risk factors include low bone density; poor nutritional status and low body mass index; low calcium intake; comorbid conditions, such as hypertension and diabetes; poor performance in activities of daily living; low levels of engagement in physical activity; poor cognitive function; poor perceived health status; poor vision; environmental factors affecting balance or gait; family history of hip fracture; and alcohol consumption (Boonyaratavej and others 2001; Clark and others 1998; Jitapunkul, Yuktananandana, and Parkpian 2001).

Some studies have identified other factors that may be more relevant in the context of LMICs. For example, studies in Thailand suggest that factors associated with poor socioeconomic status may increase risk—for example, not having electricity in the house and living in Thai-style houses or huts (Jitapunkul, Yuktananandana, and Parkpian 2001).

The literature specifically identifying risk factors for falls in younger people in LMICs is sparse, but the information there is indicates that such falls usually occur in and around the home, with a significant proportion being associated with falls from heights, including rooftops and trees (Adesunkanmi, Oseni, and Badru 1999; Bangdiwala and Anzola-Perez 1990; Kozik and others 1999; Raja, Vohra, and Ahmed 2001). However, falls other than from heights predominate and are frequently related to engagement in vigorous levels of physical activity.

Risk Factors for Burn-Related Injuries. Despite the focus of WHO's data on burn-related injuries sustained as a result of fires, a number of country-specific surveys conducted in medical facilities suggest that scalds from hot water may be equally important or more important causes of burn-related injuries (Chan and others 2002; Delgado and others 2002; Forjuoh, Guyer, and Smith 1995; Rossi and others 1998). However, in some countries, including China and particularly India, fire-related injuries clearly outweigh scald-related injuries (Ahuja and Bhattacharya 2002; Jie and Ren 1992).

Overall, women are at greater risk of fire-related burn injuries than are men; however, data from population-based and medical center surveys suggest that in some settings (excluding India), males may be at greater risk of burns than are females (Chan and others 2002; Zhu, Yang, and Meng 1988). In many studies, burn-related injuries account for a much higher proportion of injuries in young children compared with other age groups (Jie and Ren 1992; E. H. Liu and others 1998).

Rural location appears to be a consistent risk factor for burn-related injuries (Courtright, Haile, and Kohls 1993; Zhu, Yang and Meng 1988), as is the home (Delgado and others 2002; Forjuoh, Guyer, and Smith 1995; E. H. Liu and others 1998).

Investigators have undertaken case-control studies aimed at identifying risk and protective factors for burn-related injuries in Africa, Asia, and South America, and all focus on identifying risk factors for children. Environmental risk factors that have been identified include lack of a water supply, storage of a flammable substance in the home, cooking equipment in the kitchen within reach of children, and housing that is located in slums and congested areas. Persons with personal and socioeconomic risk factors included children who were not the first born, who had a pregnant mother, whose mother recently was dismissed from a job, who had recently moved, who had a pre-existing impairment, whose sibling died from a burn or had a history of burn, whose parents lacked alertness to burns, whose clothing was made of synthetic fabrics, whose parents were illiterate, and whose parents were of low economic status. Protective factors included the presence of a living room, better maternal education, and a history of previous injury among males who lived in good environmental conditions (Daisy and others 2001; Delgado and others 2002; Forjuoh and others 1995; Werneck and Reichenheim 1997).

Risk Factors for Drowning. Most drowning incidents in LMICs are not associated with recreation or leisure, as is commonly the case in HICs, but instead are associated with everyday activities near bodies of water, including rivers, wells, and buckets (Celis 1997; Hyder and others 2003; Kobusingye, Guwatudde, and Lett 2001).

As noted earlier, men account for a higher proportion of drowning incidents than women, and children age one to four and young people appear to be at greatest risk, with drowning accounting for a high proportion of injury-related deaths in those age groups (Celis 1997; Kibel and others 1990; Kozik and others 1999; Tan, Li, and Bu 1998). Some surveys also suggest that older people may be at particularly high risk (Tan, Li, and Bu 1998).

Descriptive surveys indicate that those living in rural areas are at greater risk than those living in urban areas (Kobusingye, Guwatudde, and Lett 2001), probably indicating greater exposure to unprotected water surfaces. A number of studies find that most adult drowning incidents appear to be associated with positive blood alcohol tests (Carlini-Cotrim and da Matta Chasin 2000; Celis 1997).

Case-control studies of drowning in young children have identified both sociodemographic risk factors and risk factors associated with proximity to bodies of water. Ahmed, Rahman, and van Ginneken's (1999) study in Bangladesh shows that the risk of drowning increased with the age of the mother and increased much more sharply the larger the number of children in the family. Celis's (1997) case-control study in Mexico finds that the risk of drowning associated with having a well at home was almost seven times that for children in homes without a well.

INTERVENTIONS

Interventions to prevent unintentional injuries have traditionally been considered in terms of the three E's—education, enforcement, and engineering—and within the framework of the Haddon matrix. That is, interventions are considered in terms of preventing the occurrence of the injury, minimizing the severity of injury at the time of the injury, and minimizing the severity of injury following the injury event.

Although randomized controlled trials are the gold standard for assessing the effectiveness of injury interventions, such trials are still relatively rare in relation to injuries, and in many cases such trials may be impractical to implement. Studies comparing the incidence of injury before and after the implementation of an intervention, sometimes with reference to a control population in which the intervention has not been introduced, more commonly provide the only evidence of effectiveness. In some areas, findings from observational studies, such as case-control studies, provide the best available evidence. However, randomized controlled trials are clearly not needed for some interventions because their benefits are

obvious. Other interventions, particularly those that may have modest but important benefits, may require rigorous evaluation methods.

Evidence of the effectiveness of interventions in LMICs, as opposed to HICs, is also relatively uncommon. Although the proven efficacy of some interventions in HICs does not require replication in LMICs—for example, the use of motorcycle helmets—strategies that may be effective in increasing the rates of helmet wearing in HICs may not necessarily be appropriate in LMICs. Thus, WHO and others increasingly endorse tailoring interventions found to be effective in HICs to LMICs, followed by rigorous evaluation (Peden and others 2004). Table 39.3 provides a summary of promising and recommended interventions, as well as interventions that have specifically been shown to be effective in LMICs.

Road Traffic Injuries

Many working to reduce RTIs use the “safer roads, safer vehicles, safer people, and safer systems” motto. A recent augmentation of this motto derives from the recognition of the important

Table 39.3 Promising and Effective Interventions for Injuries in LMICs

Injury	Promising interventions	Interventions shown to be effective in LMICs (references)
RTIs	<p>Reducing motor vehicle traffic: efficient fuel taxes, changes in land-use policy, safety impact assessment of transportation and land-use plans, provision of shorter and safer routes, trip reduction measures</p> <p>Making greater use of safer modes of transport</p> <p>Minimizing exposure to high-risk scenarios: restricting access to different parts of the road network, giving priority to higher occupancy vehicles or to vulnerable road users, restricting the speed and engine performance of motorized two-wheelers, increasing the legal age for operating a motorcycle, using graduated driver's licensing systems</p> <p><i>Safer roads</i></p> <p>Safety awareness in planning road networks, safety features in road design, and remedial action in high-risk crash sites: making provisions for slow-moving traffic and vulnerable road users; providing passing lanes, median barriers, and street lighting</p> <p>Traffic calming measures, such as speed bumps</p> <p>Speed cameras</p> <p><i>Safer vehicles</i></p> <p>Improving the visibility of vehicles, including requiring automatic daytime running lights</p> <p>Incorporating crash protective design into vehicles, including installing seat belts</p> <p>Mandating vehicle licensing and inspection</p> <p><i>Safer people</i></p> <p>Legislating strategies and increasing enforcement of, for example, speed limits, alcohol-related limits, hours of driving for commercial drivers, seat belt use, bicycle and motorcycle helmet use</p>	<p>Increasing the legal age of motorcyclists from 16 to 18 years (Norghani and others 1998)</p> <p>Speed bumps in reducing pedestrian injuries (Afukaar, Antwi, and Ofosu-Amaah 2003)</p> <p>Daytime running lights on motorcycles (Radin Umar, Mackay, and Hills 1996; Yuan 2000)</p> <p>Increases in fines and suspension of driver's licenses (Poli de Figueiredo and others 2001)</p> <p>Legislation and enforcement of motorcycle helmets (Ichikawa, Chadbunchachai, and Marui 2003; Supramaniam, Belle, and Sung 1984).</p>

Table 39.3 Continued

Injury	Promising interventions	Interventions shown to be effective in LMICs (references)
Poisonings	Better storage, including positioning and nature of storage vessels Use of child-resistant containers Warning labels First-aid education Poison control centers	Free distribution of child-resistant containers (Krug and others 1994)
Fall-related injuries	<i>Older people</i> Muscle strengthening and balance retraining, individually prescribed Tai chi group exercise Home hazard assessment and modification for high-risk individuals Multidisciplinary, multifactorial screening for health and environmental risk factors <i>Younger people</i> Multifaceted community programs of the Children Can't Fly type	
Burn-related injuries	<i>Fire-related injuries</i> Introducing programs to install smoke alarms Separating cooking areas from living areas Locating cooking surfaces at heights Reducing the storage of flammable substances in households Supervising children more effectively Introducing, monitoring, and enforcing standards and codes for fire-resistant garments <i>Scald-related injuries</i> Separating cooking areas from play areas Improving the design of cooking vessels <i>Fire- and scald-related injuries</i> Increasing awareness of burns prevention Providing first-aid education	
Drowning	Limiting exposure to bodies of water close to dwellings, such as by fencing Providing learn-to-swim programs Providing education about risks for drowning Increasing supervision and providing lifeguards at recreational facilities Equipping boats with flotation devices and ensuring their use Legislating and enforcing rules about the numbers of individuals carried on boats Having trained and responsive coast guard services	

Source: Authors.

role of appropriate transport and land-use policies in managing exposure to the risk of an RTI (Peden and others 2004).

Managing exposure to risk involves strategies aimed at reducing motor vehicle traffic, encouraging the use of safer modes of travel, and minimizing exposure to high-risk scenarios, as outlined in greater detail in table 39.3. Evidence from Malaysia shows that increasing the legal age of motorcyclists from 16 to 18 has been beneficial (Norghani and others 1998), but evidence of the effectiveness of many of the other strategies is not yet available for LMICs.

Safer Roads. Intervention strategies focusing on safer roads should incorporate safety awareness in planning road networks, safety features in road design, and remedial action for high-risk crash sites. HICs have adopted many of these strategies, and though they have not been examined in rigorously controlled studies, such strategies form the basis of best-practice guidelines and manuals now being used in LMICs (Ross and others 1991).

Traffic calming measures are among the strategies recommended for incorporating safety features into road design.

Although evidence from randomized controlled trials is not yet available (Bunn and others 2003), a before-and-after study conducted in Ghana suggested that speed bumps were effective in reducing traffic injuries, especially pedestrian injuries (Afukaar, Antwi, and Oforu-Amaah 2003). A recent summary of research findings also suggests that automated speed enforcement virtually eliminates speeding (ICF Consulting Ltd. and Imperial College Centre for Transport Studies 2003).

Safer Vehicles. Strategies focusing on safer vehicles include improving the visibility of vehicles, incorporating crash protective design into vehicles, and promoting further development of “intelligent” vehicles. However, in LMICs, strategies that simply ensure regular maintenance of older vehicles or removal of vehicles in poor condition from the roads, as well as vehicle licensing and inspection, have the potential to be cost-effective (Peden and others 2004).

Meta-analyses of the effects of automatic daytime running lights on cars consistently show that they reduce road crashes (Elvik and Vaa 2004). Studies in both Malaysia and Singapore show similar positive effects for daytime running lights on motorcycles (Radin Umar, Mackay, and Hills 1996; Yuan 2000).

Although the fitting of seat belts—probably the most well-known and effective safer vehicle strategy—is covered by technical standards worldwide and is mandatory in most countries, anecdotal evidence suggests that vehicles in many LMICs lack functioning seat belts (Forjuoh 2003).

Safer People. Intervention strategies aimed at improving road user behavior are increasingly focusing on the introduction and enforcement of relevant legislation rather than on educational efforts. For example, Poli de Figueiredo and others’ (2001) research in Brazil indicates that increasing fines and suspending drivers’ licenses immediately reduced RTIs and deaths.

A large body of research, although little of it conducted in LMICs, shows that setting and enforcing speed limits reduces RTIs by up to 34 percent. It also shows that RTIs are reduced in varying magnitudes by setting and enforcing legal blood alcohol limits and minimum drinking-age laws, using alcohol checkpoints, and running mass media campaigns aimed at reducing drinking and driving (Peden and others 2004).

The introduction and enforcement of mandatory seat belt and child restraint laws reduces occupant deaths and injuries by up to 25 percent; however, such laws have not been introduced in all LMICs (Peden and others 2004).

Both bicycle and motorcycle helmets reduce head injuries among riders by up to 85 percent. Though education may be effective in increasing helmet use, the effect is greater when combined with legislation and enforcement, as demonstrated in Malaysia and Thailand (Ichikawa, Chadbunchachai, and Marui 2003; Supramaniam, Belle, and Sung 1984).

Poisonings

The prevention of unintentional poisonings includes consideration of both occupational and nonoccupational poisonings; however, chapter 60 provides a fuller discussion of effective interventions in relation to work-related poisonings, so these are not discussed here.

Suggested interventions to reduce exposure to nonoccupational poisonings include better storage of poisons in terms of both the location and the nature of the storage vessels used. Specific interventions include storing poisons outside the home and above children’s head height and reducing the use of secondhand household containers—for example soda bottles—along with introducing and enforcing legislation to prohibit the sale of poisons in such containers (Nhachi and Kasilo 1994).

The efficacy of child-resistant containers in preventing access to poisons has been demonstrated, and data from a controlled before-and-after study in South Africa suggest that free distribution of child-resistant containers is a highly effective means of preventing poisoning in children (Krug and others 1994).

Fall-Related Injuries

Interventions proven effective for preventing falls by older people in HICs include muscle strengthening and balance retraining that is individually prescribed at home by a trained health professional; tai chi group exercise; home hazard assessment and modification that is professionally prescribed for older people with a history of falling; and multidisciplinary, multifactorial health and environmental risk factor screening and intervention programs, both for community-dwelling older people in general and for older people with known risk factors (Chang and others 2004).

In relation to fall-related injuries among young children, other than general recommendations about increased supervision of children and the importance of height reductions and appropriate ground surfacing to prevent playground injuries, only one intervention provides evidence of effectiveness that may be relevant for LMICs. The Children Can’t Fly Program has four major components, which include surveillance and follow-up, media campaigns, community education, and the provision of free, easily installed window guards to families with young children living in high-risk areas (Spiegel and Lindaman 1977). The program has been shown to be effective in reducing falls in low-income areas.

Burn-Related Injuries

Evidence of the effectiveness of interventions to prevent fire-related injuries is limited. A randomized controlled trial of a smoke detector giveaway program in inner London was unable

to show evidence of the program's effectiveness on the incidence of fires and fire-related injuries (DiGiuseppi and others 2002). However, a more recent study suggests that installation programs may be more effective in increasing the use of these alarms than giveaway programs alone (Harvey and others 2004).

Interventions that have been proposed but whose effectiveness has not yet been proven include separating cooking areas from living areas (including efforts to reduce the use of indoor fires for cooking), ensuring that cooking surfaces are at heights, reducing the storage of flammable substances in households, and supervising young children more effectively (Forjuoh 2004). The introduction, monitoring, and enforcement of standards and codes for and the wearing of fire-retardant garments have also been proposed (Bawa Bhalla, Kale, and Mohan 2000).

Evidence of the effectiveness of interventions to prevent scald injuries is minimal but promising, although such interventions primarily focus on education, legislation, and enforcement of efforts to regulate the temperature of water flowing from household taps (Macarthur 2003).

Finally, interventions directed at increasing awareness of burn prevention have been proposed, largely because of the success of safe community interventions involving a multitude of strategies (Ytterstad and Sogaard 1995).

Drowning

Evidence for the effectiveness of interventions to prevent drowning is almost nonexistent. The only available data come from case-control studies undertaken in HICs that suggest that fencing domestic swimming pools reduces the risks of drowning (Thompson and Rivara 2000). Extrapolation of those findings to a low-income setting suggests that covering wells with grills, fencing nearby lakes or riverbanks, and building flood control embankments might be effective in reducing drowning.

COSTS, COST-EFFECTIVENESS, AND ECONOMIC BENEFITS OF INTERVENTION

Data on effective interventions for preventing unintentional injuries in LMICs and on the economic costs of these injuries are limited. As a result, published data on the costs, cost-effectiveness, and economic benefits of interventions to prevent unintentional injuries in LMICs are virtually nonexistent. The economic evaluation of interventions and the measurement of the economic costs of injuries therefore remain a high research priority.

Some data are available from HICs on the costs and, in particular, the net economic benefits of interventions for RTIs. Also, a body of evidence suggests that many of the interventions designed to provide safer roads and vehicles, and to improve driver behavior, have clear net economic benefits

(Peden and others 2004). Some data are also starting to emerge from HICs with respect to the cost-effectiveness of fall-related injury prevention programs for older people. However, data on either the costs or the cost-effectiveness of interventions to prevent poisonings, burns, or drownings are limited.

Cost-effectiveness studies done in HICs can only be suggestive for LMICs, because the costs of property losses, disability, and medical care are so vastly different. Furthermore, basic efficacy is not always guaranteed when a control strategy that worked in a modern city is exported to a poor LMIC village. Consequently, the ability to extrapolate from high-income to low-income countries is severely limited. Yet as middle-income countries progress, they will begin to consider interventions that have already been proven.

Despite the methodological challenges, we modeled the cost-effectiveness of five potential interventions to prevent unintentional injuries using information presented earlier on known effective interventions in LMICs. In each case, the evidence for effectiveness in an LMIC setting was strong. However, because so few interventions have been evaluated in LMICs, we had to make certain assumptions to extrapolate findings about costs and effectiveness in one LMIC setting to other settings (for an outline of the assumptions associated with this modeling, see Bishai and Hyder 2004). Our economic analyses are highly generalized and indicative of what might be achieved with the interventions considered.

For the analyses, we present all cost estimates in local currency converted to U.S. dollars (2001 exchange rates). We adopt a societal perspective for each intervention, but if appropriate, we comment on cost-effectiveness from a government perspective. The time horizon for each intervention is one year of sustaining the intervention. Costs are annualized so that a typical year of operating the intervention is known. As with any intervention, annual operating costs may fall as those involved learn ways to carry out their tasks more efficiently. Each year of program operation prevents an estimated number of deaths and injuries. In each case, we present estimates of the raw numbers of deaths and the undiscounted numbers of life years they represent. However, from an economic perspective, the life years and DALYs of those who sustain nonfatal injuries count less than the deaths. For comparability with other economic estimates, and in accordance with the economic analysis guidelines provided to authors, we discount estimates of DALYs using both a 3 percent and a 6 percent discount rate. The 3 percent discount rate is standard for economic evaluations in HICs; however, a higher discount rate may be appropriate in LMICs.

Increased Penalties for Speeding and Other Effective Road Safety Regulations

Poli de Figueiredo and others (2001) provide evidence from Brazil on the effectiveness of an intervention to publicize and

enforce traffic speed and other road safety regulations. This intervention required three components—legislation to impose stiffer penalties, media coverage of the new regime, and better enforcement—and achieved a 25 percent reduction in traffic fatalities between 1997 and 1998.

On the basis of a model of the costs of media coverage and of better police enforcement, we estimate that implementing such an intervention in a population of 1 million people might range from as low US\$8,100 in South Asia to US\$196,000 in LMICs in Europe and Central Asia (table 39.4). Those intervention costs are incremental costs that assume that the population already has 50 percent of the necessary police strength. We define adequacy as one officer for every 5,000 vehicles and use regional data on vehicles per 1 million people to estimate the number of police officers and amount of equipment needed to enforce traffic laws. The assumption is that after the intervention the population will have enough officers to issue citations to one-third of their beat's 5,000 vehicles each year. This effort would require them to write about 7 to 10 citations per workday. Using the estimates of traffic injury burdens in the regions listed in the table and the potential to lower traffic deaths by 25 percent, as reported in the Brazilian study, we estimate potential DALY reductions and cost per DALY averted (table 39.4; for details of the calculations see Bishai and Hyder 2004).

The cost estimates shown in table 39.4 do not include potential cost offsets from savings derived by preventing expenditures on medical care or vehicle repair. Including those potential savings would lower the societal cost and enhance the estimated cost-effectiveness. Those cost offsets will vary widely by region. To demonstrate the importance of cost offsets, we use data from Bangladesh, for which the Transport Research Laboratory Ltd. (2003) has estimated the medical and property costs of traffic crashes. On the basis of these estimates, we calculate 1 fatality, 8 serious injuries, and 28 slight injuries occur for every fatal crash in Bangladesh. Each serious injury is associated with US\$2,016 in costs for property, administration, lost output, medical care, and pain and suffering, and each slight

injury incurs US\$929 in similar costs (Bishai and Hyder 2004). Thus, if we associate 1 prevented traffic fatality with preventing 8 serious injuries worth US\$16,128 ($8 \times \text{US}\$2,016$) and 28 slight injuries worth US\$26,012 ($28 \times \text{US}\929), then total additional cost savings would amount to US\$42,140.

If intervention costs in Bangladesh were close to the US\$8,105 shown in table 39.4 for South Asia, then the intervention would save society more than it cost if it prevented only one death and the expected proportion of nonfatal injuries. If an enforcement intervention in Bangladesh were as effective as the one documented in Brazil, it could lower fatalities by 25 percent. With 83 traffic fatalities per 1 million population, the intervention could prevent 21 deaths and lead to net savings of US\$876,835—or ($21 \times \text{US}\$42,140$) – US\$8,105—for every million population receiving this intervention.

Speed Bumps

A study in Ghana (Afukaar, Antwi and Ofosu-Amah 2003) showed that road traffic fatalities fell by more than 50 percent following the introduction of speed bumps. Because speed bumps are usually most effective when installed at the most hazardous junctions or near pedestrian crossings, planners need to know which junctions are the most hazardous. We assumed that half of a city's crashes occur at junctions and that cities have different numbers of treatable junctions. A few junctions would have multiple fatalities per year, but most would have one or zero fatalities per year. We assumed that the number of fatalities per junction would be distributed as a negative exponential to calculate how many junctions might lack effective speed control modifications and could thereby be targeted as those responsible for 10 percent or 25 percent of a city's preventable fatalities. Assuming a 10-year useful life for a speed bump and using regionalized estimates of speed bump construction costs, we modeled the annualized cost of constructing speed bumps at junctions responsible for 10 percent or 25 percent of fatalities. As before, we lacked an evidence

base from which to estimate cost offsets from prevented medical care or vehicle repair and could not include those potential savings.

Table 39.5 presents the costs of DALYs saved and costs per DALY saved by building speed bumps at the top 10 percent of the most lethal junctions in a city of 1 million people. We assumed the speed bumps could lower injuries by 50 percent, as observed in the Ghana study. Given the low costs per DALY averted and the typical high expenditures for medical care for crash victims, we are confident that the medical savings to society would more than offset the intervention's costs, but we lack the data to prepare complete estimates.

Bicycle Helmet Legislation and Enforcement

Thompson, Rivara, and Thompson's (1989) case-control study indicates that the effectiveness of a bicycle helmet for a single rider is 85 percent. The effect on lives saved and DALYs averted depends on how many people in a population ride bicycles and the roadway environment for riders. Although the degree of energy transferred to the brain in a crash and the clinical efficacy of helmets may be the same worldwide, few data are available on exposure and the bicycle crash burden in LMICs. Thus, in modeling the effects of bicycle helmet legislation, we were limited to assessing the case of the one country with adequate data on bicycle injury epidemiology: China. In China, bicycle-related deaths kill 22 people per 1 million population per year (Li and Baker 1997). Given estimates of the annualized cost of helmet acquisition for all the bicyclists in a Chinese population of 1 million and of the enforcement costs of penalizing unhelmeted riders, we estimate that protecting bicyclists with helmets would cost US\$265,000. Assuming that China could convert from zero to 100 percent adherence to helmet use, it could achieve an 85 percent reduction in head injuries from this intervention and would avert

2,478 DALYs at a 3 percent discount rate and 1,562 DALYs at a 6 percent discount rate. Thus, the cost-effectiveness of going from zero to 100 percent helmet use in China would be US\$107 (US\$265,000/2,478) per DALY at a 3 percent discount rate or US\$170 (US\$265,000/1,562) per DALY at a 6 percent discount rate.

Motorcycle Helmet Legislation and Enforcement

As with bicycles, we have epidemiological data for China, where motorcycle-related deaths kill 16 people per 1 million population per year (Zhang and others 2004). We assume that a population of 1 million in China has 125,000 regular motorcyclists, which will require the equivalent of half the time of a police officer to cite 1 percent of them for helmet violations. At Chinese salary levels, this effort would cost the equivalent of US\$7,500 per year. The helmets for this population would cost US\$250,000 at US\$2 per year of helmet use. Thus, the total cost of the intervention would be US\$257,500. Assuming a mean age of injury of 20 years and a disability weight of 0.4 for head injury, we estimate the DALYs averted by motorcycle helmet legislation as 589 at a 3 percent discount rate and 357 at a 6 percent discount rate. This intervention therefore costs US\$437 (US\$257,500/589) per DALY based on a 3 percent discount rate or US\$721 (US\$257,500/357) per DALY based on a 6 percent discount rate.

Childproof Paraffin Containers

The use of childproof paraffin containers is relevant primarily in Sub-Saharan Africa, where households use paraffin as a cooking fuel and frequently store it in bottles previously used to store beverages. Studies from South Africa have significantly enhanced our understanding of the cost-effectiveness of distributing child-resistant containers. According to Krug and others'

(1994) findings, a population of 1 million who used paraffin regularly in South Africa experienced 1,040 poisonings a year. After child-resistant containers were distributed, the incidence dropped to 540, indicating that 500 poisonings per year had been prevented. We therefore assume that (a) in a population of 1 million, child-resistant containers would need to be distributed to 200,000 households; (b) each child-resistant container costs R 0.85 (US\$0.33), including the costs of distribution; and (c) total direct costs would be US\$66,000 ($200,000 \times \text{US}\0.33).

The average cost of treating a poisoned child in a South African hospital was R 256.13 (US\$100). Thus, indirect cost savings would be US\$50,000 ($500 \times \text{US}\100), which would partially offset the US\$66,000 in direct costs, leading to a net cost of US\$16,000 to intervene. The mean age of children who suffered poisoning in South Africa was 12 to 24 months. Although no deaths were reported among children in the South African study, the most common figure in the literature is a 2 percent case fatality rate (Krug and others 1994), suggesting that the prevention of 500 poisonings averted 10 deaths among children around two years old. Life tables provided to the authors for Sub-Saharan Africa show life expectancy at age 2 is 49 years; thus, the US\$16,000 intervention could save 490 life years. Therefore, a rough estimate of the cost-effectiveness of child-resistant containers as a way of preventing paraffin poisoning in South Africa would be US\$1,600 ($\text{US}\$16,000/10$) per death averted.

Most survivors of paraffin poisoning do not suffer permanent disability, and because we lack any objective means for assigning disability weights to those who are disabled, we neglect years lived with a disability in calculating DALYs. The investment of US\$16,000 thus results in 10 children surviving for 49 more years. Undiscounted, this is 490 (10×49) life years. The impact is 263 DALYs averted at a 3 percent discount rate or 166 DALYs averted at a 6 percent discount rate. The cost-effectiveness is US\$61 ($\text{US}\$16,000/263$) per DALY at a 3 percent discount rate or US\$96 ($\text{US}\$16,000/166$) per DALY at a 6 percent discount rate.

Summary

Estimated costs per DALY from the interventions considered here range from negative (that is, savings) to a few hundred U.S. dollars per DALY. The order of magnitude of the costs per DALY averted using these injury countermeasures suggests that they could be categorized as highly cost-effective (Murray and others 2000). Our estimates of intervention costs neglect the potential savings from prevented medical spending but still appear quite promising. Although our estimates provide some indicative information about the economic properties of counterinjury interventions, these findings point primarily to the lack of information about the global economic burden of injury that could enable more comprehensive estimates.

IMPLEMENTATION OF PREVENTION AND CONTROL STRATEGIES

Investments in the health sector to address specific problems are a critical indicator of political commitment, sectoral efforts, and priorities at the national and international levels. In some cases, investments are so low that they provide a useful reference point for assessing the returns on additional investments in the future. Such a situation has been described as a null point in health systems, and current expenditures on injury prevention and control in LMICs approximate this concept (Murray and others 2000).

This concept can be illustrated by considering investments in preventing RTIs, which are responsible for the majority of the burden of unintentional injuries and about which much is known regarding effective interventions, even though such interventions have not been examined in the context of rigorously controlled studies in LMICs (see box 39.1).

Peden and others (2004) recognize that, despite the global burden of RTIs, the levels of investment are pitifully small, largely because of a lack of awareness of the scale of the problem and a lack of awareness that interventions can prevent and reduce the levels of harm. As a consequence, the report directs a number of recommendations at governments and communities in the hope that these recommendations will enable countries, particularly LMICs, to begin a sustainable process that will eventually lead to the adaptation and implementation of effective preventive strategies. The recommendations include the following:

- Identify a lead government agency to guide the national road safety effort.
- Assess the problems, policies, and institutional settings relating to RTIs and the capacity for preventing RTIs in each country.
- Prepare a national road safety strategy and plan of action.
- Allocate financial and human resources to address the problem.
- Implement specific actions to prevent crashes, minimize injuries and their consequences, and evaluate the effect of those actions.
- Support the development of national capacity and international cooperation.

Although few data are available to show the levels of investment in other areas of unintentional injury prevention, those levels are no doubt considerably lower than for RTIs. With increases in the proportions and numbers of older people in many LMICs, the burden of fall-related injuries is likely to increase significantly in the coming years. Recognition of the changing demographics in countries such as China, Mexico, and Thailand plus a growing body of evidence on effective

Box 39.1

Implementation: Case Study of RTIs

Bishai and others (2003) quantify the magnitude of government investment in road safety and the extent of RTIs in Pakistan and Uganda. They estimate that Pakistan spent \$0.07 per capita, or 0.015 percent of gross domestic product (GDP) per capita, on road safety in 1998 and that Uganda spent \$0.09 per capita, or 0.02 percent of GDP per capita. This type of evidence stands in stark contrast with the high burden of RTIs in these countries.

These findings occur in the context of public expenditure on health of 1.8 percent of GDP by Pakistan and 1.6 percent by Uganda (UNDP 1998). Per capita health spending by households in Uganda was \$7.70 in 1995/96, and public spending on health at the district level was \$4.84 per capita in 1997/98 (Hutchinson 1999). Public spending on road safety amounts to about 1 percent of public spending on health in each country. It is equivalent to 0.2 percent of military spending in Pakistan and 1.1 percent of Uganda's military budget.

A review of road safety initiatives in Benin, Côte d'Ivoire, Kenya, Tanzania, and Zimbabwe found similar underinvestment in road safety and attributes this insuffi-

cient investment to conflicts between government ministries, inefficient civil services, and corruption rather than to a lack of knowledge about possible road crash countermeasures (Assum 1998).

RTIs have an inverted U-shaped relationship to economic development—injuries rise early during development, then plateau with investments in road safety, and then fall as appropriate interventions succeed (van Beeck, Borsboom, and Mackenbach 2000). This biphasic pattern is known as a Kuznets curve. Attempts to estimate a Kuznets curve for road fatalities suggest that the inflection point at which fatalities begin to decline occurs at GDP per capita in the range of \$5,000 to \$10,000 (Bishai and others, forthcoming; Kopits and Cropper 2005). This relationship, although based on historical records from HICs, has an important lesson for LMICs: they do not need to experience massive death and disability from RTIs provided that they undertake safety investments now. Waiting for overall economic development before implementing specific interventions will result in the needless loss of millions of lives.

Note: All dollars in box 39.1 are 1998 international dollars.

interventions to prevent falls suggest that investments in this area could lead to significant benefits. Similarly, increasing recognition of the significance of the burden of drowning in children is leading to growing awareness of the need to invest in that area. However, the absence of any effective evidence-based interventions may be a barrier to further investment, suggesting that research into the burden of drowning must be a priority.

Investment in prevention and control activities in other areas of unintentional injuries is minimal in most LMICs, in large part because the burden of those injuries is unrecognized and because evidence of effective interventions is lacking. Therefore, there is clearly a need to consider the development, implementation, and evaluation of prevention strategies in combination, so that effective interventions can be identified and promulgated and so that ineffective interventions can be identified and discarded.

RESEARCH AND DEVELOPMENT AGENDA

The Global Forum for Health Research (2002) estimates that of the US\$73.5 billion spent on health research globally in 1998,

less than 10 percent was spent on addressing problems related to 90 percent of the world's population. Analyses revealed that RTIs were a highly neglected area for investment compared with the burden of disease RTIs represented as measured in U.S. dollars per DALY. As a result, increasing the level of investment for research and development (R&D) on RTIs and other injuries should be a focus of global advocacy efforts, and investment is critical for promoting an R&D agenda on injuries in LMICs.

Developing and prioritizing a global R&D agenda for unintentional injuries, though, is challenging, and such an exercise may be more useful at national or large subnational levels. However, a number of issues requiring R&D are likely to be common across a range of LMICs.

Epidemiological research to describe the existing burden, causes, and distribution of unintentional injuries in LMICs is still needed. Often the data are most limited for areas with the greatest potential burden of injuries. Assessing the loss of health and life from unintentional injuries—whom they affect, how, and under what specific circumstances—is thus a continuing research agenda for LMICs. Problems of underreporting and other biases in available data also need to be addressed.

The lack of intervention research in LMICs is a huge gap in global health research. For the most part, no scientific trials of injury interventions have been conducted in LMICs, and existing and new interventions need to be modified, adapted, and tested in those specific settings. Three broad domains should be the foci of intervention research:

- R&D to enhance the efficiency of currently available efficacious interventions. For example, increasing the use of helmets would prevent motorcycle injuries in East Asia.
- R&D to enhance the cost-effectiveness of interventions that are currently not being implemented or that could be used more widely. For example, seat belts and child restraints are known effective interventions, and reducing the cost of such interventions might enhance their wide-scale implementation in LMICs.
- R&D to develop new interventions for unintentional injuries and to respond to that proportion of the burden that is not currently being addressed. For example, childhood falls from rooftops in South Asia have been recognized as an issue, but a locally derived intervention is currently unavailable.

Although some might argue that intervention research should be the priority in most LMICs, unless the basic underpinning research on the burden and determinants of unintentional injuries has been undertaken, the political and financial support for such research will not be forthcoming.

The dearth of economic and policy analysis of unintentional injuries in LMICs is an embarrassment for the global health research community. A recent review of economic analysis of road traffic interventions found a complete absence of any detailed studies from the developing world (Waters, Hyder and Phillips 2004). This gap in health systems research would need to be addressed to develop and implement successful injury prevention programs.

Defining a research agenda is necessary but is not by itself sufficient to conduct research or to implement the results. Two key conditions are required for moving forward: a critical mass of people to conduct research and appropriate funds to support R&D. Developing human resources for all aspects of injury prevention and control in the developing world should be a high priority. Individuals need to be trained and institutions supported and empowered to conduct quality scientific research in their own countries and on issues relevant to their locations, which would then be used within their countries. This approach involves paying attention to the issue of strengthening the capacity for research, a major cross-cutting theme for the health sector in the developing world.

Funding is and always will be a limiting factor for research; however, the mismatch between the burden of injuries and R&D investments can be corrected. Unintentional injuries are

a major health problem. They cause preventable loss of life and health, and they have major economic implications. As a result, R&D investments are a health and economic imperative for developing countries and donor organizations.

CONCLUSIONS: PROMISES AND PITFALLS

Unintentional injuries are an important contributor to global death and disability burdens, especially in LMICs. However, the significance of the burden is not matched by substantive knowledge about risk factors or effective interventions in LMICs. Nevertheless, the models outlined in this chapter indicate that several interventions for preventing unintentional injuries are highly cost-effective and in some cases could result in significant cost savings.

Recent evidence shows that public efforts in injury control, such as traffic safety, are poorly funded in developing countries (Bishai and others 2003). The low expenditure compares unfavorably with expenditure on other health conditions and with expenditures in more developed nations, where government efforts in relation to such issues as traffic safety are well funded. Even adjusting for the 20-fold to 30-fold difference in gross domestic product per capita between HICs and LMICs, the investment disparities suggest that LMICs attach a low priority to injury prevention.

Given the current low level of investment, initial investments in safety, if chosen with care, could turn out to be extremely beneficial to public health and welfare. If, in the first instance, investments were to be made only in the interventions modeled here, then injury reductions would likely be significant. The next step would be to modify other interventions that have proven effective in HICs and to combine the introduction of such interventions with evaluations of their effects. Policy makers will be concerned that many of the cost-effective interventions are not low-cost interventions. They save many lives but require an extensive upfront investment. Using cost-effectiveness analyses of these interventions to document high returns would encourage financing of these interventions and widespread replication efforts.

Policy makers would be unwise to wait for advanced stages of economic development to attend to the problem of road safety or other unintentional injuries. Indeed, given the limited but growing knowledge that low-cost, effective interventions exist, for governments not to intervene would be unethical. Even though institutional obstacles are formidable in developing countries, governments routinely overcome them to address other perceived threats to public well-being—such as crime, terrorism, and war—that disrupt fewer lives than unintentional injuries. The real enigma is that such a profound loss of life can take place each year in LMICs without an outcry that would trigger sustained and effective political commitment by governments and civil society.

ACKNOWLEDGMENTS

We would like to acknowledge the assistance of Kristina McDaid and Kylie Monro of the George Institute for International Health in preparing this chapter. We would also like to acknowledge useful comments on the initial draft of the chapter provided by David Sleet of the Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, and by Tony Bliss of the World Bank.

Chapter 40

Interpersonal Violence

Mark L. Rosenberg, Alexander Butchart, James Mercy, Vasant Narasimhan, Hugh Waters, and Maureen S. Marshall

Violence kills more than 1.6 million people each year. The impact of nonfatal violence cannot be quantified, but it is even more pernicious given resultant disabilities and long-term physical, psychological, economic, and social consequences.

The direct and indirect costs of violence are enormous. Violence directly affects health care expenditures worldwide. Indirectly, violence has a negative effect on national and local economies—stunting economic development, increasing economic inequality, eroding human and social capital, and increasing law enforcement expenditures (Waters and others 2004).

The U.S.-based Centers for Disease Control and Prevention identified violence as a leading public health problem in the mid 1980s and early 1990s (Rosenberg 1985; Rosenberg and Fenley 1991), as did the World Health Assembly in 1996 (Resolution WHA49.25). Contributing to the World Health Organization (WHO) report on global violence and health, Dahlberg and Krug (2002) divided violence into the following categories:

- self-directed violence, or violence in which the perpetrator is the victim (for example, suicide)
- interpersonal violence, or violence inflicted by another individual or a small group of individuals
- collective violence, or violence committed by larger groups, such as states, organized political groups, militia groups, and terrorist organizations.

This chapter focuses on interpersonal violence, which disproportionately affects low- and middle-income countries (LMICs).¹ The WHO report on violence and health estimates

that more than 90 percent of all violence-related deaths occur in LMIC countries (Dahlberg and Krug 2002). The estimated rate of violent death in LMICs was 32.1 per 100,000 people in 2000, compared with 14.4 per 100,000 in high-income countries.

This chapter is based on a public health approach to preventing interpersonal violence. A public health approach has three overriding characteristics: it applies scientific methodology, emphasizes prevention, and encourages collaboration.

Applying a scientific methodology to a public health approach involves collecting and analyzing data to define the magnitude, scope, and characteristics of the problem, examining the factors that increase or decrease the risk for violence, and identifying the factors that can be modified through interventions. Interventions are designed, tested, and evaluated. Efficacious and promising interventions are implemented, and their effects and cost-effectiveness are evaluated. Ongoing monitoring of intervention effects on risk factors and target problems builds the database to allow quantitative assessment of successes and clear identification of remaining needs.

Fundamentally, public health is focused on prevention of harm caused by disease or violence. Although criminal justice systems have traditionally focused on capturing perpetrators of violence and punishing them for their actions (typically through incarceration), the public health system attempts to prevent violence from occurring and concentrates on identifying ways to keep people from committing acts of violence. Interventions may eliminate or reduce the underlying risk factors and shore up protective factors. Prevention strategies are conceived and implemented with reference to the interaction of risk factors among people at different stages of the life cycle (Mercy and Hammond 1999; additional sources online).

A public health approach must be collaborative, drawing on contributions from different sectors and disciplines. Public health analyses of violence aim to encourage integrated actions by diverse sectors such as health, education, social services, and justice. Each sector has a role to play, and collectively their actions have the potential to reduce violence.

THE NATURE, BURDEN, AND CAUSES OF INTERPERSONAL VIOLENCE

WHO (WHO Global Consultation on Violence and Health 1996, 2–3) defines *violence* as follows: “The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community that either results in or has a high likelihood of resulting in injury, death, psychological harm, mal-development, or deprivation.” This definition emphasizes that, for the act to be classified as violence, a person or group must intend to use force or power against another person. Thus, violence is distinguished from unintended incidents that result in injury or harm.

The nature or mode of violence may be physical, sexual, or psychological, or it may involve deprivation and neglect. Given the difficulties of measuring deprivation and neglect, this chapter concentrates on the physical, sexual, and psychological modes.

Acts of interpersonal violence are classified as family violence or community violence. Family violence is further categorized by victim: child, intimate partner, or elder. *Child abuse*, as defined by WHO (1999, 15), is “physical and/or emotional ill-treatment, sexual abuse, neglect or negligent treatment or commercial or other exploitation, resulting in actual or potential harm to the child’s health, survival, development, or dignity in the context of a relationship of responsibility, trust, or power.” Behavior within an intimate relationship that causes physical, psychological, or sexual harm is typically labeled *intimate partner violence* or *domestic violence*. *Elder abuse* is mistreatment of older people, generally those older than age 60 or 65, in the home or in an institutional setting.

Community violence is categorized by two types of perpetrators: acquaintances and strangers. It includes sexual assault by strangers and violence in institutional environments, such as residential care facilities, jails, workplaces, and schools. Youth violence, with perpetrators and victims typically 10 to 29 years of age, is also a form of community violence.

Outcomes of Interpersonal Violence

Identifying the outcomes of interpersonal violence helps to determine the magnitude of the problem.

Data. As noted earlier, a fundamental aspect of the public health approach is the collection of accurate information, such as demographic characteristics of victims and perpetrators, weapon involvement, settings in which violence occurs, situa-

tional determinants, and nature and severity of resultant injuries and other harm. Data sources include death certificates, vital statistics records, medical examiners’ reports, hospital and other medical records, police and judiciary records, and self-reported information from victim surveys and special studies. Multiple data sources, with their inherent strengths and limitations, are essential.

The most widely encountered sources of information are from the health and criminal justice sectors. Reliable data on violent deaths are not routinely collected in most countries. Where data collection systems are in place, coroner and mortuary reports, death certificates, and vital statistics records usually provide additional data about the victim. The health sector typically documents characteristics of the decedent and the cause, location, circumstances, and time of death. The criminal justice sector documents deaths or arrests resulting from interpersonal violence, including sometimes recording information about the relationship between the victim and the offender, the circumstances surrounding the violence, and the demographics of the perpetrator.

Theoretically, health and criminal justice sector data include information about nonfatal violence at all levels of severity, including threats of violence and instances of psychological violence, deprivation, and neglect. In practice, however, only data about violence-related injuries presenting at hospital emergency departments are collected. Studies from a variety of countries show that for every victim reporting violence to the police, at least two more present only at health agencies (Houry and others 1999; Kruger and others 1998; Sutherland, Sivarajasingam, and Shepherd 2002; additional sources online). Victims of nonfatal violence treated by the health sector may provide information about the perpetrator-victim relationship, about the circumstances surrounding the attack, and about contextual and developmental risk factors. However, the health sector is frequently restricted in recording information about perpetrators.

In LMICs, population-based surveys are a more useful source of information about violence-related injuries at all severity levels (Sethi, Habibula, and others 2004). Such surveys have been conducted in Bangladesh (Rahman, Andersson, and Svanstrom 1998); Colombia (Duque, Klevens, and Ramirez 2003); Iraq (Roberts and others 2004); Pakistan (Ghaffar 2001); South Africa (Butchart, Kruger, and Lekoba 2000; additional sources online); and Uganda (Kobusingye, Guwatudde, and Lett 2001). Demographic and health surveys with questions about violent victimization also collect information about the relationship between violence and other health conditions, but they can provide only limited insight into the perpetrators.

Hospital emergency departments have been used in some postconflict settings to monitor weapons-related injuries and evaluate the relative contributions of collective and interpersonal violence to the caseload (Meddings and

O'Connor 1999; Michael and others 1999). Some developing countries, such as Bangladesh, Kenya, and Uganda, also use violence and injury surveillance systems based in health facilities to monitor hospitalizations resulting from violence and other causes of injury (Kobusingye and Lett 2000; Odero and Kibosia 1995; Rahman and others 2001). Where emergency and forensic medical services are reasonably well developed and where access to such services is equitable, violence and injury surveillance tools have been integrated into hospital emergency departments (Hasbrouck and others 2002; additional sources online), prenatal clinics (Dunkle and others 2004), forensic service centers for rape victims (Swart and others 2000), and mortuaries (Butchart and others 2001). Those efforts have proven effective in obtaining victim-based, descriptive epidemiological information and insights into the relationships between victims and perpetrators.

Deaths Resulting from Interpersonal Violence. Global burden of disease estimates indicate that, in 2001, approximately 1.6 million people died as a result of violence. Of those deaths, 34 percent were due to interpersonal violence (table 40.1).

Rates and patterns of violent death vary by country and region (figure 40.1). Homicide rates were highest in developing countries in Sub-Saharan Africa and Latin America and the Caribbean and lowest in East Asia, the western Pacific, and some countries in northern Africa. Studies show a strong, inverse relationship between homicide rates and both economic development and economic equality (Butchart and Engstrom 2002; Fajnzylber, Lederman, and Loayza 2000). Poorer countries, especially those with large gaps between the rich and the poor, tend to have higher rates of homicide than wealthier countries.

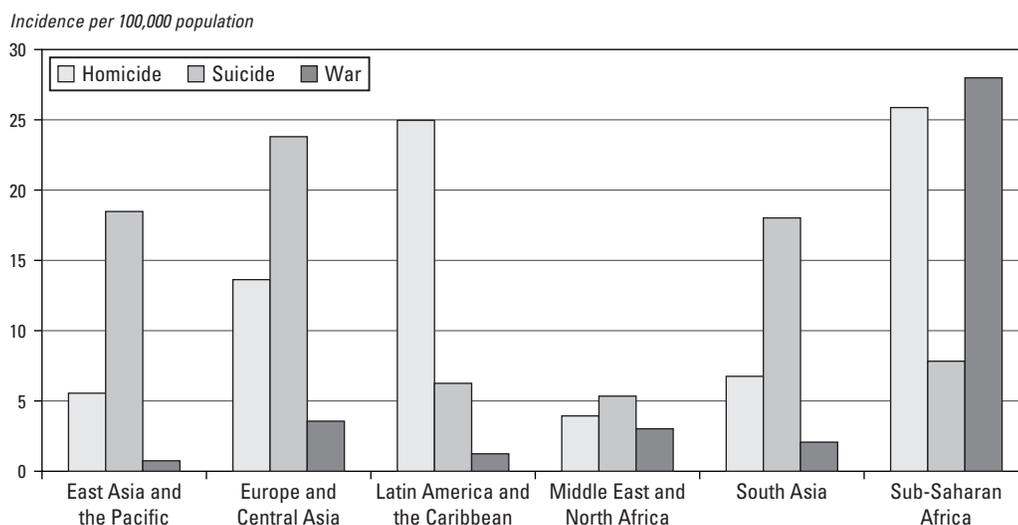

Table 40.1 Estimated Violence-Related Deaths, by Type and Region, 2001

Category	Number ^a	Rate per 100,000 population ^b	Proportion of total (percent)
Suicide	875,000	15.2	53.3
Homicide	557,000	9.3	34.0
War-related fatality	208,000	3.5	12.7
Total	1,640,000	28.0	100.0
LMICs	1,489,000	31.0	90.8
High-income countries	150,000	14.3	9.2

Source: Mathers and others 2006.
a. Rounded to the nearest thousand.
b. Age standardized.

Homicide rates differ markedly by age and sex (table 40.2). Gender differences were least marked for children. For the 15 to 29 age group, male rates were nearly six times those for female rates; for the remaining age groups, male rates were from two to four times those for females. Female homicide rates doubled after age 14 and gradually but steadily increased with age, and male rates increased more than 14 times after age 14, peaked in the 15 to 29 age group, and then gradually decreased with age. Overall, homicides resulted in the deaths of 3.4 males per female.

Violence-Related Burden of Disease. The sum of years of potential life lost because of premature mortality and years of productive life lost because of disability is not a particularly useful measure of the burden of violence. Disability-adjusted life years rely, in part, on estimates of nonfatal events. In the case of violence, those estimates are restricted to injuries and

Figure 40.1 Homicide, Suicide, and War-Related Fatality Rates, by Region, 2001

Table 40.2 Estimated Global Homicide and Suicide Rates, by Age Group, 2001
(number per 100,000 population)

Age	Homicides		Suicides	
	Males	Females	Males	Females
0–4 years	2.1	2.0	0.0	0.0
5–14 years	1.6	1.5	1.4	1.1
15–29 years	23.1	3.9	18.9	13.2
30–44 years	20.9	4.7	22.9	13.0
45–59 years	16.5	5.0	29.0	15.8
60+ years	12.6	5.4	41.7	20.8
Total	14.3	3.7	17.7	10.7

Source: Mathers and others 2006.

physical disabilities, both markedly underreported. In addition, given that psychological and other noninjury health consequences of violence are substantial, failure to include them in the measurement of disability-adjusted life years means that estimates of the nonfatal burden of violence may be grossly underestimated.

Violence-related morbidity can be analyzed as four distinct, but often co-occurring, outcome clusters: injuries and disabilities, mental health and behavioral consequences, reproductive health consequences, and other health consequences.

Studies in a number of countries show that, for every homicide among young people age 10 to 24, 20 to 40 other young people receive hospital treatment for a violent injury (Mercy and others 2002). Injuries range from minor, which can be self-treated, to severe. Severe injuries are those that may require resource-intensive emergency medical treatment and inpatient care and may result in lifelong disabilities, such as amputations, brain damage, or paraplegia. Few countries have information systems for monitoring nonfatal violent injuries, and existing systems typically record only data on violent injuries presenting at hospital emergency departments. Data from those sites cannot be directly compared, given the marked differences between and within countries in the availability and accessibility of emergency medical services.

The mental health consequences of violence are far reaching. Child abuse has well-documented sequelae of psychiatric disorders and suicidal behaviors (Runyan and others 2002). Both short- and long-term sequelae have been demonstrated (Mercy and others 2002, Heise and Garcia-Moreno 2002), including depression, anxiety disorders, substance abuse disorders, aggression, cognitive problems, sleep disorders, and post-traumatic stress disorder. The severity and duration of those consequences vary with the child's age and the length of time the child suffers the abuse, as well as the duration and intensity of the abuse, the child's relationship to the abuser, and the treatment received (Runyan and others 2002).

Intimate partner violence results in an increased incidence of suicide and suicide attempts, as well as in depression, anxiety, and phobias (Heise and Garcia-Moreno 2002). Additional consequences include substance abuse, eating and sleep disorders, poor self-esteem, posttraumatic stress disorder, psychosomatic disorders, and risky sexual behaviors. Sexual assault results in consequences that can be long lasting and severe, including posttraumatic stress disorder, depression, and conduct disorders, as well as sleep and eating disorders (Jewkes, Sen, and Garcia-Moreno 2002).

According to Jewkes, Sen, and Garcia-Moreno (2002), among adolescents and women age 12 to 45, the frequency of pregnancy as a result of rape varies from 5 to 18 percent. In addition, younger rape victims often have an increased rate of later, unintended pregnancies. Rape frequently results in gynecological problems, problems of sexual functioning, and sexually transmitted diseases, including HIV infection. HIV infection and the stigma it carries put both female and male victims of sexual assault at increased risk of further violence. A similar range of reproductive health consequences may also follow intimate partner violence.

A strong, graded relationship exists between the breadth of exposure to abuse or household dysfunction during childhood and the presence of adult diseases, including ischemic heart disease, cancer, chronic lung disease, skeletal fractures, and liver disease (Felitti and others 1998). In developed countries, abuse and other violent events of childhood have been associated with a 4- to 12-fold increased risk for alcoholism, drug abuse, depression, and suicide attempt; a 2- to 4-fold increased risk for smoking, poor self-rated health, 50 or more sexual intercourse partners, and sexually transmitted disease; and a 1.4- to 1.6-fold increased risk for physical inactivity and severe obesity (Anda and others 1999; Dietz and others 1999; Dube and others 2001, 2002; Hillis and others 2000, 2001; Williamson and others 2002). Similar exposures to violence in developing countries may have different, yet equally wide-ranging, impacts beyond direct physical and psychological injuries.

Data on Violence in Developing Countries

Studies documenting the human and economic toll of violence in LMICs are strikingly scarce. In addition to disparate levels of economic development, other differences between countries strongly influence levels and patterns of interpersonal violence and the toll that such violence takes on society. Countries with weak governments and institutions are at considerably higher risk for interpersonal violence than countries with developed institutions, and countries at war are likewise at higher risk than countries at peace. The same factors that lead to high levels of interpersonal violence—lack of economic development; weak social, political, and judicial institutions; social disturbances; and warfare—also adversely affect nations' ability to collect data and to address the causes or consequences of this violence.

Table 40.3 Risk Factors for Becoming a Victim or Perpetrator of Violence

Level of the ecological model	Risk factors
Individual (biological and personal history factors that influence how individuals behave)	<ul style="list-style-type: none"> Early developmental experience Demographic characteristics (for example, age, education, family, or personal income) Victim of child abuse and neglect Psychological and personality disorders Physical health and disabilities Alcohol or substance abuse problems History of violent behavior Youth Male Gun ownership
Relationship (with family members, friends, intimate partners, peers)	<ul style="list-style-type: none"> Marital conflicts around gender roles and resources Association with friends who engage in violent or delinquent behavior Poor parenting practices Parental conflict involving use of violence Low socioeconomic status of household
Community (neighborhoods, schools, workplaces)	<ul style="list-style-type: none"> High residential mobility High unemployment High population density Social isolation Proximity to drug trade Inadequate victim care services Poverty Weak policies and programs in, for example, workplaces, schools, residential care facilities
Societal (broad factors that reduce inhibitions against violence)	<ul style="list-style-type: none"> Rapid social change Economic inequality Gender inequality Policies that create and sustain or increase economic and social inequalities Norms that give priority to parents' rights over child welfare Norms that entrench male dominance over women Poverty Weak economic safety nets Poor rule of law Poor criminal justice system that supports the use of excessive violence by police officers against citizens and leaves perpetrators immune from prosecution Social or cultural norms that support violence Availability of means (for example, firearms) Conflict or postconflict situation

Source: Krug and others 2002a.

Risk Factors for Understanding Violence

Risk factors for violence are conditions that increase the possibility of becoming a victim or perpetrator of violence. No single factor explains why a person or group is at a high or low risk of violence. Rather, violence is an outcome of a complex interaction among many factors. This relationship is captured

in an ecological model that classifies risk factors for violence by four levels: individual, relationship, community, and societal (Dahlberg and Krug 2002). Although some risk factors may be unique to a particular type of violence, the various types of violence more commonly share a number of risk factors (table 40.3).

ECONOMIC IMPACT OF VIOLENCE

Violence exacts an extraordinary economic toll.

Costs of Violence

Estimates of the costs of violence vary broadly, with many of the differences resulting from the inclusion or exclusion of different categories. Cost categories can be broadly grouped into direct costs, which result directly from acts of violence or attempts to prevent them, and indirect costs, which include the opportunity cost of time, lost productivity, and impaired quality of life.

Those and other methodological issues lead to differing estimates of the costs of violence.² Researchers have calculated the value of a human life using lost wages, estimates of the quality of life, wage premiums for risky jobs, willingness to pay for safety measures, and individual behavior related to safety measures. The value of human life used in U.S. studies ranges from US\$3.1 million to US\$6.8 million (Fisher, Chestnut, and Violette 1989; Viscusi 1993; additional sources online). The rate used to discount future costs and benefits also varies, generally from 2 to 10 percent.³

Fromm (2001) reviews a variety of sources and calculates an aggregate total of US\$94 billion in annual costs to the U.S. economy resulting from child abuse, which is equal to 1 percent of gross domestic product (GDP). The estimate includes direct medical costs and related costs of legal services, policing, and incarceration, as well as the value of indirect productivity losses, psychological costs, and future criminality. Using secondary sources, Courtney (1999) calculates direct costs of US\$14 billion, including counseling and child welfare services, resulting from child abuse in the United States.

The Centers for Disease Control and Prevention (CDC 2003) cite an estimated 5.3 million victimizations involving intimate partner violence each year in the United States among women 18 and older, resulting in nearly 2 million injuries. More than 550,000 of those injuries require medical attention. The costs of intimate partner violence, including medical care, mental health care, and lost productivity, exceed US\$5.8 billion annually.

As a percentage of GDP, estimates of the costs of intimate partner violence are considerably higher in LMICs than in high-income countries. Morrison and Orlando (1999) calculate the costs of domestic violence against women on the basis of stratified random samples of women. Using only the lost productive capacity of the women, they extrapolate total costs of US\$1.73 billion in Chile and US\$32.7 million in Nicaragua. In a subsequent publication, Buvinic and Morrison (1999) calculate that the direct medical costs plus lost productivity are equivalent to 2.0 percent of GDP in Chile and 1.6 percent of GDP in Nicaragua.

Several studies have used the U.S. National Crime Victimization Survey, an annual survey based on 100,000 inter-

views with crime victims, to estimate the incidence and calculate the direct costs of sexual assault. For example, Miller, Cohen, and Rossman (1993) calculate average psychological costs of US\$66,600 for each rape and total costs of US\$85,000 for sexual assault resulting in physical injury. Psychological costs, also referred to as “pain and suffering,” are considered indirect costs. Because many studies do not include those types of costs, cost estimates vary widely.

Violence at the workplace also extracts an economic toll, but studies of its magnitude are not well developed and are hampered by measurement difficulties and nonstandardized methodologies. Biddle and Hartley (2002) study homicides in the workplace in the United States and calculate an annual cost of approximately US\$970 million. An international report commissioned by the International Labour Organization on the costs of violence and stress in work environments estimates that losses from stress and violence at work are equivalent to 1.0 to 3.5 percent of GDP over a range of countries (Hoel, Sparks, and Cooper 2001). All those studies use a broad definition of *workplace violence*, including psychological violence such as sexual harassment and bullying.

Violence committed by juveniles is particularly costly to society. Miller’s (2001) analysis of violent crimes committed in Pennsylvania in 1993 finds that juvenile violence accounted for 24.7 percent of all violent crimes and 46.6 percent of total victim costs from violent crime. Cohen (1988) calculates that the total cost to society of a youth engaging in a life of crime ranges from US\$1.9 million to US\$2.6 million.

Proximate Risk Factors

Alcohol, drugs, and guns contribute to the costs of interpersonal violence. According to estimates by the Children’s Safety Network Economics and Insurance Resource Center (1997), the cost of violent crime committed under the influence of alcohol equaled US\$33.3 million in 1995, or 8.3 percent of the cost of all violent crime in the United States. The National Crime Prevention Council (1999) estimates that the cost of all drug-related crime, including productivity costs, amounts to US\$60 billion to US\$100 billion annually in the United States, with violent crime accounting for approximately 10 percent of this figure.

Cook and Ludwig (2000) estimate that the annual costs of gun violence in the United States are on the order of US\$100 billion. Miller and Cohen (1997) calculate a significantly higher estimate for the toll of gun-related violence in the United States: US\$155 billion (including psychological costs and the value of quality of life). They also calculate that, on a per capita basis, the cost of gun violence in Canada equals one-third of the U.S. cost. Peden and van der Spuy’s (1998) study at the Groote Schurr Hospital in Cape Town, South Africa, finds that direct medical costs averaged R 30,628 (US\$10,308) per gunshot victim.

Effects on Public Finances

The public sector (and thus society in general) bears many of the costs of interpersonal violence. Several studies (Klein and others 1999; Payne and others 1993; additional sources online) find that 56 to 80 percent of U.S. health care costs for stabbing and gun injuries are either directly paid by public financing or are not paid at all. In the latter case, government and society absorb the costs in the form of uncompensated care financing and overall higher payment rates. In LMICs, society likely also absorbs the costs of violence through direct public expenditures and negative effects on investment and economic growth.

INTERVENTIONS

The evidence base of ways to prevent violence is expanding rapidly, but huge gaps remain in relation to effective strategies for reducing the health burden associated with interpersonal violence. The greatest strides have come in the areas of youth violence and child abuse, and almost all the prevention knowledge has been developed in high-income countries. Despite those limitations, an understanding of the epidemiology and etiology of violence and prevention provides important insights into the spectrum of policies and interventions that can be drawn on to prevent violence in LMICs.

Violence Prevention Strategies

The many commonalities among the various forms of violence in relation to their epidemiology and etiology suggest that common pathways to prevention may be available (Reza, Mercy, and Krug 2001). A typology of prevention strategies is useful in sorting through the complexities and commonalities of this problem to identify the range of strategies that might be incorporated into effective violence prevention plans. We propose a typology of prevention based on two key dimensions: the stages of human development and the ecological model mentioned earlier.

The epidemiology of violence, including its onset, desistance, and continuity, is closely related to the stages of human development (Williams, Guerra, and Elliott 1997). Increasing evidence points to the existence of discrete developmental pathways to violent behavior (Loeber and others 1993; Tolan and Gorman-Smith 1998; U.S. Department of Health and Human Services 2001; additional sources online). Thus, intervening at early developmental stages may reduce the likelihood that violence is expressed during later developmental stages.

The ecological model is also an important dimension of the typology, because violence is the product of multiple and overlapping levels of influence on behavior. The ecological model assumes that violent behavior is influenced by social contexts

and the individual attributes brought to these contexts. Intervention may therefore attempt to influence aspects or risk factors at any or all of the model's four levels (Dahlberg and Krug 2002; Mercy and Hammond 1999).

Table 40.4 presents our typology of prevention strategies. The examples presented are not exhaustive, nor have all the strategies proven effective. Rather, they illustrate the breadth of potential solutions and emphasize the need to consider addressing the problem simultaneously at different stages of human development and through different social contexts. In many cases, an intervention might have an effect on multiple forms of violence. At this time, data to prove or disprove the effectiveness of most of these interventions are insufficient, and in those cases in which sufficient data are available, they are almost always from high-income countries.

Strategic Focuses for Prevention

A simple understanding of the approaches illustrated in table 40.4 is insufficient for developing a comprehensive violence prevention strategy. A public health approach to violence prevention concentrates on identifying ways to keep people from committing violent acts. Interventions may eliminate or reduce the underlying risk factors and shore up protective factors. Interventions are typically classified in terms of three levels of prevention: primary, secondary, and tertiary (Dahlberg and Krug 2002).

Primary Prevention. Primary prevention interventions focus on preventing violence before it occurs. The literature has given rise to several strategic focuses for the primary prevention of violence that are important considerations in violence prevention planning. Some have been successfully implemented at the community level in LMICs.

The cultural context plays an important role in violent behavior. Cultural traditions are sometimes used to justify such social practices as female genital mutilation and severe physical punishment of children (Mercy and others 2003). Conversely, cultural norms can be a source of protection against violence, such as traditions that promote the equality of women or respect for the elderly. Although evidence-based approaches for changing cultural traditions as a violence prevention strategy are not yet available, some countries have adopted this strategy. In South Africa, the Soul City health promotion campaign makes residents aware of the extent and consequences of violence and encourages better parenting through role models and improved communication among family members. Evaluations have found shifts in attitudes and social norms concerning intimate partner violence and domestic relations. Willingness to change behavior and take action to stop violence has increased in urban and rural areas among both men and women (Krug and others 2002b,

Table 40.4 Prevention Strategies, by Developmental Stage and Ecological Context

Level of the ecological model	Developmental stage

a. These programs have been demonstrated to be effective in reducing violence or risk factors for violence.

b. These programs have been found to be ineffective in reducing violence.

box 9.1). In the Kapchorwa district of Uganda, a community health program has enlisted the support of elders in adopting alternative practices to female genital mutilation that are consistent with their cultural traditions (United Nations Population Fund 1998).

The lethality of interpersonal violence is affected by the means people use to carry out this violence. Reducing access to lethal means, such as firearms, may help minimize the health consequences of violence. A wide variety of strategies have been used to restrict access to firearms, such as mandating waiting periods before purchase, promoting safe storage of firearms, and limiting where firearms can and cannot be carried. In the mid 1990s, Colombian officials in Bogotá and Cali, noting that homicide rates increased during weekends following paydays, on national holidays, and near elections, implemented a ban on carrying handguns during those times, which resulted in a 13 to 14 percent reduction in homicide rates (Villaveces and others 2000). In the Australian state of Victoria, firearm-related suicides, assaults, and unintentional

deaths decreased following the 1988 implementation of legislation that required the registration of all firearms and strengthened licensing regulations; a mandatory waiting period was added in 1996 (Ozanne-Smith and others 2004). However, the evidence to determine whether such strategies are effective in reducing firearm-related homicides is currently insufficient (Hahn and others 2003), although several policies hold promise (Hemenway 2004; Ludwig and Cook 2003).

Inadequate parental involvement in children's and adolescents' activities and lack of supervision are well-established risk factors for youth violence (U.S. Department of Health and Human Services 2001). Evidence indicates that a supportive relationship with parents or other adults is protective against antisocial behavior. Although not widely evaluated, some mentoring programs that match high-risk youths with a positive adult role model appear to be effective in reducing youth violence (Grossman and Garry 1997; Thornton and others 2002); however, negative findings have also been reported for mentoring, particularly when mentors receive little training and when

the relationships between adults and youths break down. The design of mentoring programs varies considerably, and participation by both mentors and youths can be uneven.

Programs that target those who influence children are more effective than interventions that target all adults. For example, preschool enrichment, home visitation, and parenting programs have been found to have both short- and long-term effects on preventing violence (Farrington 2003; Mercy and others 2002; Utting 2003; additional sources online). Early intervention can help shape attitudes, knowledge, and behavior of children at a time when they are more open to positive influences and can affect their behavior over their lifetime (Mercy and others 1993).

Income inequality is a risk factor universally associated with interpersonal and collective violence (Butchart and Engstrom 2002; Zwi, Garfield, and Loretto 2002; additional sources online). Poverty itself does not appear to be consistently associated with violence, but the juxtaposition of extreme poverty with extreme wealth appears to be a key ingredient in recipes for violence. Economic programs or policies that reduce or minimize the effects of income inequality may be strategic in violence prevention, although the evidence base for such interventions has not been established.

Secondary and Tertiary Prevention. Although an emphasis on primary prevention is essential for reducing the health burden associated with violence, secondary prevention programs and services are necessary for addressing the immediate consequences of violent actions and behaviors, and tertiary programs focus on long-term care. Efforts targeted at victims of violence are extremely important for mitigating the physical and psychological consequences of the various forms of violence and abuse and for reducing victims' risks for future violence (National Center for Injury Prevention and Control 2002).

Physicians and other health professionals are gatekeepers in efforts to monitor, identify, treat, and intervene in cases of interpersonal violence. As previously noted, more cases of interpersonal violence come to the attention of health care providers than of police. The role of health care providers in prevention efforts is neither widely understood nor embraced, and many institutional and educational barriers limit their effectiveness (Cohen, De Vos, and Newberger 1997). Programs to educate health care providers are under way worldwide. Many hospital emergency departments, doctors' offices, and clinic settings use screening programs to identify victims of intimate partner violence, child abuse, or elder abuse, although the effectiveness of those interventions in reducing subsequent violence is not well understood (Heise and Garcia-Moreno 2002; Runyan and others 2002; Wolf, Daichman, and Bennett 2002).

Therapeutic approaches have been implemented in many parts of the world to reduce child abuse. Though some research

suggests that these interventions can improve the mental health of victims, less information is available on other benefits (Runyan and others 2002; additional sources online). One approach to preventing child sexual abuse in the United States challenges social norms by offering help to those at risk of offending and by encouraging adults to watch for and act on warnings of child sexual abuse before an offense is committed (CDC 2001). Under such programs, individuals voluntarily turn themselves in for treatment and thereby prevent potential future violence.

The outcome of injury from interpersonal violence depends not only on its severity, but also on the speed and appropriateness of treatment (Committee on Trauma Research 1985). Establishment of trauma systems designed to treat and manage injured victims efficiently and effectively is an important factor in reducing the health burden of violence. Research suggests that reductions in criminal assaults resulting in death in the United States are partly explained by the increased survival of victims. Developments in medical technology and trauma services may be reducing the number of interpersonal violence fatalities (Harris and others 2002). Hospital emergency departments may also provide an opportunity to intervene with victims who might otherwise seek revenge against their attackers or victims who are at greater risk for revictimization (Muelleman and others 1996).

COST-EFFECTIVENESS OF INTERVENTIONS

Studies show that implementing preventive interventions costs less than dealing with the outcomes of violence, in some cases by several orders of magnitude.

Examples of Cost-Saving Interventions

To date, most evaluations of preventive interventions measure cost and effects in high-income countries. Although cost savings may not be comparable in LMICs, effects may be greater.

Legislation and Shelter for Abused Women. The 1994 Violence against Women Act in the United States has resulted in an estimated net benefit of US\$16.4 billion, including US\$14.8 billion in averted victims' costs (Clark, Biddle, and Martin 2002). This wide-ranging legislation introduced programs aimed at deterring crimes against women and providing assistance to female victims of crimes. Interventions include penalties for repeat offenders, use of sexual history in criminal and civil cases, programs for victims of child abuse, safe homes for women, confidentiality of the abused person's address, and pretrial detention in sex offense cases. Chanley, Chanley, and Campbell's (2001) analysis shows that providing shelters for victims of domestic violence results in an estimated cost-benefit ratio of 18.4 to 6.8.

Parent Training and Home Visitation. Caldwell (1992) estimates that the costs of child abuse and neglect in Michigan are US\$1 billion a year, including the costs of crimes committed by the victims of child abuse later in life and the costs of their incarceration. The study estimates that prevention costs, including a home visitor program for every family and a comprehensive parent education program, are just one-nineteenth of the cost of child abuse. Armstrong's (1983) cost-benefit analysis of a child abuse prevention program in Yeadon, Pennsylvania, finds net savings of US\$647,000 per year and a cost-benefit ratio of 1.86.

Registering Firearms. Chapdelaine and Maurice (1996) quantify the costs and benefits of a Canadian law that required gun owners to register their firearms by January 1, 2001. Implementing a universal licensing and registration system cost approximately US\$70 million (2001 U.S. dollars), including a significant one-time expense, compared with annual direct health care costs of gun-related violence of US\$50 million. When the indirect costs of gun violence are included, the economic benefits of the law are much clearer. Miller (1995) estimates the total costs of firearm-related injuries in Canada at US\$5.6 billion, including lost productivity and psychological costs, equivalent to 1 percent of Canada's GDP.

Youth Intervention. Greenwood and others (1996) compare interventions to reduce youth crime in the United States and find that providing high school students with incentives to graduate, which costs US\$14,100 per program participant, is the most cost-effective intervention, resulting in an estimated 258 serious crimes prevented per US\$1 million spent. Parent training prevents an estimated 157 serious crimes per US\$1 million, compared with 72 for delinquent supervision programs and 11 for home visits and day care. All those interventions (excluding home visits) are more cost-effective than California's "three strikes" law, which incarcerates for life those individuals convicted of three serious crimes.

Need for LMIC Cost-Benefit Data

Though violence disproportionately affects LMICs, studies of the economic effects of violence in those countries are scarce. Comparisons with high-income countries are complicated by the tendency to undervalue economic losses related to productivity in lower-income countries, because such losses are typically based on forgone wages and income. Thus, when the costs of violent homicides are calculated, the estimates range from US\$15,319 per homicide in South Africa, to US\$829,000 in New Zealand, to more than US\$2 million in the United States. Given the existing methodological differences and widespread gaps in the literature, systematic research into the costs of

violence and the costs versus benefits of prevention efforts is urgently needed.

IMPLEMENTATION OF PREVENTION STRATEGIES

Promoting violence prevention involves encouraging and supporting the development, implementation, and evaluation of programs explicitly designed to stop the perpetration of violence at local, regional, and national levels.

The 2003 World Health Assembly Resolution (WHA56.24) on implementing the recommendations of the *World Report on Violence and Health* (Krug and others 2002b; see also Butchart and others 2004) advocates a five-point strategy.

Increasing Capacity for Collecting and Managing Data

Increased capacity for collecting health, criminal justice, and social service sector data on violence and its consequences is fundamental to building a sustained, high-level policy and intervention programming response in LMICs. Population-level data are needed to design and evaluate community-level intervention trials. Health sector data can cover a larger and often different subset of violence-related injuries than police statistics and, with criminal justice and social service data, can strengthen abilities to define the problem, identify causes and risk factors, design appropriate interventions, and monitor the interventions' effectiveness.

Information systems play a large role in recent efforts to address infectious diseases such as tuberculosis and HIV, allowing better identification of high-risk populations and appropriate interventions. A similar role is imminent for violence prevention. As previously stated, information systems must integrate data from the criminal justice, labor, education, social services, and health sectors and must be linked with systems housed at multilateral agencies or regional joint initiatives. Sharing information regionally allows countries to identify opportunities for collaboration and to share best practices.

Support for Research

Supporting research on the causes, consequences, and prevention of violence has proven effective in mobilizing prevention responses in developing countries. In South Africa, the 1997 Essential National Health Research Conference identified research for improved violence prevention and control as a top priority, and in 2001, the Medical Research Council established a program to give violence prevention research the same priority as research into HIV/AIDS, tuberculosis, and malaria (Jeenah and others 1997; Medical Research Council of South Africa 2004). South Africa also has applied research data in

various prevention contexts, including establishment of a national violence and injury mortality surveillance system, passage of firearms legislation, assessment of national and municipal-level burden-of-disease estimates, and design of prevention programs (Butchart and others 2001; Groenewald and others 2003).

The currently limited evidence base and understanding of the causes of all types of violence must be expanded through planned, documented, evaluated, and shared research. Some developing countries have opportunities to develop and document prevention programs in special settings, such as for refugees, orphans, nomadic, displaced, and homeless populations.

Promoting Primary Prevention

An important first step in promoting primary prevention is systematic documentation of existing prevention programs. Records can include information on the types of violence and risk factors addressed, target populations served, interventions used, and any monitoring and measurement of the effects. Such information can help make the programs more visible to policy makers and development partners and can be used to promote increased investment in programs that apply proven and promising interventions.

WHO has outlined a methodology for systematic documentation (Sethi, Marais, and others 2004, 22–33) and has initiated a project to evaluate the feasibility and utility of such documentation in selected cities and provinces in Brazil, India, Jamaica, Jordan, the former Yugoslav Republic of Macedonia, Mozambique, the Russian Federation, and South Africa.

Strengthening Support Services for Victims

A situational analysis of the accessibility and organization of emergency, acute, long-term, and rehabilitative services can identify needs and help strengthen care and support services for victims of violence. The establishment and adequate funding of first responder systems, such as police and ambulance teams, may lower the costs of violence and contribute to prevention. Maps showing hospitals and clinics with specialized systems for treating victims of violence can help these first responders. Ready access to legal resources empowers victims. Mock and others (2004) offer guidelines for strengthening victim care and support services.

Claramunt and Cortes's (2003) assessment in Belize, Costa Rica, El Salvador, Guatemala, Honduras, and Nicaragua established baseline information that could be used to advocate for strengthened medical and legal services for victims of sexual violence. Their findings included a lack of adequate medical and legal information systems, the insufficient training of medical staff, and a lack of clear protocols for moving patients

through the system. Services in associated sectors—medical, forensic, social, and legal—should be examined, because integrated efforts can improve access to and value of services that previously existed in isolation. Training of medical and legal service providers in activities aimed at preventing violence may also affect the success of long-term prevention; however, this training strategy has not been extensively evaluated.

Developing Action Plans

A national plan of action for preventing interpersonal violence and improving victim support and care is the blueprint that provides a set of common goals, a shared time frame, a strategy for coordinating activities, and a framework for evaluating the different sectors involved. Such a plan is therefore central to organizing national and community-level interventions that involve more than one objective and that depend on input from many different sectors. Strong political support from the highest levels of government is important in aligning the various players and ensuring that the plan is implemented and that associated programs are maintained. Nongovernmental organizations may provide support and continuity in countries where programs may be interrupted because of unstable, changing governments.

Collaboration among national governments and health-related nongovernmental and multilateral organizations can establish the importance of formally addressing violence through public health approaches. Though legal and criminal justice approaches provide a deterrent, experience in high-income countries suggests that a proactive public health approach can reduce the negative health, social, and economic consequences of interpersonal violence.

CONCLUSIONS: PROMISES AND PITFALLS

Violence prevention may be seen as a luxury rather than a public health priority in LMICs; however, the magnitude of the problem and the associated health burden negate this view. Resolutions on violence prevention passed by the World Health Assembly and codified in the *World Report on Violence and Health* and reports from the United Nations Crime Prevention Council present frameworks for approaching violence prevention. The first World Health Assembly resolution was cosponsored by a developing country, South Africa, and a developed country, the United States. Both recognized the importance of making violence prevention a global public health priority even before evidence of effectiveness could be collected. Seven years after the resolution, both developing and developed countries applauded and adopted the *World Report on Violence and Health*, signaling the beginning of an exciting new agenda for public health.

The public health model for violence prevention focuses on primary prevention and intervention for victims and emphasizes the value of integrating efforts across sectors. However, the model is weakened by a paucity of sustained interventions and measured outcomes in LMICs.

Currently, the best approach may be to take small, incremental steps, focusing on relatively discrete and easily implemented interventions that address a prevalent problem. LMICs should build on programs for which some evidence of effectiveness exists in high-income countries and adopt a “learn as you go” approach.

Many LMICs face the daunting challenges of the spreading HIV/AIDS epidemic and ongoing intergroup conflict or war. Those problems can destroy the infrastructure of civil society, increase stress and economic hardship, and lead to increases in suicide and interpersonal violence of all kinds—in both sexes and at all ages. In prioritizing violence prevention efforts, policy makers and health care professionals may mitigate some of the secondary repercussions of these deadly factors.

A great deal of progress has been made in violence prevention. There is strong reason to believe that the interventions under way and the capacity to implement violence prevention will make a difference. The lessons learned to date during the public health community’s short experience with violence prevention are consistent with the lessons from the community’s much longer experience with the prevention of infectious and chronic diseases. Violence can be prevented in LMICs if their governments, their citizens, and the global community start now, act wisely, and work together.

Chapter 41

Water Supply, Sanitation, and Hygiene Promotion

Sandy Cairncross and Vivian Valdmanis

Water supply in the context of this chapter includes the supply of water for domestic purposes, excluding provision for irrigation or livestock. *Sanitation* is used here in the narrow sense of excreta disposal, excluding other environmental health interventions such as solid waste management and surface water drainage.

The effect of these other measures on disease burden is largely confined to urban areas and is considerably less than that of water supply, sanitation, and hygiene promotion (Cairncross and others 2003). More fundamentally, expenditure on solid waste disposal and drainage is rarely seen as forming part of a portfolio of investments in public health or competing with public health investments. Rather, it is generally perceived by decision makers as comparable with other investments in municipal infrastructure and services, such as roads or public transportation, which are not considered to be public health interventions.

This chapter focuses on water supply, excreta disposal, and hygiene promotion and considers the costs and benefits of each in turn. Water supply and sanitation can be provided at various levels of service, and those levels have implications for benefits. Water supply and sanitation offer many benefits in addition to improved health, and those benefits are considered in detail because they have important implications for the share of the cost that is attributable to the health sector. From the point of view of their effect on burden of disease, the main health benefit of water supply, sanitation, and hygiene is a reduction in diarrheal disease, although the effects on other diseases are substantial. In the concluding sections, the percentage reductions arrived at in the discussion throughout the chapter are used

together with data on existing levels of coverage to derive estimates of the potential effects of water supply and excreta disposal on the burden of disease, globally and by region, and with cost data to derive cost-effectiveness estimates.

WATER SUPPLY

What constitutes a perfectly satisfactory water supply to some consumers leaves others, even in developing countries, considering themselves unserved. In much of rural Africa, a hand pump 500 meters from the household is a luxury, but most residents in urban Latin America would not consider themselves served by a water supply unless they had a house connection. In Asia, urban planners would consider a community served if there were sufficient standposts on the street corner; however, if the water only flows for a few hours per week, producing lengthy nighttime queues, the residents may regard this situation as a lack of service and opt to buy water expensively from itinerant vendors. As these examples illustrate, water supply is not a single, well-defined intervention, such as immunization, but can be provided at various levels of service with varying benefits and differing costs.

Levels of Service and Their Costs

Many public health workers unfamiliar with the water sector assume that the most important characteristic of a water supply is its improved *quality*. However, most of the benefit is attributable to improved convenience of access to water in

quantity. Moreover, global statistics are not available on the coverage and costs of provision of water in terms of its quality. The *Global Water Supply and Sanitation Assessment 2000 Report* (WHO and UNICEF 2000), the most recent compilation of global statistics on water supply, changed the way that such data are compiled, from the previous unreliable estimates by provider agencies to consumers' responses in population-based surveys. The change required a departure from the old definition of *reasonable access to safe water*, because most consumers cannot tell whether their water supply is safe. They can, however, state the type of technology involved, and that fact was used to define a new indicator of *improved* water supply. In the main, improved water supplies could be expected to provide water of better quality and with greater convenience than traditional *not improved* sources. The report treated the following technologies as improved: household connection, public standpipe, borehole, protected (lined) dug well, protected spring, and rainwater collection. Unprotected wells and springs, vendors, and tanker-trucks were considered unimproved. Bottled water was also considered unimproved because of concerns about the quantity of water supplied, not because of concerns over the water quality.

Reasonable access was defined as the availability of at least 20 liters per capita per day from a source within 1 kilometer of the user's dwelling. Within the broad category of those with reasonable access to an improved water supply, two significantly different levels of service can be distinguished:

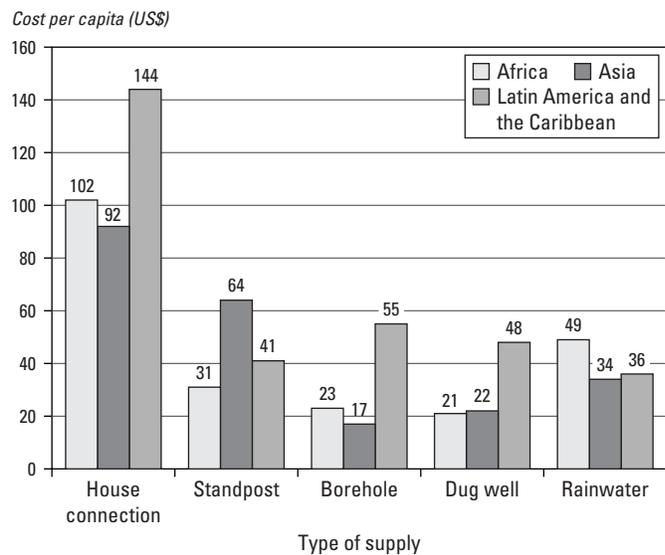

- house connections
- public or community sources.

In most settings, these subcategories correspond to very different levels of water consumption, different amounts of time spent collecting water, and as discussed in later sections, different health benefits.

The *Global Water Supply and Sanitation Assessment 2000 Report* also gives median construction costs per person served for the various technologies in the three main regions of the developing world. These costs are shown in figure 41.1. However, local conditions, such as the size of the community to be served and the presence of suitable aquifers, can cause tremendous variations in the unit cost of water supply.

For a community of given size, there are no significant returns to scale in the number of house connections made. Most of the investment in major works must be made before house connections can be offered, so that the marginal cost of each connection is only a fraction of the total. For those and other reasons, water supply is a natural monopoly requiring "lumpy" investments, which makes the unit costs difficult to calculate.

The cost of house connections may be representative in Latin America and the Caribbean, where they are often provided in rural areas. In Asia and Africa, however, the reported

Source: WHO/UNICEF 2000.

Figure 41.1 Median Construction Cost of Water Supply Facilities for Africa, Asia, and Latin America and the Caribbean

costs of house connections relate almost exclusively to urban areas because such connections are only rarely provided in smaller communities. The smaller size of rural communities means that piped systems in general—and house connections in particular—will tend to be more expensive per capita there than in urban areas. An overall unit cost figure of US\$150, just above the highest of the three continental medians, is therefore taken for house connections in the cost-effectiveness calculations.

For public water points corresponding to improved water supply, hydrogeological and other constraints mean that the cheapest technology is not feasible in every community. A cost figure of US\$40 per capita is about the middle of the range offered by different technologies (standpost, borehole, and dug well) providing this level of service for each continent (figure 41.1) and, therefore, seems reasonable for this level of service, although it can be expected to vary between US\$15 and US\$65 or more, depending on local conditions. The range of costs reported by individual countries for the *Global Water Supply and Sanitation Assessment 2000 Report* varied by more than an order of magnitude.

In calculating the cost-effectiveness of investment in water supplies, one must amortize these capital costs over an appropriate lifetime. Most major components of an urban water supply system have a potential lifetime of 50 years or more, but a prudent utility would aim to amortize them within about 20 years. A reasonable basis for calculation, for both urban and rural supplies, is to allow an amount of 5 percent of the capital cost as an annual straight-line amortization of the construction cost of the water supply.

Construction costs do not represent the full cost of water supplies. The *Global Water Supply and Sanitation Assessment 2000 Report* also gives median reported production costs per cubic meter for urban (house connection) water supplies as US\$0.20 for Asia and US\$0.30 for Africa and Latin America and the Caribbean. If we assume a mean daily water consumption of 100 liters per capita by those with household connections, those figures give annual per capita operation and maintenance costs of US\$7.30 and US\$10.95, respectively, or 8 to 10 percent of the capital cost of construction. In this chapter, a generic figure of US\$10 is used for the annual per capita operation and maintenance cost.

Reliable figures for the annual maintenance costs for rural water supplies are harder to find, particularly because much of the maintenance is carried out by the volunteer labor of villagers. Arlosoroff and others (1987), after reviewing a wide range of rural water supply projects in various countries, concluded that with a centralized maintenance system, the annual per capita cost of maintenance of a hand pump-based supply can range from US\$0.50 to US\$2.00, while well-planned, community-level maintenance can bring that figure down as low as US\$0.05 per capita per year. A nominal annual figure of US\$1.00 per capita is therefore used in this chapter. A similar figure can be applied to urban public standposts, for which volunteer labor is less forthcoming but transport costs are lower. This maintenance cost represents 2.5 percent of the construction cost arrived at above.

The Time-Saving Benefit

Benefits to health are not normally foremost in the minds of those provided with new water supplies. An exhaustive study of the economics of rural water supply by the World Bank concluded that “the most obvious benefit is that water is made available closer to where rural households need it. . . . It is not clear that rural populations think much about the relationship between water and health” (Churchill and others 1987, 21–22).

The Value of Time. The saving in time and drudgery of carrying water home from the source is substantial, and several reasons exist to attribute a money value to it. The most powerful argument for the money value of poor women’s time is that households often pay others to deliver their water, or pay to collect from nearby rather than from more distant sources that are free of charge. Thompson and others (2001) found that, of urban East African households lacking a piped supply, the proportion paying for water had increased from 53 percent to 80 percent over 30 years. In a survey of 12 sites in 10 countries, Zaroff and Okun (1984) found that households were spending a median of over 20 percent of their income on the purchase of water from vendors. The prices charged by vendors are typically more than 10 times—and can be up to 50 times—the normal tariff charged by the formal water supply utility.

Cairncross and Kinnear (1992) found that vendor prices increased with the time required to collect the water, showing that households pay more as the alternative of collecting water themselves becomes more burdensome. If the amount paid to the vendor for bringing the water is divided by the time saved from collecting it, the implicit value that people ascribe to their time can be calculated. Whittington, Mu, and Roche (1990), working in rural Kenya, showed in this way that the implicit value of the time saved was roughly US\$0.38 per hour, very close to the average imputed wage rate for such households of US\$0.35 per hour.

Because the poorest urban households typically spend more than 90 percent of their household budget on food, the money they spend on water is sacrificed from their food budget (Cairncross and Kinnear 1992). The provision of water more cheaply thus offers a substantial nutritional benefit to the poorest.

Assessing the Time Saved. The cost of water collection in rural areas is usually in time and effort rather than in money paid to vendors. The saving in time and drudgery underlies many social benefits. Given the relevance of the time-saving benefit to water supply policy and the fact that the benefit is usually uppermost in the mind of the consumer, it is remarkable how few data have been collected on the amounts of time spent collecting water.

Working in 334 study sites in Kenya, Tanzania, and Uganda, Thompson and others (2001) found a mean distance from rural un piped households to their water sources of 622 meters. In urban areas, the distance was only 204 meters, but queuing at the tap meant that a water collection journey took almost as long.

Feachem and others (1978) found in 10 villages of the densely populated lowlands of Lesotho that the installation of a water supply had saved the average adult woman 30 minutes per day. In one-third of the villages, the saving per woman was more than an hour a day. Lesotho has many springs, so that time saving is likely to be on the low side compared with Africa as a whole.

These time-saving benefits are confirmed by the Multi-Indicator Cluster Surveys of the United Nations Children’s Fund (UNICEF). A recent analysis of the responses in 23 African countries has produced a more representative account of water collection journey times in that continent (G. Keast, UNICEF, personal communication 2003). Nearly half the households interviewed (44 percent) required a journey of more than 30 minutes to collect water, implying that the women in such households spent an hour or more each day in water collection. At almost any reasonable level of service, most of that time would be saved by an improved water supply.

In Asia, an Indian national survey for UNICEF found that women spent an average of 2.2 hours per day collecting water

from rural wells (Mukherjee 1990). A study in Sri Lanka, which is generally considered to be well provided with water sources, found that 10 percent of women had to travel more than 1 kilometer to their nearest source (Mertens and others 1990).

Valuation of the Time-Saving Benefit. Putting a precise figure on the money value of the time of poor people is a tricky task, even for the most self-confident economist. In 1987, Churchill and others took US\$0.125 per hour as an illustrative but not unrealistic figure. To take the same figure today could hardly be described as extravagant. Assuming this valuation of an hour of time—and that a water supply bestows a mean saving of only 15 minutes per person per day—yields a conservative estimate of the value of the time-saving benefit of US\$11.40 per year. The data presented earlier indicate that, at least in Africa, the true figure is nearer to double that amount, enough to justify the full construction cost of a dug well or borehole supply in a single year. In Latin America and the Caribbean, costs are higher, and time savings may be less, but rural incomes are also higher—and so, therefore, is the value of people's time. Little doubt exists that, in all three regions of the developing world, the value of time saved is sufficient on its own to justify both the investment costs (at any reasonable rate of amortization) and the operation and maintenance costs of water supplies.

Even in settings where water vending is not common, contingent valuation surveys have widely demonstrated a willingness to pay for water supplies, particularly at the level of service of house connections (World Bank Water Demand Research Team 1993). In general, such measured willingness to pay has exceeded the cost of providing the supplies, and payment to vendors often exceeds it by many times.

Policy Implications. Whether the consumers actually pay for the full value of the time-saving benefit, it is what makes water supplies popular and largely it is what motivates politicians to invest in them. More than half the total annual investment in water supply in the developing countries of Africa, Asia, and Latin America and the Caribbean is from domestic sources (WHO and UNICEF 2000). Most of the investment is from the public sector. In general, investments in water supply—whether by the governments of developing countries or by external support agencies—do not come from health sector budgets and are not compared with other health interventions when investment decisions are made, even though health benefits do arise from water supply improvements.

Water supply is thus a health-related intervention that comes without cost to the budgets of the health sector. Although it undoubtedly offers health benefits, it has a sufficient economic and political rationale in other social benefits associated with time saving. The health benefits are a positive externality to this rationale. However, this fact does not mean that the authorities responsible for public health should ignore

the water sector. The function of the health sector is one of regulation, advocacy, and provision of supplementary inputs, as appropriate, to ensure that potential health benefits of water supply are realized to the optimal extent.

For example, the regulatory role of the health sector in quality surveillance of drinking water is well known and widely accepted. Substantial and largely unexploited additional potential is present in this role if quality is interpreted in the wider sense of *quality of service* rendered by the water supply utility, in terms not only of water quality but also of quantity, continuity, coverage, control of sanitary hazards, and cost. Those other aspects, as will be argued in the following sections, are no less important for health.

Where a regulatory role is not available to the health sector or agencies concerned with public health, advocacy can be no less cost-effective. For example, connection charges are a major barrier to house connections for low-income groups. In many cities of the developing world, the individual connection charge is about a month's basic wage. Advocacy of lower connection charges, with the amount recovered from the monthly water tariffs, can therefore help achieve an increase in the number of people who have house connections and who can benefit from the corresponding health gain at no cost to the public purse. Finally, the health sector can provide important complementary services, such as hygiene promotion and promotion of low-cost sanitation to increase coverage; because of the nature of such services, the water sector, with its focus on technology, is ill-equipped to offer them.

The unit costs of such regulation and advocacy are minimal. One example is the case of UNICEF's participation over the past 30 years in India's rural water supply program. UNICEF's investment has represented no more than 1 percent of the total, but its influence has played a central part in the evolution of the technical and institutional model of the program that supplies water to 1 in 10 members of the human race.

An example of the effectiveness of such measures is provided by the interventions of the Mexican Ministry of Health in June 1991. Fostered by fear of the devastating effects of cholera, these measures included the chlorination of water supplied for human consumption and the prohibition of sewage irrigation of fruit and vegetables. As a result, the incidence of diarrhea in children under five years of age fell from 4.5 to 2.2 episodes per child-year, and the corresponding mortality rate fell from 101.6 to 62.9 per 100,000 children (Gutiérrez and others 1996).

The current rate of annual investment per capita in water supply and sanitation, including both national investment and external aid funds, is reportedly US\$2.25 in Asia, US\$7.53 in Africa, and US\$8.87 in Latin America and the Caribbean (WHO and UNICEF 2000). One percent of the water sector's investment would, therefore, be US\$0.02 to US\$0.10 per capita. If each ministry of health in the developing world were to invest such a sum in public health advocacy and regulation

related to water supply, the sector's performance, at least where low-income groups are concerned, could be transformed. It is hard to put a figure on the health effects of such investment, but the Mexican example suggests that they would be substantial. For the sake of cost-effectiveness estimation, such spending is arbitrarily assumed to have the effect of ensuring improved water supplies for an additional 10 percent of the population to which it refers.

Direct Health Effects

The full list of water-related infections is large and varied, but most are only marginally affected by water supply improvements. The first effort to simplify the relationship between water supplies and health in developing countries was made by David Bradley (White, Bradley, and White 1972), who developed a classification of disease transmission routes in terms of whether they were

- *waterborne*, in the strict sense in which the pathogen is ingested in drinking water
- *water-washed*—that is, favored by inadequate hygiene conditions and practices and susceptible to control by improvements in hygiene
- *water-based*, referring to transmission by means of an aquatic invertebrate host
- *water-related insect vector* routes, involving an insect vector that breeds in or near to water.

Whereas the prevention of waterborne disease transmission requires improvements in water quality, water-washed transmission is interrupted by improvements in the availability—and hence the quantity—of water used for hygiene and the purposes to which it is put. Water supply may affect water-based transmission (for example, if it reduces the need for people to enter schistosomiasis-infected water bodies) or water-related

insect vectors of disease (for example, if a more reliable supply averts the need for the water-storage vessels in which dengue vectors breed), though that will depend on the precise life cycle of the parasite involved and the preferred breeding sites and behavior of the vector.

Classification and Burden of Water-Related Diseases. Before Bradley's classification can be applied to diseases (rather than transmission routes), it requires a small adjustment (Cairncross and Feachem 1993) to allow for the fact that practically all potentially waterborne infections that are transmitted by the feco-oral route can potentially be transmitted by other means (contamination of fingers, food, fomites, field crops, other fluids, flies, and so on) all of which are water-washed routes. In addition to the feco-oral infections, a number of infections of the skin and eyes can be considered water washed but not waterborne. The final classification is shown in table 41.1.

The classification can now be used to assess how the disease burden prevented by water supply is distributed among disease groups. Bradley himself did this, a time long before the disability-adjusted life year (DALY) had been invented as a unit of benefit measurement (White, Bradley, and White 1972, 191). He used official statistics on the number of cases of each disease diagnosed and treated by health services in East Africa and combined them with notional percentages by which morbidity and mortality caused by each condition could be expected to fall if water supply were "excellent."

Those notional reductions were based on subjective assessments of the literature available at the time and were described by their author as "little more than guesses," but it is hard to prove many of them seriously at fault, even today. A selection is presented in table 41.2.

The result of these calculations was that the feco-oral disease group accounted for 91 percent of the deaths preventable by water supply, 50 percent of inpatient bed nights, and 33 percent

Table 41.1 The Bradley Classification of Water-Related Infections

Transmission route	Description	Disease group	Examples
Waterborne	The pathogen is in water that is ingested	Feco-oral	Diarrheas, dysenteries, typhoid fever
Water-washed (or water-scarce)	Person-to-person transmission because of a lack of water for hygiene	Skin and eye infections	Scabies, trachoma
Water-based	Transmission via an aquatic intermediate host (for example, a snail)	Water-based	Schistosomiasis, guinea worm
Water-related insect vector	Transmission by insects that breed in water or bite near water	Water-related insect vector	Dengue, malaria, trypanosomiasis

of outpatient consultations. Rosen and Vincent (2001) have made a similar calculation for the whole of Africa in 1990 and found that the feco-oral group accounted for 85 percent of the preventable DALYs. When measured in terms of deaths or DALYs, feco-oral infections account for the vast majority of the impact, because of the high mortality caused by diarrheal diseases among young children. Most deaths from diarrheal diseases are of children younger than age five, and most of those are among children younger than two. A child death averted is worth 30 DALYs. Varley, Tarvid, and Chao (1998) have calculated that for diarrhea morbidity reduction to have the same effect in DALYs as averting one such death, it would have to prevent 115,000 child-days of diarrhea. After the diarrheal diseases, the next most important category in terms of DALYs (12 percent of the total) is the water-based group, primarily schistosomiasis. The purely water-washed diseases, mainly skin infections, represent a more conspicuous portion only when compared in terms of the burden placed on health services by inpatients or outpatients.

How representative is this African breakdown of the developing world as a whole? Diarrheal disease among poor communities is cosmopolitan. A global review of studies of the incidence of diarrhea morbidity could find no clear geographic or climatic trend (Bern and others 1992), so the burden of disease is no doubt similar around the developing world. The second most important disease group is represented by schistosomiasis, which is absent from much of Asia and Latin America. The relative importance of feco-oral disease is, therefore, likely to be still greater in the poor communities of Asia and the Western Hemisphere than it is in Africa.

Epidemiological Questions and Problems. The predominant contribution of feco-oral diseases to the burden of disease attributable to water supply raises an important question,

because this group can be transmitted by both waterborne and water-washed routes. It is important for the water engineer to know whether scarce funding should be spent on improved water treatment and measures to protect water quality or instead on providing a limitless supply of water at a high level of access and convenience and encouraging its use for improved hygiene practices. We need to know, that is, whether the feco-oral infections endemic in poor communities are mainly waterborne or mainly water washed.

Moreover, the fact that some diarrheal diseases are still prevalent in communities with a high level of water supply service indicates that water supply alone cannot completely prevent these diseases. A further question then, is this: by how much do water supply improvements reduce diarrheal diseases?

Numerous studies have sought to answer these questions, but they are hard to answer rigorously, for several reasons. First, it is almost impossible, ethically and politically, to randomize the intervention. Where the intervention is an improvement in the level of access to water, it cannot be blinded; no placebo exists for a standpost. Where quasi-experimental studies have been used—opportunistically exploiting an intervention allocated by political or technical means—significant confounding has frequently been found (Briscoe, Feachem, and Rahaman 1985).

Confounding has been especially intractable in studies in which the allocation of facilities has been on a household basis, so that the exposure groups are self-selected—for instance, studies in which individual households that have chosen to install a private tap are compared with others that have chosen not to do so. The former households are likely to be wealthier, better educated, and more conscious of hygiene than their neighbors, so it would not be surprising if they were also more likely to do many other things that protect their families from feco-oral disease. The more sophisticated studies have used multivariate models to control for confounding, but where relative risks are low and the exposure groups are self-selected, even those models do not guarantee that confounding is eliminated (Cairncross 1990).

A further difficulty arises from the fact that cases of feco-oral disease in a given community cannot be considered independent events, because such diseases are infectious. The sample size, it can be argued, is the number of such villages rather than the number of individuals enrolled in the study. Yet a number of important studies in the literature compare a single intervention area with only one control area.

Other epidemiological weaknesses exist in the data. Blum and Feachem (1983) reviewed 50 studies of the health effect of water supply and sanitation projects and noted that every one contained one or more of these basic errors of methodology. A further weakness in the evidence for the effect of water supply on diarrheal disease burden is that most of it relates to diarrheal disease morbidity, and significant assumptions are

Table 41.3 Median Reductions in Diarrhea Morbidity Reported from Different Water Supply and Sanitation Interventions

Intervention (object of improvement)	Number of rigorous studies from which morbidity reductions could be calculated	Median reduction in diarrheal morbidity (percent)
Water quality only	4	15
Water quantity only	5	20
Water quantity and quality	2	17
Sanitation only	5	36
Water and sanitation	2	30
Hygiene promotion only	6	33

Source: Esrey and others 1991.

needed to extrapolate such evidence to an effect on diarrheal mortality.

Effect on Diarrheal Disease. Esrey and Habicht (1985) and Esrey and others (1991) reviewed the same literature from a different perspective. Though conscious of the methodological shortcomings of most studies, they sought to assess the overall reductions in diarrheal disease that water supply could be expected to cause. They applied a number of criteria of epidemiological rigor and took the median reduction in morbidity reported from each type of intervention. Their conclusions are summarized in table 41.3.

For more than a decade, this review has remained the most authoritative on the subject. However, the small reductions in disease that it reports for water supply conceal an important heterogeneity. Though these overall results are frequently quoted, the following remark by Esrey and others (1991, 613) has usually been overlooked:

In the studies reporting a health benefit, the water supply was piped into or near the home, whereas in those studies reporting no benefit, the improved water supplies were protected wells, tubewells, and standpipes.

In the studies in the two reviews by Esrey and Habicht (1985) and Esrey and others (1991) in which the water supply was provided in the home, the median reduction in diarrheal disease is 49 percent (from 12 studies), and the reduction from the two better studies is 63 percent. Those reductions are several times greater than the overall median impacts in table 41.3. The 63 percent figure will be used in the burden of disease calculations that follow. In the two better studies, the members of the comparison group were using not an unimproved water supply, but a protected water source away from the home. The reductions they found are, therefore, in addition to those resulting from a public standpost level of service.

Some subsequent studies have confirmed this pattern. For example, Bukonya and Nwokolo (1991) showed in Papua

New Guinea that use of a household tap was associated with 56 percent less diarrhea than use of public standposts providing water of good quality.

Conditions for Health Effect. Providing a public water point appears to have little effect on health, even where the water provided is of good quality and replaces a traditional source that was heavily contaminated with fecal material. By contrast, moving the same tap from the street corner to the yard produces a substantial reduction in diarrheal morbidity. How is this pattern to be understood?

The first step to an explanation is an understanding that most endemic diarrheal disease is transmitted by water-washed routes and is not waterborne. Although waterborne epidemics of diarrheal diseases such as cholera and typhoid have been notorious in the history of public health, the endemic pattern of transmission seems to be different, particularly in poor communities. Five types of evidence support this view:

- *Negative health impact studies.* As mentioned earlier, Esrey and Habicht (1985) and Esrey and others (1991) cite a number of studies of the health impact of water supplies in which water quality improvements have failed to have a significant effect on diarrheal disease incidence.
- *Food microbiology.* Studies of the microbiology of foods in developing countries—particularly the weaning foods fed to children in the age group most susceptible to diarrheal disease—have shown such food to be far more heavily contaminated with fecal bacteria than is drinking water (Lanata 2003), even when the water has been stored in open pots.
- *Seasonality of diarrhea.* In countries with a seasonal variation in temperature, bacterial diarrheas peak in the warmer season, whereas viral diarrheas peak in the winter. This pattern suggests that the bacterial pathogens show environmental regrowth at some stage in their transmission route, which means that they must have a nutritional substrate. Water is, thus, a less likely vehicle than food.

- *Fly-control studies.* Trials in rural Asia and Africa have shown that fly control can reduce diarrheal disease incidence by 23 percent (Chavasse and others 1999).
- *Hand-washing studies.* A recent systematic review of the effect of hand washing with soap has shown that this simple measure is associated with a reduction of 43 percent in diarrheal disease and 48 percent in diarrheas with the more life-threatening etiologies (Curtis and Cairncross 2003).

Those five types of evidence suggest that domestic hygiene—particularly food and hand hygiene—is the principal determinant of endemic diarrheal disease rates and not drinking water quality.

The second step is an understanding of how the level of service and convenience of a water supply influence such hygiene practices in the home. Taking the amount of water used per capita as an indicator of hygiene changes, other things being equal, one finds that providing a source of water closer to the home—and therefore more convenient to use—has very little effect on water consumption unless the old source was more than 1 kilometer (30 minutes’ roundtrip journey) away from the user’s dwelling (Feachem and others 1978).

However, water consumption doubles or triples when house connections are provided (White, Bradley, and White 1972), and reason exists to believe that much of the additional consumption is used for hygiene purposes. For example, Curtis and others (1995) found that provision of a yard tap nearly doubled the odds of a mother washing her hands after cleaning her child’s anus and more than doubled the odds that she would wash any fecally soiled linen immediately.

In conclusion, water supplies are likely to have an effect on diarrheal disease when they lead to hygiene behavior change—that is, when the old source of water was more than 30 minutes’ roundtrip away or when house connections are provided.

By a happy coincidence, then, the health benefits of water supply are most likely to be realized in exactly those cases in which the time-saving benefit is greatest—when the old source of water is farthest away, and when the new one is on the plot of the individual household. Though water supplies offering house connections are more expensive, the additional time

savings offered by this level of service mean that people are willing to pay more for them. Moreover, collecting revenue from households with private connections is far simpler than collecting it from public taps because the sanction of disconnection can be used against households that default on payment of the tariff.

Calculating the burden of disease associated with inadequate water supply requires a figure for the reduction associated with the levels of service for which coverage statistics are available. The following burden of disease calculations are based on a reduction of 17 percent from an improved public water supply (table 41.3) and of a further 63 percent from house connections.

The effect of water supply improvements (and of hygiene practices such as hand washing) on diarrhea mortality can be expected to be at least as great as—and probably greater than—their effect on morbidity for several reasons. A theoretical argument for this improvement pattern is given by Esrey, Feachem, and Hughes (1985) in terms of infectious doses. Esrey and others (1991) also reported a median reduction of 65 percent in diarrhea mortality attributable to water supply, sanitation, or both in three studies, compared with 22 percent from 49 studies of morbidity. The effect of hand washing on life-threatening diarrheas—shigellosis, typhoid, cholera, and hospitalized cases—is greater than that on diarrhea morbidity as a whole (Curtis and Cairncross 2003). Finally, the two known direct studies in the literature of the effect of house connections on diarrhea mortality (“Serviço Especial da Saúde Pública,” an unpublished study in Palmares, Pernambuco, Brazil, cited by Wagner and Lanoix 1959; Victora and others 1988) found reductions of 65 percent (relative to a public standpost) and 80 percent (relative to various communal sources, some polluted), respectively.

Effect on Other Disease Categories. Water supplies have a beneficial effect on a number of disease groups other than diarrhea, although the corresponding burden of disease is far less. The median reductions in morbidity from other water-related conditions, reported by Esrey and others (1990), are shown in table 41.4.

Table 41.4 Median Reductions in Morbidity Associated with Improved Water Supply and Sanitation: Conditions Other Than Diarrhea, Related Most Closely to Water Supply

Disease	All studies		Better studies		
	Number of studies	Median reduction (percent)	Number of studies	Median reduction (percent)	Range (percent)
Dracunculiasis	7	76	2	78	75–81
Schistosomiasis	4	73	3	77	59–87
Trachoma	13	50	7	27	0–79

Source: Esrey and others 1990.

To be effective in controlling schistosomiasis, the water supply must be so convenient as to discourage water contact for laundry and bathing. It is unlikely that this level of convenience can be achieved without house connections.

Evidence suggests that water availability and hygiene can produce substantial reductions in trachoma (Emerson and others 2000). Because the reductions come from hygiene improvements such as hand and face washing, they are also likely to be greatest with house connections. Dracunculiasis is affected by water quality, but the simplest improved water supply is adequate to prevent transmission.

Conflicting evidence exists about whether water supply or improved water-washed hygiene affects the transmission of intestinal helminths. On one hand, Henry (1981) found in an intervention study in St. Lucia that piped water supplies were associated with a 30 percent reduction in ascariasis among children under age three over a two-year period. On the other hand, Han and others (1988) showed in Burma that an intervention to promote hand washing with soap had no effect on prevalence or intensity of infection with *Ascaris* spp. However, the potential contribution of water supply to reducing the burden of disease through its effect on these other infections is relatively minor when compared with its effect on diarrheal disease.

EXCRETA DISPOSAL

In much the same way as with water supply, care is needed to ensure that different people who talk about sanitation are referring to the same thing. When the WHO-UNICEF Joint Monitoring Program was compiling the *Global Water Supply and Sanitation Assessment 2000 Report* (WHO and UNICEF 2000), a major effort was needed to persuade some of the Latin American partners that a pit latrine, considered a status symbol in much of rural Africa, was an acceptable form of excreta disposal. In some countries, even engineered sewerage systems are considered unacceptable if not connected to a functioning wastewater treatment plant.

Levels of Service, Technologies, and Their Costs

A wide range of technologies is used, particularly for settings in which low-cost solutions are required, and this variation has led some to inquire whether the different types of latrine might confer differing health benefits. In the early 1980s, the World Bank established a Technology Advisory Group for low-cost sanitation, and this question was among those it was asked to investigate. Using field studies and a thorough literature review, the group concluded that all types of systems can be operated hygienically, and that

The greatest determinants of the efficacy of alternative facilities are, first, whether they are used by everyone all the

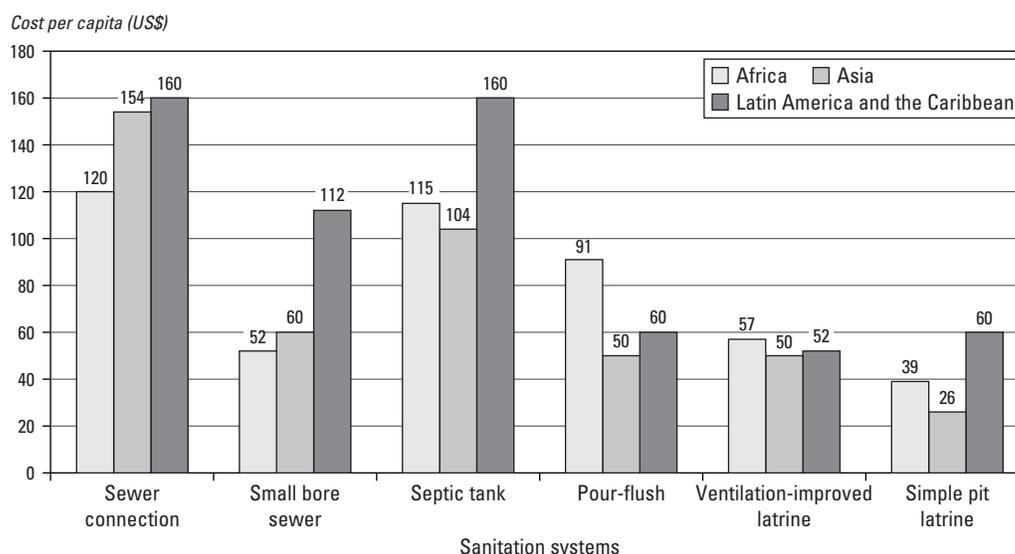

time, and second, whether they are adequately maintained. . . . Pit latrines would, from the viewpoint of health rather than convenience, approximate the same rating as a waterborne sewerage system. (Feachem and others 1983, 49–50)

The group therefore judged it most appropriate not to distinguish between sanitation technologies and to consider all of them as providing adequate access to sanitation as long as they were private or shared (but not public) and hygienically separated human excreta from human contact. This definition was followed in the *Global Water Supply and Sanitation Assessment 2000 Report*, which accepted only sewerage, septic tanks with soakaways, pour-flush latrines, and pit latrines as improved technologies. Service or bucket latrines and latrines with an open pit were not accepted. The effect of technology type on health benefit is discussed further in the sections that follow.

Public latrines, however, do not provide an adequate solution to the excreta disposal needs of a community. Quite apart from the notorious and widespread inadequacies in their maintenance, they are not usually accessible at night or by the elderly, by those with disabilities, or—if there is an entry charge—by young children. Thus, some promiscuous defecation continues to be practiced, particularly by children, in communities where public latrines are the only level of service available.

Figure 41.2 shows the regional median construction costs per capita of the various sanitation technologies found by the *Global Water Supply and Sanitation Assessment 2000 Report*. Although the simple, on-site systems tend to be cheaper than systems such as sewerage and septic tanks, the difference is less than might be expected. For example, a World Bank survey in several developing countries found the mean cost of conventional sewerage to be 10 times that for on-site systems such as improved pit latrines and pour-flush toilets (Kalbermatten, Julius, and Gunnerson 1982). It is likely that the off-site costs of sewerage systems and the cost of the additional water needed for them to function have not been fully included in national reports to the *Global Water Supply and Sanitation Assessment 2000 Report*. For the purposes of calculating cost-effectiveness, a construction cost of US\$60 per capita seems adequate for basic sanitation facilities (a household pit latrine, ventilation-improved latrine, or a pour-flush toilet) in any region of the developing world. Taking a relatively short lifetime of five years for a latrine and straight-line amortization gives an annual cost of US\$12 per capita per year. In such a short lifetime, very little maintenance is normally required, other than occasional cleaning; the cost of maintenance is, therefore, considered to be included in the amortized annual cost.

That said, it should be borne in mind that substantially cheaper solutions are often feasible, such as the “15 taka latrine”

Figure 41.2 Median Construction Cost of Sanitation Technologies in Africa, Asia, and Latin America and the Caribbean

(costing only US\$0.27 per household) developed in Bangladesh, which includes a pour-flush pan made of tin sheet and an odor- and insect-proof seal made of flexible plastic pipe.

Social Benefits

Like water supply, sanitation offers a number of social benefits in addition to direct health gains, which tend to feature more prominently in the minds of the users. This outcome is illustrated by the responses given by a sample of householders in rural Benin when asked to rate the importance they ascribed to the various benefits of latrines on a scale of 1 to 4 (table 41.5). Health-related benefits (shown bold in table 41.5) were rarely mentioned spontaneously and generally rated among the less important benefits.

With sanitation as with water supply, strong gender differences exist in the perception of the social benefits of sanitation. For male heads of household in Benin as in other countries around the world, enhanced social status figures highly among the benefits of latrine ownership, whereas for women, security, convenience, and aesthetic factors count for more. Women who lack sanitation often risk sexual harassment on the way to and from their defecation site. In some cultural settings, women are constrained to go out for defecation and urination only during the hours of darkness, effectively becoming prisoners of daylight. Though no systematic study has been made of the health implications of such practices, they are likely to include an increased prevalence of urinary tract infections. The emancipation that a latrine bestows on such women cannot lightly be dismissed.

Table 41.5 Benefits of Latrine Ownership as Perceived by 320 Households in Rural Benin

Benefit	(Average importance rating, scale 1–4)
Avoid discomforts of the bush	3.98
Gain prestige from visitors	3.96
Avoid dangers at night	3.86
Avoid snakes	3.85
Reduce flies in compound	3.81
Avoid risk of smelling or seeing feces in bush	3.78
Protect my feces from enemies	3.71
Have more privacy to defecate	3.67
Keep my house or property clean	3.59
Feel safer	3.56
Save time	3.53
Make my house more comfortable	3.50
Reduce my family's health care expenses	3.32
Leave a legacy for my children	3.16
Have more privacy for household affairs	3.00
Make my life more modern	2.97
Feel royal	2.75
Make it easier to defecate because of age or sickness	2.62
Be able to increase my tenants' rent	1.17
For health (spontaneous mention)	1.27

Willingness to Pay. The governments of developing countries cannot afford to provide heavily subsidized sanitation to all—or even to the majority—of their populations. The 2.6 billion people in Africa, Asia, and Latin America who do have adequate sanitation—53 percent of the population of those regions—have paid most of the cost themselves. Even those of the urban poor who do not have sanitation have expressed a willingness to pay for its full cost—or at least the local cost (excluding major interceptor sewers and treatment works, if required)—in a number of surveys, as long as credit is available on reasonable terms to smooth the cash flow (Altaf 1994). With regard to the rural poor, the success of well-conceived sanitation promotion programs in achieving coverage close to 100 percent, without a substantial subsidy, in some of the poorest rural communities in the world (Allan 2003) shows that people are willing to pay for sanitation if a suitable product is offered to them on suitable terms.

Why then do 2.4 billion people still lack sanitation? Several factors constrain the expression of the existing demand.

The constraint most frequently mentioned by unserved householders is cost, but this factor is usually more a perceived constraint than an objective one, for several reasons. First, many households are unaware of the true cost of latrines in their area, or the lower-cost models are not offered because local suppliers and artisans do not know about them or are attracted by the greater margins to be made on the more expensive technologies. Second, the high cost of capital to the poor rules out their borrowing the cost of a latrine, which to them would be a substantial investment. Third, they may be wary of investing in a property that belongs to their landlord, lest it be used as an excuse for a rent increase or even eviction. They may also feel, with some reason, that it is for the landlord to make the investment, rather than themselves, and they may be waiting for the landlord to do so. This belief has a similar effect to the common misapprehension of citizens, often encouraged by politicians, that the local government is responsible for sanitation and will eventually come to their aid; in either case, the outcome is inaction.

Other constraints include lack of ready access to necessary techniques and skills or to specific building materials and components. Where the skills exist locally, residents may lack confidence in the quality of work and value for money offered by the local artisans, or they may not know how to contact the right artisans. In many urban areas, local building regulations make low-cost sanitation technologies illegal.

Those constraints are compounded by the fragmentation of governmental responsibility for sanitation. Often it is devolved to local governments with little capacity to implement sanitation improvements. At the national level, one ministry may be responsible for sewerage and another for low-cost technologies; one may be responsible for construction, another for promotion, and a third for enforcing building codes and planning regulations.

Policy Implications. There are important externalities to households' investment in sanitation. Households are protected from their own feces by their sanitation facilities, but so, too, are their neighbors, and this factor is probably more important in epidemiological terms. If households are not fully aware of the health benefit—or if much of it accrues to others—a case exists for public intervention to increase coverage because these externalities exist.

This public intervention need not be in the form of subsidy. Strong arguments can be marshaled against a subsidy for low-cost sanitation (Cairncross 2003a). Subsidy limits the number of facilities that are built to the size of the subsidy budget; it encourages the design and marketing of unaffordable sanitation systems; it frequently leads to capture by the better-off, who install expensive toilets while the poor go without; and it distorts the market, diverting the efforts of latrine builders who would otherwise be seeking to meet the needs of low-income groups.

The intervention can be by regulation. National and local governments have substantial regulatory powers that can be used to increase sanitation coverage without significantly increasing costs or public expenditure. For example, more than 90 percent of households in the town of Bobo Dioulasso, Burkina Faso, have their own latrine (Traoré and others 1994) as a direct result of the local administration's practice in the past of withdrawing rights of land tenure from owners who did not build a latrine on their plot within a specified time. Another regulatory intervention is to enforce the obligation of landlords to provide sanitation for their tenants.

An alternative strategy is to provide support to the marketing of sanitation. This strategy can be undertaken in a number of ways that are not feasible for the existing producers, mainly artisan builders and small component manufacturing workshops. Those interventions would aim principally at overcoming the constraints to the expression of effective demand for sanitation and could include the following:

- advertising and other forms of promotion
- facilitation of building regulation approval
- brokerage to put potential purchasers in touch with providers
- quality assurance and guarantee schemes
- training in low-cost construction techniques and in marketing
- centralized production of essential components
- provision of pit emptying and desludging services.

Promotion of improved hygiene practices, including appropriate use and maintenance of the sanitation facilities, is another possible intervention by the public sector. All of those measures will help increase sanitation coverage and health benefits and are appropriate interventions for the health sector. The costs of several of them are recoverable (after an initial

launch period) as fees, so that public intervention need not require public expenditure.

Costs of Promotion. The costs of promotion and administration found in two government-run rural sanitation programs documented by the World Bank were US\$16.80 (Zimbabwe) and \$20.00 (the Philippines) per latrine, respectively (Cairncross 1992). Because these costs are largely fixed, the cost per unit falls as the number of units built increases. Unit costs will therefore be high in relatively unsuccessful programs. Successful programs, on the other hand, often engender the construction of more latrines than they can account for, which also gives an upward bias to the promotional costs per unit built. For example, for every latrine built by Lesotho's rural sanitation program in the late 1980s, four others were built independently but as a result of its promotional activities.

More recently, successful sanitation programs managed by nongovernmental organizations (NGOs) have documented slightly lower unit costs for promotion. For example, the Zimbabwean NGO AHEAD (Applied Health Education and Development), working through district-level health staff and a network of community health clubs, achieved the construction of 3,400 latrines in Makoni district within two years at a total promotional cost of US\$45,660, or US\$13.43 per unit, equivalent to US\$2.24 per household member served (Waterkeyn 2003). In Bangladesh, WaterAid and its partner, a local NGO named VERC (Village Education Resource Centre), have developed an approach that has successfully achieved 100 percent sanitation coverage and the elimination of open defecation in more than 100 villages in six districts at a cost of US\$8 per household, or US\$1.50 per capita (Allan 2003). Both pro-

grams also promoted domestic hygiene practices in addition to the construction and use of latrines. In Bangladesh, all (and in Zimbabwe, most) of the costs of latrine construction were paid by the population themselves.

The programs in Bangladesh and Zimbabwe were particularly successful and well managed. The promotion cost is taken as US\$2.50 per capita for cost-effectiveness calculations, which is slightly above the higher of the two, to allow for the imperfections of sanitation programs in the real world.

Direct Health Benefits

Evidence supports the claim that improved excreta disposal helps prevent a number of diseases, including diarrhea, intestinal worm parasites, and trachoma. Of these, the effect that accounts for the largest burden of DALYs is that on diarrheal disease.

Diarrheal Disease. The effect of sanitation on diarrhea morbidity has already been mentioned. Table 41.3 shows the results of Esrey and others' (1991) review, attributing a median reduction in incidence of 36 percent to sanitation. Although this figure is the median of the five "better" studies, it must be interpreted with great care because almost all the known studies on the health effects of sanitation are observational studies that use self-selected exposure groups. Confounding by a sense of hygiene is likely to be a significant problem in any such study. From Brazil to Bangladesh, the owners of latrines have been observed to behave more hygienically than their neighbors in practices such as hand washing that are not affected by the presence of a latrine (Hoque and others 1995—see table 41.6;

Table 41.6 Factors Associated with Hand-Washing Behavior by 90 Women in Bangladesh

Associated factor	Hand-washing behavior observed after defecation		Ratio of prevalences of good practice (95 percent confidence interval)
	Good	Poor	
<i>Uses own sanitary latrine</i>			
Yes	22	11	1.73
No	22	35	(1.15–2.59)
<i>Uses tubewell water exclusively</i>			
Yes	18	10	1.53
No	26	36	(1.03–2.29)
<i>Owns agricultural land</i>			
Yes	36	24	2.25

No	21	18	(0.66–1.55)

Source: Hoque and others 1995.

Strina and others 2003). It is thus impossible to prove, except by an intervention study, that any health benefit associated with latrine ownership is due to the latrine and not to the hygiene habits of latrine owners.

The overall reduction in diarrhea from sanitation quoted by Esrey and others (1991) likely disguises considerable heterogeneity in terms of the context rather than the type of sanitation technology. For example, sanitation is likely to have a greater effect on diarrheal disease in high-density urban areas, where open defecation leads to gross fecal pollution of the neighborhood, and less effect in rural communities, where all but the youngest children use communal defecation sites some distance away from their homes.

For example, Moraes and others (2003), working in urban *favelas* in northeast Brazil, found that diarrhea incidence among children in households with a toilet was half that in households that did not have one. This comparison is likely to be affected by confounding because the households with toilets were a self-selected group. Comparison between communities is less likely to be affected by confounding, but Moraes and others found a greater reduction. The mean incidence of diarrhea in young children in communities with sewers was only one-third of that in the communities that, for administrative and technical reasons, did not have sanitary drainage.

Thus, although the quality of the studies reviewed by Esrey and others (1991) was in general poor and the range of reductions wide, little doubt exists that excreta disposal can be associated with significant reductions in diarrhea morbidity. Studies showing that proximity to open or overflowing sewers (Moraes and others 2003), failure to dispose hygienically of children's stools (Traoré and others 1994), or the presence of excreta on the ground in the household compound (Bukonya and Nwokolo 1991) is a risk factor for fecal-oral infections provide supporting evidence for the likely effect of sanitation infrastructure, particularly in urban settings, on diarrheal disease transmission.

In conclusion, there are some reasons, such as the likelihood of confounding, to believe that Esrey and others' (1991) median reduction is an overestimate, but reasons exist also to believe that the reductions measured were not as great as they might have been had the provision of sanitation been accompanied by hygiene promotion to ensure that the facilities were fully and appropriately used (especially by young children) and maintained. A systematic review of the effect of sanitation on diarrheal disease is urgently required. Meanwhile, and on balance, Esrey and others' median reduction of 36 percent in diarrhea incidence is the most authoritative estimate available.

Interaction with Water Supply. The results of Esrey and others' (1991) review suggest that the effect of water supply and sanitation combined is no greater than that of either on its

own. However, that conclusion is based on only two studies, and the percentage reductions found in the individual studies of each type of intervention exhibit a wide range. Reflection on how in practice each of the two interventions interrupts the transmission of fecal-oral pathogens would suggest that their effects would be largely independent: whereas water supply helps prevent contamination of drinking water, hands, and food, excreta disposal helps prevent contamination of the household yard and surroundings, including children's play areas. Esrey and others (1990) reported three other studies in which sanitation and water supply had a greater effect together than individually, but the reductions in diarrhea incidence in those studies could not be calculated.

For the purpose of burden of disease calculations, therefore, the effects of water supply and sanitation improvements on diarrhea are considered here to be independent and additive, which has the advantage of simplicity.

Effect on Other Disease Categories. The first evidence for the health benefits of excreta disposal related not to its effect on diarrheal disease but on intestinal helminths.

A prolonged series of in-depth studies from 1920 to 1930 by researchers of the Rockefeller Foundation established beyond doubt that promiscuous defecation, especially in the household surroundings and particularly by children, played a major role in the transmission of *Ascaris* spp., *Trichuris* spp., and hookworms in a range of settings from Panama to China and the southeastern United States. By implication, the use of sanitary toilets should interrupt transmission by that route.

However, more recent attempts to measure the reductions in parasite prevalence or intensity attributable to improved sanitation have often suffered from the same shortcomings as the studies of their impact on diarrheal disease; many have been cross-sectional studies and, therefore, subject to confounding.

Esrey and others (1991), in reviewing this literature, found that water supply and sanitation reduced the prevalence of ascariasis by a median of 28 percent (range 0 to 83 percent) and of hookworm infection by 4 percent (0 to 100 percent). Those reductions are likely caused by the sanitation rather than by the water-supply improvements. Indeed, three of the nine positive studies of ascariasis and three of the five positive studies of hookworm involved sanitation alone. It is also likely that the effect of excreta disposal on *Trichuris* infection is similar to that on ascariasis (Henry 1981).

Much emphasis has been placed in recent years on chemotherapy as a control intervention for intestinal helminths, particularly the chemotherapy of schoolchildren. However, that option is not always sustainable because the children are quickly reinfected by the eggs and larvae that remain in the environment. Sanitation, particularly school sanitation, has been adopted by the major international donor

agencies as an integral component of the FRESH (Focusing Resources on Effective School Health) framework to ensure its sustainability.

A study in Bangladesh (Mascie-Taylor and others 1999) suggested that chemotherapy was more cost-effective (though less effective) as a helminth control intervention than a health education program that included the promotion of sanitation. However, the health education program was excessively labor intensive and, therefore, expensive; it involved the constant deployment of six health educators and a supervisor in each study area of only 550 households, resulting in a cost of Tk 1600 (US\$30) per household, compared with Tk 330 (US\$6) per year for chemotherapy. That cost compares with the total cost of US\$8 per family for WaterAid's successful "100 percent sanitation" approach in rural Bangladesh (Allan 2003). Whereas the promotion of sanitation is a one-time cost, the cost of chemotherapy is a recurrent annual expenditure. Allowing for such a sanitation promotion initiative once every five years—and using the chemotherapy costing of Mascie-Taylor and others (1999)—sanitation promotion is more cost-effective against helminths in Bangladesh than is chemotherapy. If the cost were apportioned between the effect on diarrheal disease and the effect on helminths, sanitation would be far more cost-effective than chemotherapy.

Sanitation can also help prevent trachoma. More than 70 percent of the incidence of this infection has been shown to be caused by flies, mainly of the species *Musca sorbens*, which breeds preferentially in scattered human feces. Pit latrines have been shown to reduce the population of these flies by depriving them of their breeding sites (Emerson and others 2004).

HYGIENE PROMOTION

To a greater degree than with water supply and sanitation, lamentably little reliable evidence exists on the cost or the effectiveness of interventions to change hygiene behavior and still less on the relative cost-effectiveness of different approaches to the design of such interventions.

The Shortage of Evidence

With regard to effectiveness, Loevinsohn (1990) reviewed health education interventions in developing countries and applied four relatively modest criteria of scientific rigor to the 67 published studies he found:

- a description of the intervention in sufficient detail to allow its replication
- an objective outcome measure, based either on health status or on behavior change
- a control group and a sample size greater than two clusters or 60 individuals

- a description of the target population (in terms of their level of education and other factors) adequate to permit a judgment of the relevance of the study to other contexts.

Only three studies were found to meet all four criteria. One (Stanton and Clemens 1987) dealt with environmental hygiene promotion and raises some doubts—although the hygiene behavior of the intervention group was better than the control, both were significantly worse than they had been before the intervention.

A subsequent review of 31 studies (Cave and Curtis 1999) found 5 more studies that could be considered methodologically sound, but none showed a clear effect on behavior. Of a further 11 studies of "reasonable" rigor, only two showed a major effect on behavior.

Shortcomings also exist in the cost data. Many costings are based on budget forecasts and not on real expenditures. Even when actual expenditures are used, major difficulties exist in apportioning the overhead costs that make up a significant proportion of the total. Health educators and the resources they use (such as vehicles) are rarely dedicated exclusively to health education. A further problem in the derivation of unit costs is agreeing on the denominator, which can be the number of people attending health education sessions, the number of members in their households, or the number of people in the target catchment area. For those reasons, different analysts are likely to derive different unit costs from the same data; indeed, the same authors have on occasion arrived at widely differing unit cost figures from the same data.

Time adds a further dimension to this discussion. Do interventions to promote hygiene behavior change have to be implemented continuously, or at least annually, if their effect is to be sustained, or are such changes self-sustaining?

Sustainability

We will take the last question first. Wilson and Chandler (1993) returned after two years to a population in which a four-month intervention to promote hand washing with soap had included provision of free soap. They found that 79 percent of mothers, the original target group, had continued the practice despite the fact that they now had to buy the soap.

Further evidence of the sustainability of new hygiene behaviors was found by Cairncross and Shordt (2003) in a collaborative study with partner organizations in six developing countries in Africa and South Asia. Target populations of previous hygiene promotion projects were visited at 12-month intervals, and various indicators of hygiene behavior were assessed and compared. In four of the six countries, indicators for populations in which the intervention had ended relatively recently were also compared with those in areas where the last intervention had ended several years previously. Those two

types of comparison, with the various indicators assessed in each country, allowed a total of 46 comparisons to be made. Only in three such comparisons was there any indication of a falling-off of hygiene with time since the intervention ended; in one case, the falling-off was attributable to the deteriorating condition of the latrines from wear and tear rather than to a decline in compliance.

In some cases, new hygiene practices have become stronger or more prevalent after the ending of external intervention to promote them, as they become self-propagating and consolidated in the community's material culture (Allan 2003).

It is likely that hygiene promotion activities need to be repeated from time to time—say, every five years—but are not required on a continuous basis. It follows from this observation that calculations of cost-effectiveness should take into account the morbidity and mortality averted not only during the implementation of the intervention, but also for a number of years—perhaps five—thereafter.

Costs

Cases in which the costs as well as the effectiveness of hygiene promotion programs have been documented objectively are few indeed. In the absence of suitable data, Varley, Tarvid, and Chao (1998) calculated a costing for a typical program from first principles, arriving at a cost of US\$3 (range US\$2 to US\$3) per household per year, or US\$0.60 per capita.

One of the few cases in which data exist is a program in urban Burkina Faso described by Borghi and others (2002). Their data show that the total cost to the provider of the three-year intervention was US\$0.65 per capita, or US\$4.54 per seven-person household, after deducting the cost of the international research component. Of this total, 63 percent is composed of administration and undifferentiated start-up costs of the project. Most of the remaining costs were accounted for in roughly equal measure by house-to-house visits, discussions in health centers, hygiene lessons in schools, and street theater presentations.

Additional costs were incurred by the 18.5 percent of households that complied, practicing improved hygiene as a result of the program, amounting to US\$8 per household per year. More than 90 percent of that sum was the cost of soap for hand washing.

However, on the basis of the observed increase in prevalence of hand washing with soap, the intervention was estimated to have averted sufficient diarrhea morbidity and mortality to save US\$2.80 per household per year (US\$15 per compliant household per year) in direct costs of medical care and indirect costs attributable to lost productivity. Of this total, 93 percent represented the lost future productivity associated with the deaths of young children.

Waterkeyn (2003) provides an example from rural Zimbabwe. In the two districts in which the Community

Health Clubs approach was examined, it was successful in increasing the prevalence of hand washing with soap among the club members by 6 percent and 37 percent, respectively, and it was successful in reducing the prevalence of open defecation by 29 percent and 98 percent, respectively. The marginal cost of the intervention, which used existing health staff, was US\$4.00 per club member, or an average of US\$0.67 per member of an affected household. Including the salaries of staff members would roughly double the figure to about US\$1.40 per capita.

Those figures can be compared with an estimate of US\$5.00 per mother (in 1982 dollars) by Phillips and others (1987) based on a review of several programs. Assuming that roughly 1 in 10 members of the population are mothers of young children, this cost is equivalent to about US\$0.50 per capita. For cost-effectiveness analysis, a nominal cost of US\$1.00 per capita is, therefore, taken because it is roughly the midpoint of the range of recent estimates.

Effect on Diarrhea

Esrey and others (1991) found only six studies of the effect of hygiene promotion interventions on diarrhea morbidity, with a median reduction of 33 percent. A subsequent review by Huttly, Morriss, and Pisani (1997) arrived at a similar result—a median reduction of 35 percent.

The interventions promoting the single hygiene practice of washing one's hands with soap tended to achieve greater reductions in disease than those that promoted several different behaviors. That finding was confirmed by a systematic review of the literature on hand washing (Curtis and Cairncross 2003), which concluded that hand washing with soap—and interventions to promote it—could reduce diarrhea morbidity by 43 percent and life-threatening diarrhea by 48 percent. Because the effect of diarrhea prevention in DALYs is mainly attributable to the prevention of diarrhea deaths, the higher of these two figures is more appropriate for calculating the effect of hygiene promotion on the burden of disease.

It is not surprising that interventions advocating more behavior changes should have less effect, because numerous messages dilute one another in the minds of the target audience. Because some of the interventions in the systematic review were planned without an adequate prior program of formative research, it is possible that they could have had a still greater effect if they were better conceived.

Effect on Respiratory Infections

Reasons exist to believe that hand washing with soap could be a cost-effective intervention not only against diarrheal diseases, but also for the prevention of acute respiratory infections (ARIs). The intervention is plausible, given what is known about the transmission routes of ARIs, and there is also

epidemiological evidence, in that all six published studies of the effect of hand washing on ARIs show a significant reduction (Cairncross 2003b).

These two disease groups are the most important causes of child mortality worldwide, and respiratory infections also cause significant adult mortality, for which no alternative preventive intervention is yet available, field-tested, and ready for implementation. A randomized, controlled trial of the efficacy of hand-washing promotion on an ARI outcome is an urgent priority for future research.

Interactions with Water Supply and Sanitation

It can be argued that there is little point in encouraging people to wash their hands if they do not have access to water or to use a latrine if they do not have one.

The argument has only limited validity where sanitation is concerned; an important role for any hygiene promotion is to promote sanitation itself. With regard to water, in the studies reviewed by Curtis and Cairncross (2003), the reductions in disease achieved by hand washing in settings with indoor piped water supply were not significantly different from those achieved elsewhere. Given that the rationale is ambivalent and the evidence inconclusive, the simplest plausible assumption is that the effects of water supply, sanitation, and hygiene promotion on diarrhea are independent and additive to one another.

EFFECT ON BURDEN OF DISEASE

The effect of water supply, sanitation, and hygiene on the global burden of disease can now be estimated, in two stages. First, the evidence presented in this chapter is used to arrive at the reductions in diarrhea that are expected to result from the various combinations and levels of service and that are assumed for the calculation. Then, these figures are applied to the coverage levels for individual countries and the burden of diarrheal disease prevailing in the different regions of the world. Because such a calculation has been done before by Prüss and others (2002) from rather different premises, it was desirable to examine the comparability of the results.

Assumptions: Reductions in Diarrheal Disease

In summary of the discussion of health effects in this chapter, water supply, sanitation, and hygiene promotion are considered to be associated, under typical conditions, with the reductions in diarrheal disease morbidity shown in table 41.7. These reductions are considered to be independent of one another, so that the relative risks for several interventions can be multiplied.

Table 41.7 Assumed Reductions in Diarrhea Attributable to Water Supply, Sanitation, and Hygiene Promotion

Intervention	Reduction in diarrhea (percent)	Corresponding relative risk
Water supply		
Public source	17	1.20
Additional, for house connection	63	2.70
Excreta disposal	36	1.56
Hygiene promotion	48	1.92

Source: Authors.

These assumptions can be compared as follows with the assumptions underlying a previous calculation of the global burden of disease from water, sanitation, and hygiene (Prüss and others 2002; WHO 2002). For that calculation, the following seven scenarios were considered:

- VI. No improved water supply or basic sanitation
- Va. Basic sanitation only
- Vb. Improved water supply only
- IV. Improved water supply and basic sanitation
- III. Improved water supply and basic sanitation plus house connection water supply, or improved hygiene or water disinfected at point of use
- II. “Regulated” water supply (presumably house connection) and full sanitation
- I. Ideal situation, corresponding to absence of disease transmission through water, sanitation, and hygiene.

Scenario II is essentially the position prevailing in industrial countries. Leaving out scenarios I and III, which apply to only a small proportion of the population, the following scenarios are broadly equivalent to the categories considered earlier in this chapter:

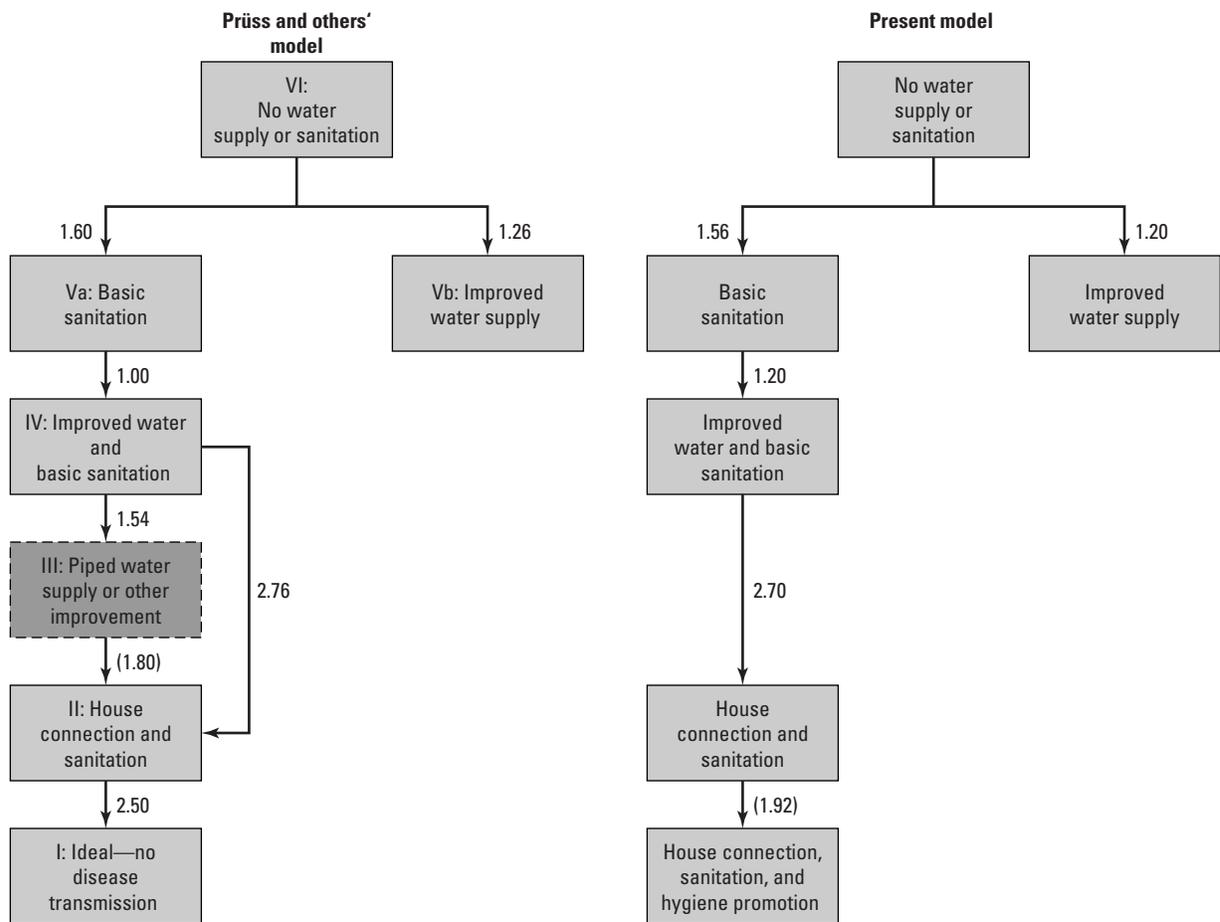

- VI. No improved water or sanitation
- Va. Sanitation only
- Vb. Improved water supply (public source)
- IV. Both improved water supply and sanitation
- II. House connection water supply, and sanitation.

In the Prüss model, the relative risks associated with transition from scenarios Va and Vb to VI are taken as 1.26 and 1.60, respectively, comparable with the figures of 1.20 and 1.56 in table 41.7. However, Prüss and others (2002) assume equal risks in scenarios IV and Va, whereas a relative risk of 1.20 follows from the assumption in this chapter that the effects of water supply and sanitation are independent. The Prüss model assumes a relative risk of 1.54 between scenarios III and IV, corresponding to the diarrhea reduction of 35 percent from

hygiene promotion found by Huttly, Morriss, and Pisani (1997). Scenario III is essentially a theoretical construct, and between it and scenario II a further relative risk of 1.8 is assumed (in what Prüss and others term their *realistic approach*), on the basis of some recent trials of home disinfection of water, giving a total of 2.76 between scenarios IV and II. The latter figure is close to the corresponding value of 2.70 implied by the assumptions made here, for different reasons. Scenario I, like scenario III, is included not because it is prevalent in reality, but to illustrate a point. Its equivalent would be the generalized and effective implementation of a well-conceived hygiene promotion intervention. Because such hygiene promotion has hardly ever been provided to whole populations, it is similarly hypothetical. From that perspective, the corresponding relative risks of 2.5 (Prüss and others 2002) and 1.92 (table 41.7) are of a similar order of magnitude.

The similarity of the two sets of assumptions, based on rather different premises, is illustrated in figure 41.3.

To allow for the uncertainty in their assumptions, Prüss and others (2002) calculated the burden of disease attributable to water supply, sanitation, and hygiene using two approaches. The *realistic approach* used the assumptions described above and shown in figure 41.3. The *minimal approach* assumed no difference in risk between scenarios II and III. Given the ideal and hypothetical nature of scenario I and the low probability of intensive hygiene promotion being funded for a population that already benefits from high levels of water supply and sanitation provision, we consider the model on the right of figure 41.3 as *optimistic* and prefer to take for our more *realistic* approach the less ambitious baseline of house connections and full sanitation, which approximates the current position in most of Western Europe and North America. This approach responds to recent calls for “baselines and counterfactuals which should include alternative, operationalizable policy/program options (including the status quo)” (Ezzati 2003, 458). It also has the advantage of providing an estimate of burden of

Note: The numbers show relative risk of diarrhea in upper relative to lower boxes. Relative risks in parentheses are set to 1.0 for the minimal version of the Prüss model and for the realistic version of the present model.

Figure 41.3 Comparison of Assumptions Made by Prüss and others (2002) and in this chapter.

disease to which the industrial countries contribute only a negligible amount.

Calculation of Burden of Disease

Prüss and others (2002) worked with water and sanitation coverage data for individual countries (WHO and UNICEF 2000) to derive distributions of the population in each region between five of the seven scenarios, as shown in table 41.8. They then combined these figures with the relative risks in figure 41.3 and diarrhea incidence and case fatality rates from Murray and Lopez (1996) to derive estimates of the number of DALYs attributable to water supply, sanitation, and hygiene in each region and mortality subregion. The results are shown, for their realistic and minimal models, in the first two columns of table 41.9. The realistic estimates are those presented in the *World Health Report 2002* (WHO 2002, 225).

Using the same spreadsheets but the relative risks on the right of figure 41.3, we derive the results in the third and fourth columns of table 41.9 for the optimistic and realistic versions of

the present model. The figures for the burden of disease attributable to deficient water supply, sanitation, and hygiene in the industrial countries of Europe, North America, and the Pacific are very different, but the global totals are remarkably similar.

It should be no surprise to find that the attributable burden in the industrial (that is, low-mortality) countries of Europe, North America, and the Pacific is zero or very close to zero. The realistic model was deliberately designed to take as its baseline the conditions prevailing in those countries. This finding does not mean that no diarrheal disease in those countries can be attributed to deficient water supply, sanitation, or hygiene; rather, it means that the baseline there is the current condition, because no realistic policy option is available to reduce the burden of such disease in the immediate future.

Table 41.10 shows the two realistic assessments of DALYs attributable to water supply, sanitation, and hygiene in terms of percentages of the total DALYs in each region and subregion. Again, the two estimates are close. The proportion of the total disease burden attributable to water, sanitation, and hygiene is greatest in the high-mortality countries of the Eastern

Mediterranean region, reaching 6 to 7 percent of the total. They are followed by the high-mortality countries of Southeast Asia and Africa, where the water and sanitation complex accounts for 4 to 5 percent of the total. Globally, improvements in water supply, sanitation, and hygiene could eliminate 3 to 4 percent of the global burden of disease.

Cost-Effectiveness

The assumptions regarding effect on diarrheal disease are summarized in table 41.7. Because the effect on diarrheal disease accounts for the vast majority of the effect, no effort is made to apportion the costs between their effectiveness in preventing the other diseases affected by water supply, sanitation, and hygiene. The costs derived in this chapter are summarized in table 41.11.

The annual costs used for water supply included both the amortized construction cost and operation and maintenance costs. Given that investments in water supply and sanitation are made largely by other sectors (and for other motives) than health, an alternative cost-effectiveness estimate is made that is based only on the costs of regulation, advocacy, and promotion.

The other assumptions used to calculate the cost-effectiveness of improved water supply—of house connections, of sanitation, and of hygiene promotion—other than those set out above, are as described by Varley, Tarvid, and Chao (1998). The key parameters are as follows:

- proportion of population under age five: 17 percent
- diarrhea incidence: five cases per child under age five per year

Table 41.10 DALYs Due to Diarrhea Attributable to Poor Water Supply, Sanitation, and Hygiene by Subregion, as a Percentage of Total DALYs

Source: See Acknowledgments.

- median age at onset of disease: 1 year
- average duration: 8 days
- case fatality rate: 0.5 percent
- coverage by oral rehydration therapy: 30 percent
- oral rehydration therapy reduction in case fatality rate: 50 percent

On this basis, we arrived at the cost-effectiveness values in table 41.12.

All of these figures underestimate the cost-effectiveness of investments in water and sanitation, for several reasons:

- The effects of these interventions on diseases other than diarrhea have not been taken into account; they seem to be relatively minor for water supply but may be substantial if hand washing proves to affect ARI.
- Effects on diarrhea mortality, which account for 98 percent of the DALYs, are likely to be greater than the reductions in morbidity shown in table 41.7.
- The cost figures have generally been taken so as to be sufficient for all contexts, whereas water supply and sanitation can be implemented more cheaply in favorable settings—such as where a convenient aquifer or reliable rainfall exists.
- Potential economies exist in combining the interventions; for example, sanitation promotion can be combined with hygiene promotion and water pipes laid with sewers.
- The current global initiative to promote hand washing, involving commercial marketing expertise, may identify more cost-effective approaches to hygiene promotion.
- If a sustainable low-cost sanitation industry can be developed, it will have an interest in promoting its own product.

As they stand, the cost-effectiveness values above, except for house connections and construction of latrines, are well below the US\$150/DALY cutoff value proposed by the World Bank

Table 41.11 Costs Assumed for Cost-Effectiveness Calculations (US\$ per capita)

Intervention	Construction cost (US\$ per capita)	Amortization lifetime (years)	Amortized annual cost (US\$ per capita)	Operation and maintenance cost (US\$ per capita)
Water supply				
House connections	150.00	20	7.50	10.00
Hand pump or standpost	40.00	20	1.00	1.00
Water regulation and advocacy				
Sanitation	≤60.00	5	≤12.00	n.a.
Sanitation promotion	2.50	5	0.50	n.a.
Hygiene promotion	1.00	5	0.20	n.a.

(1993) as a criterion of cost-effectiveness. Allowing only for the cost component that should fall to the health sector puts them all well within this ceiling. For comparison, the cost-effectiveness of promoting oral rehydration therapy, the principal other measure available to prevent diarrhea mortality, has been estimated at US\$23/DALY. The cost-effectiveness of promoting sanitation and hygiene as derived above (US\$11.15 and US\$3.35, respectively, per DALY) compares favorably with that figure.

ACKNOWLEDGMENTS

The calculations of the burden of disease were made by Dr. D. Campbell-Lendrum, using spreadsheets derived by Annette Prüss-Üstün. Their collaboration is gratefully acknowledged.

Indoor Air Pollution

Nigel Bruce, Eva Rehfuess, Sumi Mehta, Guy Hutton,
and Kirk Smith

Access to modern energy sources has been described as a “necessary, although not sufficient, requirement for economic and social development” (IEA 2002). It is, therefore, of great concern that almost half the world’s population still relies for its everyday household energy needs on inefficient and highly polluting solid fuels, mostly biomass (wood, animal dung, and crop wastes) and coal.

The majority of households using solid fuels burn them in open fires or simple stoves that release most of the smoke into the home. The resulting indoor air pollution (IAP) is a major threat to health, particularly for women and young children, who may spend many hours close to the fire. Furthermore, the reliance on solid fuels and inefficient stoves has other, far-reaching consequences for health, the environment, and economic development.

NATURE, CAUSES, AND BURDEN OF CONDITION

About 3 billion people still rely on solid fuels, 2.4 billion on biomass, and the rest on coal, mostly in China (IEA 2002; Smith, Mehta, and Feuz 2004). There is marked regional variation in solid fuel use, from less than 20 percent in Europe and Central Asia to 80 percent and more in Sub-Saharan Africa and South Asia.

This issue is inextricably linked to poverty. It is the poor who have to make do with solid fuels and inefficient stoves, and many are trapped in this situation: the health and economic consequences contribute to keeping them in poverty, and their poverty stands as a barrier to change. Where socioeconomic circumstances improve, households generally move up the

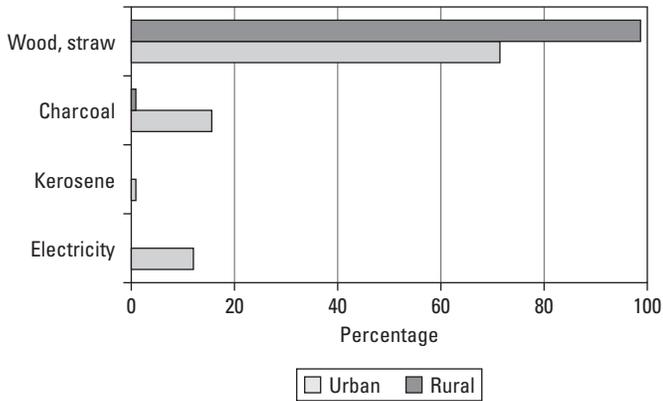

energy ladder, carrying out more activities with fuels and appliances that are increasingly efficient, clean, convenient, and more expensive. The pace of progress, however, is extremely slow, and for the poorest people in Sub-Saharan Africa and South Asia, there is little prospect of change.

Illustrated in figures 42.1 and 42.2 are findings for Malawi and Peru, respectively, from Demographic and Health Surveys (ORC Macro 2004). The examples are selected from available national studies with data on main cooking fuel use to represent the situation in poor African and South American countries. The main rural and urban cooking fuels are illustrated in figures 42.1a and 42.2a; the findings are then broken down nationally by level of education of the principal respondent (woman of childbearing age) in figures 42.1b and 42.2b, and in urban areas by her level of education in figures 42.1c and 42.2c.

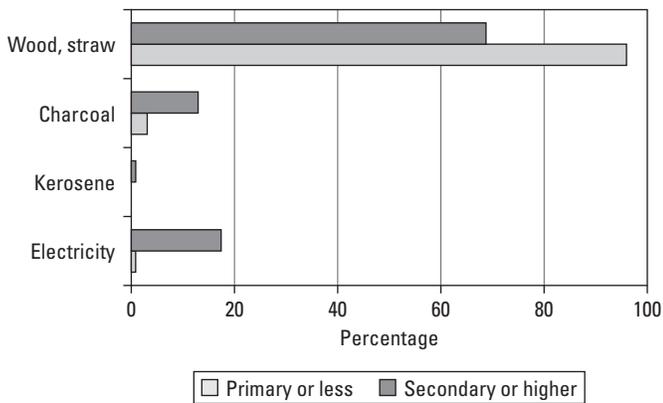

Biomass is predominantly, though not exclusively, a rural fuel: indeed, in many poor African countries, biomass is the main fuel for close to 100 percent of rural homes. Marked socioeconomic differences (indicated by women’s education) exist in both urban and rural areas. During the 1990s, use of traditional fuels (biomass) in Sub-Saharan Africa increased as a percentage of total energy use, although in most other parts of the world the trend has generally been the reverse (World Bank 2002).

In many poorer countries, the increase in total energy use accompanying economic development has occurred mainly through increased consumption of modern fuels by better-off minorities. In Sub-Saharan Africa, however, the relative increase in biomass use probably reflects population growth in rural and poor urban areas against a background of weak (or negative) national economic growth. Reliable data on trends in

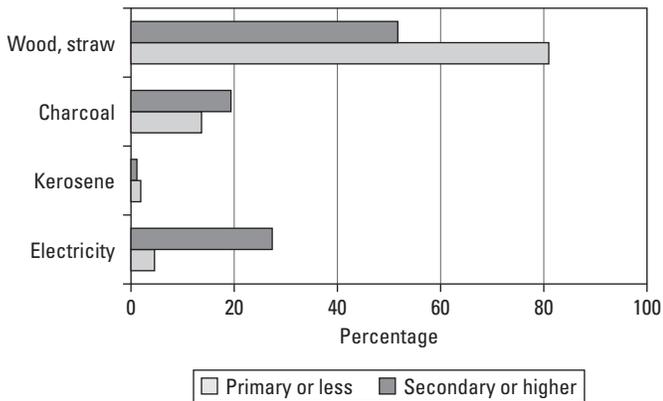

a. Primary household fuel use in urban and rural areas

b. Primary household fuel use, by level of education of respondent

c. Primary household fuel use in urban areas, by level of education of respondent

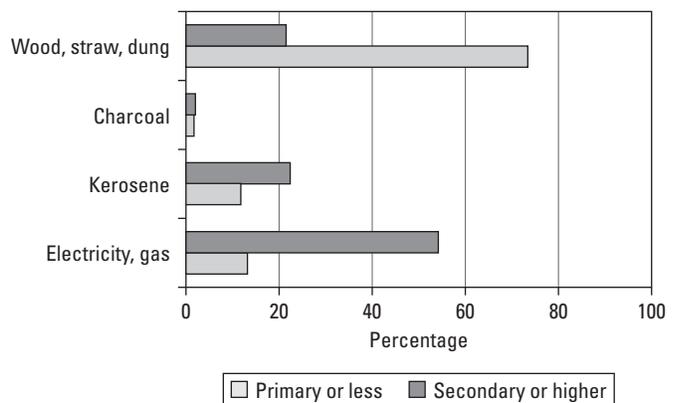

Figure 42.1 Patterns of Household Fuel Use in Malawi, 2000

household energy use are not available for most countries. Information is available from India, where the percentage of rural homes using firewood fell from 80 percent in 1993–94 to 75 percent in 1999–2000 (D’Sa and Narasimha Murthy 2004). Nationally, liquid petroleum gas (LPG) use increased from 9 to 16 percent over the same period, with a change from 2 percent

to 5 percent in rural areas, and it is expected to reach 36 percent nationally and 12 percent for rural homes by 2016. International Energy Agency projections to 2030 show that, although a reduction in residential biomass use is expected in most developing countries, in Africa and South Asia the decline will be small, and the population relying on biomass will

increase from 2.4 billion to 2.6 billion, with more than 50 percent of residential energy consumption still derived from this source (OECD and IEA 2004). The number of people without access to electricity is expected to fall from 1.6 billion to 1.4 billion. Because electricity is used by poor households for lighting and not as a cleaner substitute for cooking, electrification will not, at least in the short to medium term, bring about substantial reductions in IAP.

Levels of Pollution and Exposure

Biomass and coal smoke emit many health-damaging pollutants, including particulate matter (PM),¹ carbon monoxide (CO), sulfur oxides, nitrogen oxides, aldehydes, benzene, and polyaromatic compounds (Smith 1987). These pollutants mainly affect the lungs by causing inflammation, reduced ciliary clearance, and impaired immune response (Bruce, Perez-Padilla, and Albalak 2000). Systemic effects also result, for example, in reduced oxygen-carrying capacity of the blood because of carbon monoxide, which may be a cause of intrauterine growth retardation (Boy, Bruce, and Delgado 2002). Evidence is emerging, thus far only from developed countries, of the effects of particulates on cardiovascular disease (Pope and others 2002, 2004).

Saksena, Thompson, and Smith (2004) have recently compiled data on several of the main pollutants associated with various household fuels from studies of homes in a wide range of developing countries. Concentrations of PM₁₀, averaged over 24-hour periods, were in the range 300 to 3,000 (or more) micrograms per cubic meter ($\mu\text{g}/\text{m}^3$). Annual averages have not been measured, but because these levels are experienced almost every day of the year, the 24-hour concentrations can be taken as a reasonable estimate. By comparison, the U.S. Environmental Protection Agency's annual air pollution standard for PM₁₀ is 50 $\mu\text{g}/\text{m}^3$, one to two orders of magnitude lower than levels seen in many homes in developing countries. During cooking, when women and very young children spend most time in the kitchen and near the fire, much higher levels of PM₁₀ have been recorded—up to 30,000 $\mu\text{g}/\text{m}^3$ or more. With use of biomass, CO levels are generally not as high in comparison, typically with 24-hour averages of up to 10 parts per million (ppm), somewhat below the World Health Organization (WHO) guideline level of 10 ppm for an eight-hour period of exposure. Much higher levels of CO have been recorded, however. For example, a 24-hour average of around 50 ppm was found in Kenyan Masai homes (Bruce and others 2002), and one Indian study reported carboxyhemoglobin levels similar to those for active cigarette smokers (Behera, Dash, and Malik 1988). The health effects of chronic exposure of young children and pregnant women to levels of CO just below current WHO guidelines have yet to be studied. For additional information on levels of other pollutants in

biomass and coal smoke, see Saksena, Thompson, and Smith (2004).

Fewer studies of personal exposure have been done than of area pollution, mainly because measurement of personal PM typically requires wearing a pump, a cumbersome procedure. CO can be measured more easily and has been used as a proxy: time-weighted (for example, 24-hour average) CO correlates well with PM if a single main biomass stove is used (Naeher and others 2001). Time-activity and area pollution information can also be combined to estimate personal exposure (Ezzati and Kammen 2001). These various methods indicate that personal 24-hour PM₁₀ exposures for cooks range from several hundred $\mu\text{g}/\text{m}^3$ to more than 1,000 $\mu\text{g}/\text{m}^3$ (Ezzati and Kammen 2001), with even higher exposures during cooking (Smith 1989). Few studies have measured personal PM exposures of very young children: one study in Guatemala found levels a little lower than those of their mothers (Naeher, Leaderer, and Smith 2000).

Health Impacts of IAP

A systematic review of the evidence for the impact of IAP on a wide range of health outcomes has recently been carried out (Smith, Mehta, and Feuz 2004; see table 42.1). This review identified three main outcomes with sufficient evidence to include in the burden-of-disease calculations and a range of other outcomes with as yet insufficient evidence.

Studies for the key outcomes used in the burden-of-disease calculations—acute lower respiratory infection (ALRI), chronic obstructive pulmonary disease (COPD), and lung cancer—had to be primary studies (not reviews or reanalyses), written or abstracted in English (and for lung cancer, Chinese), that reported an odds ratio and variance (or sufficient data to estimate them) and provided some proxy for exposure to indoor smoke from the use of solid fuels for cooking and heating purposes.

A limitation of almost all studies has been the lack of measurement of pollution or exposure: instead, proxy measures have been used, including the type of fuel or stove used, time spent near the fire, and whether the child is carried on the mother's back during cooking. The studies do not, therefore, provide data on the exposure-response relationship, although a recent study from Kenya has gone some way to addressing this omission (Ezzati and Kammen 2001).

In some countries, household fuels carry locally specific risks. It has been estimated that more than 2 million people in China suffer from skeletal fluorosis, in part resulting from use of fluoride-rich coal (Ando and others 1998). Arsenic, another contaminant of coal, is associated with an increased risk of lung cancer in China (Finkelman, Belkin, and Zheng 1999). There has been concern, however, that reducing smoke could increase risk of vectorborne disease, including malaria. Some

Table 42.1 Status of Evidence Linking Biomass Fuels and Coal with Child and Adult Health Outcomes

Health outcome	Age	Status of evidence
<i>Sufficient evidence for burden-of-disease calculation</i>		
Acute lower respiratory infections	Children < 5 years	<i>Strong.</i> Some 15–20 observational studies for each condition, from developing countries. Evidence is consistent (significantly elevated risk in most though not all studies); the effects are sizable, plausible, and supported by evidence from outdoor air pollution and smoking.
Chronic obstructive pulmonary disease	Adult women	
Lung cancer (coal exposure)	Adult women	
Chronic obstructive pulmonary disease	Adult men	<i>Moderate-I.</i> Smaller number of studies, but consistent and plausible.
Lung cancer (coal exposure)	Adult men	
<i>Not yet sufficient evidence for burden-of-disease calculation</i>		
Lung cancer (biomass exposure)	Adult women	<i>Moderate-II.</i> Small number of studies, not all consistent (especially for asthma, which may reflect variations in definitions and condition by age), but supported by studies of outdoor air pollution, smoking, and laboratory animals.
Tuberculosis	Adult	
Asthma	Child and adult	
Cataracts	Adult	
Adverse pregnancy outcomes	Perinatal	<i>Tentative.</i> Adverse pregnancy outcomes include low birthweight and increased perinatal mortality. One or a few studies at most for each of these conditions, not all consistent, but some support from outdoor air pollution and passive-smoking studies.
Cancer of upper aerodigestive tract	Adult	
Interstitial lung disease	Adult	
Ischemic heart disease	Adult	Several studies from developed countries have shown increased risk for exposure to outdoor air pollution at much lower levels than IAP levels seen in developing countries. As yet, no studies from developing countries.

Source: Smith, Mehta, and Feuz 2004.

studies have shown that biomass smoke can repel mosquitoes and reduce biting rates (Palsson and Jaenson 1999; Paru and others 1995; Vernede, van Meer, and Alpers 1994). Few studies have examined the impact of smoke on malaria transmission: one from southern Mexico found no protective effect of smoke (adjusted odds ratio 1.06 [0.72–1.58]; Danis-Lozano and others 1999), and another from The Gambia found that wood smoke did not protect children in areas of moderate transmission (Snow and others 1987).

Method Used for Determining Attributable Disease Burden

Smith, Mehta, and Feuz (2004) have provided a full explanation of the calculation of the disease burden associated with IAP. Summarized here are the methods they used to estimate the two most critical components of these calculations: the number of people exposed and the relative risks.

Exposure. The absence of pollution or exposure measurement in health studies required use of a binary classification: the use or nonuse of solid fuels. The authors obtained estimates of solid fuel use for 52 countries from a range of sources, mostly household surveys, and statistical modeling was used for countries with no data (the majority) (Smith, Mehta, and Feuz 2004). They assumed, conservatively, that all

countries with a 1999 per capita gross national product (GNP) greater than US\$5,000 had made a complete transition either to electricity or cleaner liquid and gaseous fuels or to fully ventilated solid fuel devices. To account for differences in exposure caused by variation in the quality of stoves, they applied a *ventilation factor* (VF), set from 1 for no ventilation to 0 for complete ventilation. In China, a VF of 0.25 was used for child health outcomes and 0.5 for adult outcomes, reflecting a period of higher exposure (to open fires) before the widespread introduction of chimney stoves. Countries with a 1999 GNP per capita greater than US\$5,000 were assigned a VF of 0, and all other countries a value of 1, reflecting the very low rates of use of clean fuels or effective ventilation technologies. The authors obtained the final point estimate for exposure by multiplying the percentage of solid fuel use by the VF. They arbitrarily assigned an uncertainty range of ± 5 percent to the estimates.

Risk. Smith, Mehta, and Feuz (2004) carried out meta-analyses for the three health outcomes with sufficient evidence (table 42.2). They used fixed-effects models and sensitivity analysis that took account of potential sources of heterogeneity, including the way in which exposure was defined and whether adjustment had been made for confounders (Smith, Mehta, and Feuz 2004).

Table 42.2 Summary of Relative Risk Estimates for Health Outcomes Used in Burden-of-Disease Estimates

Health outcome	Age and sex group	Number of studies	Relative risk	95 percent confidence interval
ALRI	Children < 5 years	8	2.3	1.9–2.7
COPD	Women > 30 years	8	3.2	2.3–4.8
	Men > 30 years ^a	2	1.8	1.0–3.2
Lung cancer (coal)	Women > 30 years	9	1.9	1.1–3.5
	Men > 30 years	3	1.5	1.0–2.5

Sources: Smith, Mehta, and Feuz 2004.

a. Because of the limited quantity and quality of available evidence, the male COPD relative risk and range have been fixed to include 1.0 (no effect) as the lower estimate.

The Burden of Disease from Solid Fuel Use

Information on the proportions exposed and risk of key disease outcomes was combined with total burden-of-disease data to obtain the population attributable fractions associated with IAP (WHO 2002b). Globally, solid fuels were estimated to account for 1.6 million excess deaths annually and 2.7 percent of disability-adjusted life years (DALYs) lost, making them the second most important environmental cause of disease, after contaminated water, lack of sanitation, and poor hygiene (table 42.3). Approximately 32 percent of this burden (DALYs) occurs in Sub-Saharan Africa, 37 percent in South Asia, and 18 percent in East Asia and the Pacific. In developing countries with high child and adult mortality, solid fuel use is the fourth most important risk factor behind malnutrition, unsafe sex, and lack of water and sanitation, and it is estimated to account for 3.7 percent of DALYs lost (WHO 2002b).

Overall, there are more female deaths but similar numbers of male and female DALYs (table 42.3b). The reason can be found by looking further at the health outcomes. Deaths and DALYs from ALRI in children under five years of age are slightly greater for males (table 42.3c). Women experience twice the DALYs and three times the deaths from COPD (male smoking-attributable COPD deaths excluded). Far fewer cases of lung cancer are attributable to IAP, but women experience about three times the burden of men.

Table 42.3 also shows how the poorest regions of the world carry by far the greatest burden, particularly for ALRI. More than half of all the deaths and 83 percent of DALYs lost attributable to solid fuel use occur as a result of ALRI in children under five years of age. In high-mortality areas, such as Sub-Saharan Africa, these estimates indicate that approximately 30 percent of mortality and 40 percent of morbidity caused by ALRI can be attributed to solid fuel use, as can well over half of the deaths from COPD among women. Because they derive from WHO risk assessments, these estimates include age weights, such that years of life lost at very young or advanced

ages count less than years lost in the prime of adult life. Age weighting makes little difference to the DALYs lost per death up to age five; how much it affects the DALY cost of adult deaths depends on the age distribution of deaths from COPD. Because these are likely to occur at age 45 or beyond, the DALY losses are underestimated compared with estimates without age weighting that follow the usual practice in this volume.

Other Effects of Household Energy Use in Developing Countries

A number of other health impacts—for example, burns from open fires—were not assessed because the burden-of-disease assessment process allowed inclusion of only those health effects resulting directly from pollution. Children are at risk of burns and scalds, resulting from falling into open fires and knocking over pots of hot liquid (Courtright, Haile, and Kohls 1993; Onuba and Udoidiok 1987). Modern fuels are not always safe either, because children are also at risk of drinking kerosene, which is often stored in soft drink bottles (Gupta and others 1998; Reed and Conradie 1997; Yach 1994).

Families—mainly the women and children—can spend many hours each week collecting biomass fuels, particularly where environmental damage and overpopulation have made them scarce. This time could be spent more productively on child care and household or income-generating tasks. There are also risks to health from carrying heavy loads and dangers from mines, snake bites, and violence (Wickramasinghe 2001). Inefficient stoves waste fuel, draining disposable income if fuel is bought. Although women carry out most of the household activities requiring fuels, they often have limited control over how resources can be spent to change the situation (Clancy, Skutsch, and Batchelor 2003). These conditions can combine to restrict income generation from home-based activities that require fuel energy (for example, processing and preparing food for sale).

Homes that are heavily polluted and dark can hinder productivity of householders, including children doing homework and others engaged in home-based income-generating activities such as handicrafts. In many poor homes, lighting is obtained from the open fire and simple kerosene wick lamps, which provide poor light and add to pollution.

Solid fuel use has important environmental consequences. Domestic use of solid fuels in high-density rural and urban environments contributes to outdoor air pollution. Many low-income urban populations rely on charcoal, the production of which can place severe stress on forests. The use of wood as fuel can contribute to deforestation, particularly where it is combined with population pressure, poor forest management, and clearance of land for agriculture and building timber. Damage to forest cover can increase the distance traveled to obtain wood and can result in the use of freshly cut (green) wood, dung, and

Table 42.3 Deaths and DALYs Lost Because of Solid Fuel Use

twigs, which are more polluting and less efficient. In some urban communities, poverty and supply problems are resulting in the use of plastic and other wastes for household fuel (IEA 2002).

Stoves with inefficient combustion produce relatively more products of incomplete combustion, such as methane, which have a markedly higher global-warming potential than carbon dioxide (Smith, Uma, and others 2000). It has, therefore, been argued that, although the energy use and greenhouse gas emissions from homes in developing countries are small relative to the emissions generated in industrial countries, cleaner and more efficient energy systems could provide the double benefit of reduced greenhouse gas emissions (with opportunities for carbon trading) and improved health through reduced IAP (Wang and Smith 1999).

The evidence available for assessing these effects, which together could have a substantial influence on health and economic development, is patchy at best. This area is important for research (Larson and Rosen 2002).

INTERVENTIONS AND POLICY

The uses of energy in the home—for example, for cooking and keeping warm and as a focus of social activities—have important attributes that are specific to the locality, culture, and individual households and are often associated with established traditions and deeply held beliefs. Encouraging the use of cleaner and more efficient energy technologies by populations that are among the poorest in the world has not been easy, but recent years have seen progress being made with respect to suitable technology that meets the needs of households and with respect to the development of supportive policy.

Poverty Reduction and the Millennium Development Goals

Given the close relationship between socioeconomic conditions and solid fuel use, poverty reduction must be a key element of policy to alleviate IAP. The United Nations Millennium Development Goals set targets for poverty eradication, improvements in health and education, and environmental protection; they represent the accepted framework for the world community to achieve measurable progress (United Nations Statistics Division 2003). Although reducing IAP can contribute to achieving a number of these goals, it is particularly relevant to reducing child mortality (Goal 4) from ALRI.

Goal 7, Target 9, aims at integrating sustainable development into country policies and programs. The proportion of population using solid fuels has been adopted as an indicator for Target 9. Alleviating drudgery resulting from collecting fuel and using inefficient stoves, together with the involvement of

women in implementing changes, can promote gender equality and empower women (Goal 3). Household energy interventions can also contribute to eradicating extreme poverty (Goal 1) through health improvements, time saving, and better environments for education and facilitating income generation (WHO 2004a).

Interventions

Although the main focus of this chapter is IAP, the many other ways in which household energy can affect health and development emphasize why interventions should aim to achieve a range of benefits, including the following:

- reduced levels of IAP and human exposure
- increased fuel efficiency
- reduced time spent collecting fuel and using inefficient stoves
- reduced stress on the local environment
- increased opportunities for income generation
- contribution to an overall improvement in the quality of the home environment—in particular, the working environment and conditions for women.

Interventions for reducing IAP can be grouped under three headings: those acting on the *source of pollution*, those improving the *living environment* (aspects of the home), and changes to *user behaviors* (table 42.4).

It should not be assumed that an intervention that reduces IAP will necessarily achieve other aims listed previously. For example, in colder areas, an enclosed stove with a flue that reduces IAP may reduce radiant heat and light, forcing households to use other fuels for those purposes. If not addressed with households, such problems may well result in disappointing reductions in IAP exposure, poor acceptance of interventions, and lack of motivation to maintain them.

Policy Instruments

Although a range of interventions is available, poor households face many barriers to their adoption, and enabling policy is needed (table 42.5). This area of practice is complex and evolving, often requiring solutions that are highly setting specific.

INTERVENTION COSTS AND EFFECTIVENESS

The cost-effectiveness analysis discussed in this chapter is based on recent work by Mehta and Shahpar (2004). The key components of this analysis are described here, with particular emphasis on the underlying assumptions.

Table 42.4 Interventions for Reducing Exposure to IAP

Table 42.5 Policy Instruments for Promoting Implementation of Effective Household Energy Interventions

Policy instruments	Examples	Applications
Information, education, and communication	Schools	Learning about household energy, health, and development should be integrated in school curricula, particularly in countries where these topics are a priority for health and economic development. This goal can be achieved through programs such as the WHO Global School Health Initiative, which promotes environmental health education, including education about IAP.
	Media	Local and national radio, television, and newspapers can be used to raise awareness and disseminate information on technologies and opportunities to support implementation, such as promotions and microcredit. These media can be directed at a range of audiences, including decision makers, professionals, and the public where radio is widely used.
	Community education	Opportunities such as adult literacy programs can be used to raise awareness and share experience of interventions, and innovative methods can be used (for example theater).
Taxes and subsidies	Tax on fuels and appliances	Reduced tax on fuels and appliances may promote development of distribution networks and uptake, and it may be seen as efficient if there is evidence of health, education, and economic benefits.
	Subsidy on fuels and appliances	General (for example, national) subsidies on fuels such as kerosene have been applied to promote use by poor households. Subsidies have been found to be inefficient instruments, however, often benefiting the better off rather than the poor. Time-limited subsidy on specific products (for example, clean fuel appliances, connection to grid) may be a useful method for promoting initial uptake, generating demand, and thereby providing market conditions for lower prices and more consistent quality.
Regulation and legislation	Air quality standards	Although some developing countries have air quality standards for urban air, none have them for indoor air in settings where solid fuels are widely used. Routine monitoring and enforcement is not practical, but it may be useful to set standards and targets linked to specific assessments. For more routine use, information from censuses and surveys, such as fuel type, stove type, and venting for smoke, offers a practical alternative for setting air quality standards for IAP in developing countries.
	Design standards for appliances	Design standards can be applied to safety (prevention of burns, gas leaks, and explosions); venting of emissions; and efficiency. Although such standards may be difficult to enforce in an informal economy, they could become valuable with wider-scale production.
Direct expenditures	Public program provision of appliances	Large-scale public provision of appliances, such as improved stoves or clean-fuel appliances, has generally been found unsuitable. Some form of targeted provision or partial subsidy where households have made informed choices and commit to cost sharing may be useful to stimulate demand and act in favor of equity.

Table 42.5 Continued

Policy instruments	Examples	Applications
Research and development	Funding of finance schemes	Experience has shown that credit is most likely to be made available and adopted for energy applications that contribute directly to productive, income-generating activities (such as food processing for sale). Meeting everyday cooking and space-heating needs is seen as a lower priority. Good opportunities may exist where biomass fuel is purchased and where cost saving combines with other valued benefits, such as increased prestige and cleaner kitchens. Support for such schemes, mainly in the form of raising awareness, skills training in managing funds, and seed funding (the main source of funds being from users) may be cost-effective.
	Surveys	Surveys of fuel and appliance use, knowledge of risks to health, willingness to pay for interventions, knowledge of and confidence in credit schemes, and the like are important for planning interventions.
	Development and evaluation of interventions	Evaluation of interventions should be conducted in a range of settings, using harmonized methods, if possible, that allow local flexibility but permit comparison with other types of interventions and other locations.
	Studies of health effects	Stronger and better-quantified evidence of the effects on health of reducing IAP, which includes exposure measurement, is required not only for key outcomes such as ALRI, but also for other health outcomes for which evidence is currently tentative.
	Research capacity development	Capacity for carrying out a wide range of research—from national and local surveys, to monitoring and evaluation of interventions, to more complex health studies—requires strengthening in those countries where the problems associated with household energy and IAP are most pressing.

Source: Authors.

Costs

Intervention costs have a number of components, the relative importance of which will vary with the type of fuel and device (box 42.1).

The level of costs incurred by consumers and others, including government, depends not only on the type of intervention but also on how it is delivered, supplied, and adopted.

Experience indicates that successful interventions are sustainable in local markets, implying that the consumer pays the majority of initial and recurrent costs. The contributions of the government, utilities, nongovernmental organizations (NGOs), and the commercial sector will depend on many factors, including the type of intervention and fuel, location (urban or rural), existing level of supply and distribution

Box 42.1

Cost Components for Household Energy Interventions

- *Fuels*, which vary from zero (in direct cash terms, though not in opportunity cost) for collected biomass to a U.S. dollar or so per week for kerosene and several U.S. dollars per week for electricity (where used for cooking).
- *Stove appliances*, which vary from zero for a simple three-stone fire (stones arranged on the floor to support cooking pots, with the fire lit between the stones), to US\$50 (and in some cases more than US\$100) for a good-quality woodstove with a chimney and up to several hundred U.S. dollars for a bio-gas installation.
- *Additional appliances*—for example, an LPG storage bottle has a moderately high initial cost but should last for many years.
- *Maintenance costs*, which vary from zero for a three-stone fire up to modest, but not negligible, costs of repairing (and periodically replacing) woodstoves and chimneys. Appliances for using kerosene, LPG, and electricity also require maintenance and periodic replacement.
- *Program costs*, which apply to various aspects of provision of energy services, particularly LPG and electricity, but may also include costs of, for example, establishing more sustainable biomass reserves and administrative costs.

Box 42.2

Cost Issues in Switching to Cleaner Fuels for a “Typical” Poor Kenyan Family

Ruth¹ and her family live 3 kilometers from a small town on the main road about one hour by bus from Kisumu. They are subsistence farmers, with a small income from selling vegetables, from irregular laboring work obtained by her husband, and from making and selling handicrafts. Ruth, a mother of five, cooks over a three-stone fire using mostly wood, which she collects every other day from plots up to two hours walking distance from home. She spends 8 to 12 hours each week collecting wood. Ruth and her family use about 2 liters of kerosene each week for wick lamps and for cooking. They use dry cell batteries for the radio; grid electricity runs nearby, but connection is far too expensive. In all, the family spends an equivalent of US\$1 to US\$2 per week on fuel and batteries.

Through her women’s group, Ruth hears that a few families are using LPG, now available at a nearby petrol station. The women say it is very quick and easy to use, and it keeps pots, clothes, and walls clean. The women and children seem to feel better, with less cough, runny eyes, and headaches. But those families run small shops and

have been able to find the money to buy the gas bottle and cooker.

She talks with her husband about LPG, and although quite supportive, her husband thinks they cannot afford it. They could spend a little more on fuel, but income is irregular. Why abandon free fuel when they are so poor? Ruth thinks she could earn more money from her handicrafts in the time she saves collecting wood. On balance, they reckon they could probably afford the cost of the gas if they could be sure of more regular income, but they do not know where they could find the money to pay for the cooker and bottle.

Ruth then learns about a revolving fund set up by her women’s group with the help of an NGO. If she can make small regular payments, she and her husband could get a loan to buy the stove and gas bottle next year. But they have never saved before, and what if they need money for medicines or for the children at school? Will they be able to keep saving each week to make sure they have enough to refill the gas bottle when needed?

1. Not her real name.

networks, and support for credit (for example, seed funds and fund capital) and targeted subsidies.

Some degree of market support may be required to stimulate demand and to encourage adoption by poor households, particularly those using three-stone fires (and other simple stoves) and collected biomass, because those methods do not incur direct monetary costs. Some countries have applied subsidies on fuels such as kerosene to assist poor families, but general subsidies are now considered to be an inefficient instrument for this purpose (von Schirnding and others 2002). Targeted subsidy and small-scale credit may be more appropriate ways of helping poor families acquire new household energy technologies and can have low default rates. Experience shows, however, that households are more likely to access credit for directly productive (with regard to income) uses of energy, rather than for everyday cooking and space-heating needs. Because the latter are the most important sources of IAP, more promotion of other benefits is needed, such as improved family health; fuel cost savings; time saved by faster cooking and reduced need for biomass; greater prestige; and cleaner homes, clothes, and utensils. A number of these benefits may result in reduced expenditure or increased income generation.

Box 42.2 illustrates how these various issues can influence the decisions of a “typical” poor rural African household considering transition from gathered biomass to predominant use of a commercial fuel (LPG).

Effectiveness

Most evidence available for assessing intervention effectiveness deals with the effect on IAP levels and in some cases personal exposure. No experimentally derived evidence is available, however, on the effect of reducing IAP exposure on incidence of ALRI or the course of COPD in adults. A randomized trial of an improved chimney stove is currently under way in Guatemala, focusing on ALRI in children up to 18 months of age (Dooley 2003). A cohort study in Kenya by Ezzati and Kammen (2001) describes significant exposure-response relationships for all acute respiratory infections—and for ALRI specifically—associated with the use of traditional and improved woodstoves and charcoal. However, those effect estimates require confirmation because the study has small numbers of children (93 children under age five, living in 55 homes). For the other major health outcome, lung cancer, Lan and

others (2002) reported adjusted hazard ratios of 0.59 (95 percent confidence interval: 0.49 to 0.71) for men and 0.54 (0.44 to 0.65) for women using improved coal stoves compared with traditional open coal fires in a 16-year retrospective cohort study in rural China.

Measuring evidence on reductions in pollution and exposure is nonetheless an important step in assessing effectiveness. Summarized here are the main findings of studies that have measured pollution levels in homes using traditional open fires, various improved stoves, kerosene, and LPG (see also Saksena, Thompson, and Smith 2004) and one that examined the effect of rural electrification in South Africa (Rollin and others 2004).

Effect of Improved Stoves. In East Africa, cheap improved stoves without flues, burning either wood or charcoal, are popular. These wood-burning stoves can reduce kitchen pollution by up to 50 percent, but levels still remain high (Ezzati, Mbinda, and Kammen 2000). Charcoal emits much less PM (but with a higher CO-to-PM ratio than wood), and stoves such as the Kenyan *jiko* yield particulate levels in the region of 10 percent of those from wood fires.

In a number of Asian and Latin American countries, improved stoves with flues have been promoted quite extensively, although many such stoves are found to be in poor condition after a few years. Some studies from India have shown minimal or small reductions in PM (Ramakrishna 1988; Smith, Aggarwal, and Dave 1983). Other studies, from Nepal, have shown reductions of about two-thirds, although the very high baseline levels mean that homes with stoves still recorded total suspended particulate values of 1,000 to 3,000 $\mu\text{g}/\text{m}^3$ during cooking (Pandey and others 1990; Reid, Smith, and Sherchand 1986). Results from Latin American countries are similar, although the IAP levels are generally lower. Studies have shown that *plancha*-type stoves (made of cement blocks, with a metal plate and flue) reduce PM by 60 to 70 percent and by as much as 90 percent when they are in good condition. Typical 24-hour PM levels (PM_{10} , $\text{PM}_{3.5}$ [respirable], and $\text{PM}_{2.5}$ have variously been reported) with open fires of 1,000 to 2,000 $\mu\text{g}/\text{m}^3$ have been reduced to 300 to 500 $\mu\text{g}/\text{m}^3$, and in some cases to less than 100 $\mu\text{g}/\text{m}^3$ (Albalak and others 2001; Brauer and others 1996; Naeher, Leaderer, and Smith 2000). One study from Mexico found little difference between homes with open fires and with improved stoves (Riojas-Rodriguez and others 2001), but the 16-hour levels of PM_{10} at about 300 $\mu\text{g}/\text{m}^3$ with open fires were relatively low.

Improved stoves with flues have so far had little success in Sub-Saharan Africa, although recent work developing hoods with flues for highly polluted Kenyan Masai homes reported reductions in 24-hour mean respirable PM of 75 percent from more than 4,300 $\mu\text{g}/\text{m}^3$ to about 1,000 $\mu\text{g}/\text{m}^3$ (Bruce and others 2002).

Personal exposures were usually found to have been reduced proportionately less than area pollution levels. For example, in Kenya, where hoods with flues achieved a 75 percent reduction in 24-hour mean kitchen $\text{PM}_{3.5}$ and CO, the woman's mean 24-hour CO exposure was reduced by only 35 percent (Bruce and others 2002). Similar results were found for child exposures in a study of improved wood stoves in Guatemala (Bruce and others 2004). We are aware of only one study that has used direct measurement of personal particulate exposure in very young children (Naeher, Leaderer, and Smith 2000). This study, also in Guatemala, reported mean 10- to 12-hour (daytime) $\text{PM}_{2.5}$ levels for children under 15 months of age of 279 $\mu\text{g}/\text{m}^3$ (+SD of 19.5) for the open fire and 170 $\mu\text{g}/\text{m}^3$ (+154) for the *plancha* stoves, a 40 percent reduction.

Impact of Cleaner Fuels. Good evidence shows that kerosene and LPG can deliver much lower levels of pollution, although it is important to determine the extent to which the cleaner fuel is substituting for biomass. For example, a study in rural Guatemala comparing LPG with open fires and *plancha* chimney stoves found that LPG-using households typically also used an open fire for space heating and cooking with large pots. As a result, the *plancha* stoves achieved the lowest pollution levels in that setting (Albalak and others 2001). Still, a number of studies, mainly from India, show that introducing kerosene and LPG dramatically reduces kitchen pollution, which perhaps reflects different cooking requirements and less need for space heating. In rural Tamil Nadu, two-hour (mealtime) kitchen respirable PM levels of 76 $\mu\text{g}/\text{m}^3$ using kerosene and of 101 $\mu\text{g}/\text{m}^3$ using gas contrasted with levels of 1,500 to 2,000 $\mu\text{g}/\text{m}^3$ using wood and animal dung (Parikh and others 2001). Personal (cook) 24-hour exposure to respirable PM was 132 $\mu\text{g}/\text{m}^3$ with the use of kerosene as opposed to 1,300 and 1,500 $\mu\text{g}/\text{m}^3$, respectively, with the use of wood and dung (Balakrishnan and others 2002). Other studies confirm those findings, for example, with the use of gas in Mexico (Saatkamp, Masera, and Kammen 2000).

Delivering electricity to rural homes requires extensive infrastructure, and most poor people with access to electricity can afford to use it only for lighting and running low-demand electrical appliances. Without marked improvements in socioeconomic conditions, electrification has little potential to bring about substantial reductions in IAP. South Africa is one of the few countries with a large rural population traditionally dependent on biomass that has the resources for rural electrification. An investigation of three rural villages with similar socioeconomic characteristics, two not electrified and one electrified, in the North West province found that 3.6 years (average) after connection to the grid, 44 percent of the electrified homes had never used an electric cooker (Rollin and others 2004). Only 27 percent of electrified homes cooked primarily with electricity; the remainder used a mix of electricity, kerosene, and solid fuels. Despite the mixed fuel use, households

cooking with electricity had the lowest pollution levels. Overall, homes in the electrified village had significantly lower 24-hour mean respirable PM and CO levels and significantly lower mean 24-hour CO exposure for children under 18 months of age than homes in the nonelectrified villages.

Effect of Other Interventions. Little systematic evaluation has been made of other interventions listed in table 42.4. Investigation of the potential of improving ventilation has, overall, shown that although enlarging eaves can be quite effective (Bruce and others 2002), removing smoke generally requires a well-functioning flue or chimney. Behavioral changes are currently the subject of an intervention study in South Africa (Barnes and others 2004a, 2004b).

Cost-Effectiveness Analysis

Although clean fuels can be expected to have a greater health effect than improved stoves (even those with flues), clean fuels may be too expensive and inaccessible for many poor communities over the short to medium term. Furthermore, even though clean fuels may be the best longer-term goal, an intermediate stage of improved biomass stoves may promote change by raising awareness of benefits and thus creating demand by improving health, saving time, and mitigating poverty. For those reasons, this cost-effectiveness analysis (CEA) examines both improved biomass stove and clean fuel options in the following scenarios:

- access to improved stoves (stoves with flues that vent smoke to the exterior), with coverage of 95 percent
- access to cleaner fuels (LPG or kerosene), with coverage of 95 percent
- part of the population with access to cleaner fuels (50 percent) and part with improved stoves (45 percent).

In each case, the intervention is compared with the current level of coverage of the respective technology or fuel.

Cost Assumptions. The assumptions for costs include program costs, fixed costs (including stoves), and recurrent fuel costs. Household costs for each region were drawn from the most comprehensive estimates available in the literature (von Schirnding and others 2002; Westoff and Germann 1995). For LPG, costs include the initial price of a cooker and cylinder and the recurrent refill costs. Assumed household annual costs, discounted at 3 percent, range from US\$1 to US\$10 for improved stoves and from US\$3 to US\$4 for kerosene or up to US\$30 for LPG. Recurrent costs of fuel were found to be the most significant cost for the cleaner fuel interventions. Wood fuel costs are estimated at US\$0.25 per week and assumed to be the same for traditional and improved stoves.

Costs were estimated separately for cleaner fuel and improved stove programs, using an “ingredients” approach (Johns, Baltussen, and Hutubessy 2003) and a costing template developed by WHO (2003). In summary, all the ingredients—including administrative, training, and operational costs—necessary to set up and maintain a given program must be added up. For regional estimates, costs of all traded goods were in U.S. dollars, whereas nontraded (local) costs were estimated in local currency and converted to U.S. dollars using relevant exchange rates. All costs were annualized using a 3 percent discount rate. Costs for tradable goods are scaled, using region-specific standardized price multipliers to reflect the increasing costs of expanding coverage caused by higher transportation costs to more remote areas (Johns, Baltussen, and Hutubessy 2003). Price multipliers were not applied to improved stoves because they tend to be manufactured locally with mainly local materials. Program costs were found to make up a small proportion of the overall intervention costs. Savings from averted health care costs are not included; because many of these cases currently go untreated, it can be argued that including treatment costs could result in inflated cost-effectiveness ratios (CERs).

Effectiveness and Health Outcome Assumptions. For this analysis, cleaner fuels are assumed to remove exposure completely, whereas improved stoves are assumed to reduce exposure by 75 percent (ventilation factor of 0.25). The effect on health of the exposure reduction will vary from region to region, because it depends on current levels of exposure as well as region-specific rates of morbidity and mortality. A number of assumptions have been made about households in carrying out analyses at the regional level. First, regional estimates of household composition (numbers of people, by age group and sex) and, hence, the effect of interventions on exposure and health apply at the level of individual households. Second, the age distribution of household members is similar in exposed and nonexposed groups; for example, the number of children per household is the same irrespective of household fuel use and ventilation characteristics. That assumption is likely to be conservative, since poorer, more polluted homes will typically have higher fertility and more children under five; all other factors being equal, such households would therefore experience a higher burden of disease from IAP exposure.

The health outcomes included are ALRI and COPD, because they were responsible for nearly all of the 1.6 million deaths attributable to IAP. The risk estimates used are those derived from the meta-analyses, as summarized in table 42.2. Smoking is an important confounding variable for COPD, particularly with men, because they generally smoke more than women do in developing countries. At present, information is sparse on the independent effect of solid fuel use on COPD in the presence of smoking. To avoid possible overestimation of the impact of IAP on COPD, attributable fractions for COPD from solid fuel use

were applied to disease burdens remaining after removal of smoking-attributable burdens (Ezzati and Lopez 2004). Current estimates of exposure are used in combination with estimates of disease burden to obtain region-specific disease burdens for exposed and unexposed populations. Regional patterns of disease for 2000 have been used, including incidence, mortality, remission, duration, and case-fatality rate, obtained from WHO (2004b). In contrast to the estimates of burden in table 42.3, no age weighting has been used in the cost-effectiveness analysis. Health impacts are discounted at 3 percent.

Implementation Period. The implementation period is 10 years, although effects have been evaluated over 100 years in order to approximate the benefits for an entire population cohort. Thus, health effects are calculated for a cohort with a typical age structure for the population concerned that experiences the intervention for 10 years. It is assumed that after 100 years, all of the cohort (including children born during the 10-year implementation period) will have died.

The implementation period has critical implications, particularly in situations in which it takes several years to establish an intervention (for example, developing local markets for cleaner fuel), in which there are high start-up costs, and in which disease prevention is experienced in the distant future. This is especially true for chronic health effects (for example, COPD) that result from exposure over many years. If the intervention is implemented and exposure reduced for only 10 years, the disease burden is effectively deferred by 10 years, whereas longer-term implementation would result in many more cases being averted. For this analysis, using the 10-year intervention scenario specified for the Disease Control Priorities Project-2, incident cases are deferred by 10 years. For COPD, it is assumed that reduced exposure results in a milder form of COPD, accounted for by using a lower severity weighting.

Findings for Cost-Effectiveness Analysis. Findings from the CEA are expressed, for the four intervention scenarios with differing coverage (50 percent, 80 percent, 95 percent), by region, as (a) total healthy years gained in each region, (b) CERs in U.S. dollars per healthy year gained, and (c) healthy years gained per US\$1 million (table 42.6). For all regions, the cleaner fuels yield the greatest gain in healthy years, but improved stoves also have a significant effect. The largest total population gains in healthy years are in Sub-Saharan Africa and South Asia for all types of interventions and in East Asia and the Pacific (mainly China) for cleaner fuels.

In the two regions with the largest burden of disease attributable to solid fuel use (Sub-Saharan Africa and South Asia), CERs are lowest (most favorable) for improved stoves, although in both regions kerosene has CERs just over twice those of improved stoves. In East Asia and the Pacific, kerosene is most cost-effective, followed by improved stove and clean fuel combinations and then by LPG (for coverage over

50 percent). In Latin America and the Caribbean, kerosene has the most favorable CER, followed by kerosene in combination with improved stoves. When the 50 percent and 80 percent coverage scenarios are compared, large differences in the ratio are seen in regions where coverage for that intervention is already substantial, and there is much less health gain at lower levels of coverage. Where no result is given, the specified coverage of the intervention has already been reached.

Multivariate sensitivity analysis was conducted to assess the effect of uncertainty in cost and effectiveness estimates. Costs were assumed to vary with a standard deviation of 5 percent, and effectiveness by the range of the confidence interval around the relative risk for each health endpoint. Results for Southeast Asia are shown in figure 42.3: the “clouds,” or uncertainty regions, illustrate the range of possible point estimates emerging from the sensitivity analysis. This example is representative because other regions show essentially similar results. Despite the uncertainty, the ranking of the interventions remains the same (Mehta and Shahpar 2004).

Discussion. Results of this cost-effectiveness analysis indicate that an improved biomass stove is the most cost-effective intervention for South Asia and Sub-Saharan Africa, the two regions with the highest solid fuel-related disease burden. This finding is important given International Energy Agency projections to 2030, which indicate that biomass will remain the principal household fuel for the poor in South Asia and Sub-Saharan Africa and that actual numbers of users will increase over that period (IEA 2002). Cleaner fuels (particularly kerosene) are the most cost-effective options for East Asia and the Pacific, the other region with a high burden of solid fuel-related disease. Cleaner fuels, in particular LPG, appear relatively costly for South Asia and Sub-Saharan Africa, but circumstances in individual countries may vary considerably and in ways that make this fuel much more cost-effective. Sudan, for example, has abundant cheap supplies of LPG and favorable excise arrangements for imported appliances, which would result in a lower CER for LPG than in other countries in the region. Furthermore, as will be discussed later, costs and benefits from the user's perspective will differ markedly, depending on whether the starting point is free fuel collection or purchased biomass fuel.

In interpreting the results, one should bear in mind the assumptions underlying the CEA. Much of the evidence indicates that, although improved biomass stoves may reduce kitchen pollution by up to 75 percent, the reduction in exposure of women and children is typically no more than 30 to 40 percent (equivalent to VF of 0.6 to 0.7). Achievement of the 75 percent reduction in exposure (VF = 0.25) assumed for this analysis is consistent only with well-designed and -maintained chimney stoves that meet most of the cooking and heating energy needs of the household and high population coverage (to avoid exposure from neighbors and others). Those conditions may be

Figure 42.3 Multivariate Sensitivity Analysis for Three Types of Interventions and Combined Intervention Scenarios, Southeast Asia Region

achievable and should be the goal, but they are not currently widespread. The relative cost-effectiveness advantage for improved stoves over cleaner fuel reported here should therefore be viewed as relating more to what might be achievable with good biomass stoves rather than to what is currently being achieved. The assumption that kerosene and LPG are equally clean and achieve zero exposure ($VF = 0$) presumes, at the very least, the use of high-quality kerosene fuel and pressurized burners. In many places, kerosene is of low quality, and the types of kerosene stoves and lamps used result in poor combustion.

Cost comparisons for the various fuels also need careful consideration. For example, the cost of solid fuel has been assumed to be constant for traditional open fires and improved stoves. As a general assumption this is reasonable, because the efficiency of “improved” stoves varies, and some may even be less fuel efficient than are open fires. However, new stove technology is markedly improving efficiency, and some designs reduce daily fuel consumption by 40 percent or more, resulting in savings of time (where fuel is collected) and money (where fuel is bought) (Boy and others 2000).

Transition from biomass (collected free) or charcoal (typically paid for daily in small amounts) to LPG would almost certainly require changes in saving and budgeting habits for a poor household (see also box 42.2). Those changes may entail arranging a loan to purchase the gas bottle and stove and saving money for the relatively large, periodic outlay to refill the cylinder. Such changes are very likely to have other consequences for the family that should not be overlooked. However, those consequences are complex and difficult to allow for within the current CEA framework. Empirical data are required on how

household budgets change with various interventions and approaches to implementation.

The calculations have been undertaken for whole regions and provide no indication of how CERs differ among countries and specific communities. As local data on exposure, risk factors, health outcomes, and intervention effectiveness become available, similar analyses should be conducted at national and subnational levels.

Averted treatment costs have not been included on the grounds that most users of solid fuel are poor and have limited access to health services; many do not seek medical care for ALRI and even fewer do so for COPD. Inclusion of averted costs would increase cost-effectiveness. However, efforts to raise awareness about health risks and the importance of seeking care for ALRI (and COPD), which should accompany an intervention program, may increase care seeking and costs to the consumer. As more complete information becomes available, future CEAs should include treatment costs, with the option of allowing for an increase in care seeking associated with the intervention.

Interpretation of the results of this CEA, particularly with respect to comparisons with other types of intervention, needs to acknowledge that, although public organizations and other agencies will (or may) have some involvement in funding intervention programs, most of the cost of market-based interventions will be borne by households and those involved in production and marketing. Furthermore, it is hoped that, in addition to reducing IAP, interventions (and the means of accessing them) will have other positive effects, including on household budgets, in creating opportunities for income generation and empowering women in decisions about how energy is used. The promotion of market-based solutions implies new opportunities for artisans and entrepreneurs, but also the loss of traditional employment. The balance sheet for interventions is therefore complex, is specific to the setting, and will evolve as markets and enterprise develop.

Cost-Benefit Analysis

The CER gives cost per unit of health gained (healthy year) based on reduced risk of specified disease outcomes (ALRI, COPD). As discussed earlier, however, household energy interventions can affect a wide range of social, economic, and environmental issues, with important implications for health and development. In an economic analysis of water and sanitation interventions, Hutton and Haller (2004) found that time saved was the most important benefit. Those other effects cannot easily be expressed in units of health gain. Cost-benefit analysis (CBA) offers an alternative approach that may be better suited to environmental health interventions, given that health arguments alone will not motivate the multiple sectors involved in financing and implementing household energy interventions.

All main benefits in CBA are expressed in a common unit of monetary value and compared with costs in the cost-benefit

ratio (CBR). The assessment of costs in CBA would have many assumptions and methods in common with CEA. The key differences lie in the selection of effects for inclusion as benefits and the methods for valuing them. In principle, there is no reason all the full range of effects discussed earlier could not be included (table 42.7), although in practice some, such as global climate effects, may be too uncertain. Where disadvantages of interventions are identified, they should also be included.

Benefit valuation presents particular challenges: effects are highly setting specific; evidence for some is limited, and their effects poorly quantified; and valuation in monetary units of benefits, such as lost working time averted for women, is difficult because women frequently are unpaid or work in informal markets. As a result, methods of valuation based on human capital may not be suitable, and alternative approaches such as contingent valuation, in which communities are involved in agreeing on market values for nontradable commodities, may be preferable. A related issue is valuing benefits that relate to

sustainability and health, which would be experienced after many years and by subsequent generations. Larson and Rosen (2002) used a mix of valuation of statistical life and contingent valuation methods to examine the CBRs for improved stoves with respect to mortality (Guatemala, East Africa) and morbidity (Pakistan), concluding that ratios appeared favorable. Although they discuss other benefits, those benefits were not included in their valuations. Their observation that the favorable CBRs are not reflected in the generally low adoption of improved stoves led them to conclude that the information required for assessing household demand correctly is not currently available.

IMPLEMENTATION OF CONTROL STRATEGIES: LESSONS FROM EXPERIENCE

The past 30 to 40 years have seen many diverse programs on household energy, from small-scale NGO- and community-led

Table 42.7 Possible Data Requirements for Quantifying Benefits

Impact category	Variables or elements to identify
<i>Direct benefits related to specific health outcomes</i>	
Expenditure and time for health care-seeking	Health service use of those with diseases caused by IAP (number of cases, visits or days per case) Health service use of those having accidents or injuries due to reasons related to fuel use: Direct: burns, poisoning Indirect: injuries in collecting fuel Access features to get to health services (distance, mode of transport, time; average visits per case) Other consumption related to health care-seeking Time loss of seeking health care, both of the patient and of those accompanying patient
<i>Other direct benefits in and around the home</i>	
Time gained owing to less illness and death	Activities of those with diseases caused by IAP Impact of disease on activities (time input, productivity)
Time saving of changed technology	Value of time of various occupations Reduced time spent collecting fuel Reduced time spent cooking and on other tasks requiring fire or stove Value of time of various occupations Income-generating activities achieved through increased time
Change in household environment and production	Impact on household cleanliness and hygiene and need for cleaning Effect of improved lighting on evening activities (education, production) Effect of availability of electricity and other fuels on household production activities Impact on ergonomics related to cooking
Consequences of process of acquiring new technology and related changes	Increased confidence in capacity of the household to save for immediate or future needs More involvement of women in decision making with respect to changes in household energy use and related issues
<i>Indirect benefits related to the environment</i>	
Local environment	Impact of fuel scarcity on local environment, average fuel collection time Increased risk of environmental effects (such as soil fertility) or disasters (such as flooding, landslides)
Global environment	Contribution of local area to greenhouse gases

initiatives to ambitious national programs, the largest of which has been the installation of some 200 million improved stoves in rural China. Although few have been subjected to rigorous evaluation, an assessment has been made of the Indian national stove program (box 42.3; ESMAP and World Bank 2001); the Chinese national stove program (box 42.4; Sinton and others 2004; Smith and others 1993); and LPG promotion (box 42.5; UNDP and ESMAP 2002). Experience with a number of smaller initiatives has also been reported—for example, the ceramic and metal stoves in East Africa, which have proved popular and provided local employment (Njenga 2001), and improved stove interventions in Guatemala (UNDP and ESMAP 2003).

Implementation of the Chinese national program differed substantially from that in India. Although the Chinese rural populations concerned are poor, they do have greater effective purchasing power than the poor in many developing countries, allowing development of a program with the majority of con-

sumers purchasing stoves at close to full cost (Smith and others 1993). Among the key features of the Chinese program reported to have contributed to its success are decentralization of administration; a commercialization strategy that provided subsidies to rural energy enterprise development and quality control through the central production of critical components, such as parts of the combustion chamber; and engagement of local technical institutions in modifying national stove designs to local needs. National-level stove competitions were held among counties for contracts, ensuring local interest and allowing the best-placed counties to proceed first; financial payments were provided to counties only after completion of an independent review of their achievements. No large flows of funds came from the central government (in contrast, for example, to India); local governments provided the major financial contributions. As a result, delays and other problems associated with transferring large amounts of money have been

Box 42.3

Key Features and Lessons from India's National Stove Program

The Indian National Programme of Improved Cookstoves was established in 1983 with goals common to many such initiatives:

- conserving fuel
- reducing smoke emissions in the cooking area and improving health conditions
- reducing deforestation
- limiting the drudgery of women and children and reducing cooking time
- improving employment opportunities for the rural poor.

Although the Ministry of Non-Conventional Energy Sources was responsible for planning, setting targets, and approving stove designs, state-level agencies relayed this information to local government agencies or NGOs. A technical backup unit in each state trained rural women or unemployed youths to become self-employed workers to construct and install the stoves.

Between 1983 and 2000, the program distributed more than 33 million improved stoves. Despite extensive government promotion efforts, improved stoves now account for less than 7 percent of all stoves. Among those that have been adopted, poor quality and lack of maintenance have resulted in a life span of two years at most and typically

much less. Evaluation of the program identified four main problems:

- Most states placed inadequate emphasis on commercialization, now seen as crucial for effective and sustainable uptake.
- Overall, there was insufficient interaction with users, self-employed workers, and NGOs, so the designs did not meet needs of households, and there was very poor acceptance of user training.
- Quality control for installation and maintenance of the stove and its appropriate use was lacking.
- High levels of subsidy (about 50 percent of the stove cost) were found to reduce household motivation to use and maintain the stove.

Some more successfully managed areas of the program focused resources on technical assistance, research and development, marketing, and information dissemination. Recently, the government of India decentralized the program and transferred all implementation responsibility to state level. Since 2000, the program promotes only durable cement stoves with chimneys that have a minimum life span of five years. The introduction of these stoves will make adherence to technical specifications and quality control much easier.

Box 42.4

Household Effects of China's National Improved Stove Program

In 2002, an independent multidisciplinary evaluation was undertaken by a team of U.S. and Chinese researchers to evaluate (a) implementation methods used to promote improved stoves; (b) commercial stove production and marketing organizations that were created; and (c) effects of the program on households, including health, stove performance, socioeconomic factors, and monitoring of indoor air quality. The first two objectives were assessed through a facility survey of 108 institutions at all levels. The third objective was assessed through a household survey of nearly 4,000 households in three provinces: Zhejiang, Hubei, and Shaanxi. Key findings were as follows:

- The household survey revealed highly diverse fuel usage patterns: 28 and 34 different fuel combinations were used in kitchens in winter and summer, respectively. Most households owned at least one or more coal and one or more biomass stoves. Of the biomass stoves 77 percent, but only 38 percent of the coal stoves, were classified as improved. On average, improved stoves had a mean efficiency of 14 percent, which is well below the program target of between 20 and 30 percent, but above the mean efficiency of 9 percent for traditional stoves.
- With respect to air quality (measured with PM₄, the “thoracic fraction” of particulate matter, and CO), coal stoves showed significantly higher concentrations than biomass stoves during the summer, but not during the winter. Among households using biomass fuels (but

not among households using combinations of fuels that included coal or LPG), improved stoves showed significantly lower PM₄ and CO concentrations than traditional stoves.

- In both children and adults, coal use was associated with higher levels of exposure (as measured by CO in exhaled breath) and improved biomass stoves with lower levels. Reported childhood asthma and adult respiratory disease were negatively associated with use of improved stoves and good stove maintenance. These results should, however, be treated as indicative because of limited sample size.

Overall, several important conclusions emerge with relevance to future improved stove programs:

- A wide range of combinations of different fuel and stove types may limit the effect of an improved stove program.
- Given the importance of space heating, making available an improved biomass stove for cooking may not be a sufficient strategy to reduce IAP. Improved coal stoves need to be promoted among rural Chinese households.
- Even among households using improved stoves, PM₄ and CO levels were higher than Chinese national indoor air standards, implying that a large fraction of China's rural population is still chronically exposed to pollution levels substantially above those determined by the Chinese government to harm human health.

avoided. The Chinese program succeeded in shifting norms: most biomass stoves now available on the market have flues and other technical features that classify them as improved.

Experience in the promotion of LPG has also been reported, for example, from the Indian Deepam Scheme (ESMAP and World Bank 2004; UNDP and ESMAP 2002) and from the LPG Rural Energy Challenge (UNDP 2005). The latter initiative, developed by UNDP and the World LPG Association in 2002, is promoting the development of new, viable markets for LPG in developing countries. Key elements include developing partnerships in countries; enabling regulatory environments that facilitate LPG business development and product delivery; reducing barriers, for example, by introducing smaller (more affordable) gas bottles; and raising government and consumer

awareness of costs and benefits. McDade (2004) has recently identified a number of key lessons emerging from experience with the promotion of LPG markets (box 42.5).

Electrification has an important role in development (IEA 2002). Evidence from South Africa suggests that communities with grid access experience lower IAP exposure (Rollin and others 2004). Electricity is not expected to bring about large reductions in IAP exposure in most low-income countries, however, because most poor households can afford it only for uses such as lighting and running entertainment appliances and not for cooking and space heating. The International Energy Agency has recently carried out a detailed review of electrification, including the issues involved in supply and cost recovery among poor (and especially rural) communities (IEA 2002).

Box 42.5

Key Lessons Learned in the Promotion of New Markets for LPG in Developing Countries

- LPG can be affordable outside of urban areas, where wood fuel is currently purchased. On the other hand, for many consumers who do not participate in the monetized economy, it will be premature to promote LPG markets.
- One-time subsidies on appliances could be a good use of government (or other) resources.
- Microcredit initiatives should emphasize the cost-saving and productive potential and should seek to package both the gas (and appliances) and the financing.
- Concerns about safe handling, cylinder refilling, and transportation can be serious barriers to market expansion. These issues need to be addressed by raising awareness among consumers and strengthening regulatory environments.
- Appliances for a range of end uses required by consumers must be available.
- Government leadership is essential, backed up by policy that sets the basic parameters for successful market expansion and avoids conflict between, for example, subsidies on competing fuels that undermine efforts to promote LPG markets.
- Specific initiatives, such as integrated energy centers (as in Morocco and South Africa) offer an effective means of developing markets in rural areas.

Source: Authors, based on McDade 2004.

The key lessons from experience with interventions to date may be summarized as follows:

- Too often, intervention technologies have been developed without adequate reference to users' needs and, as a result, have been poorly used and maintained or abandoned. Consequently, it is important to involve users—particularly women—in assessing needs and developing suitable interventions.
- Sustainable adoption should also be promoted through greater availability of a choice of appropriately priced interventions through local commercial outlets (artisans, shops, markets). This situation will come about only if demand is sufficient and if producers and distributors recognize this demand.
- All too commonly, communities most at risk exhibit low awareness, low demand, and poverty (often extreme poverty). A combination of user involvement and market approaches is needed, supported by the promotion and availability of targeted subsidies or microcredit facilities or both. The nature and extent of such financial support should depend on the purchasing power of the community.
- Local initiatives such as those outlined above must be led by national (and subnational) policy that acknowledges the contributions of a range of actors (government, business, NGOs, and so on) and sectors (energy, health, environment, finance, and so on) and that results in coordinated action. The instruments listed in table 42.5 should be considered when developing national policy.

In a recent review of the situation in Guatemala, the United Nations Development Programme and Energy Sector

Management Assistance Programme (UNDP and ESMAP 2003) found that, despite the almost total reliance of the rural population on biomass, a marked lack of national policy, leadership, and coordinated action existed in relation to household energy. Countries need to develop mechanisms for action and coordination in light of local needs, available institutional capacity, and leadership potential.

THE RESEARCH AND DEVELOPMENT AGENDA

WHO has, through a process involving multistakeholder meetings and reviews, developed some consensus on research and development priorities for household energy, IAP, and health (see for example WHO 2002a). Effective coordination is a prerequisite because of the need for input from, and collaboration between, many different organizations and “actors” that have generally not previously worked in partnership on this issue. One recent response to this need has been the establishment of the Partnership for Clean Indoor Air, following the Johannesburg World Summit on Sustainable Development in 2002 (EPA 2004; <http://www.pciaonline.org/>).

The evidence base on health effects requires further strengthening, particularly to quantify the effect of a measured reduction in IAP exposure on the risk of key outcomes (for example, ALRI). A randomized controlled trial is currently under way in Guatemala, focusing primarily on ALRI in children up to 18 months of age (Dooley 2003); however, at least one other such trial on another continent would be desirable. Also required are observational studies for outcomes for which few studies currently exist, including tuberculosis, low

birthweight and perinatal mortality, cataracts, asthma, and cardiovascular disease. A small number of such studies are in progress, but further effort is required, with perinatal outcomes being a particular priority.

Despite limitations in the evidence on health effects, what is known about the health, social, and economic consequences of current patterns of household energy use in poor countries is of sufficient concern to press ahead with an active program of research and development regarding interventions. This activity should address both the technology (and associated knowledge and behavior) and the approaches taken for implementation. Although some development and innovation in technology and fuels (for example, clean fuels derived from biomass) are likely to be valuable, the single greatest challenge is to promote wider access to—and adoption of—existing knowledge and interventions. Projects and programs currently in progress or being developed should be carefully evaluated using quantitative and qualitative methods to assess a range of effects. Work is currently under way to develop suitable methods and tools for this purpose (WHO 2005). Experience and lessons learned need to be disseminated widely to ensure that they reach governments, donors, researchers, NGOs, and communities. As part of this effort, WHO is developing a resource for countries that offers information on the effectiveness of interventions as well as the enabling factors that facilitate long-term, sustained adoption and use of suitable improved technologies in different settings (WHO 2004c).

Economic assessment, including cost-effectiveness analysis, has a valuable part to play. Critical issues resulting from limited evidence have been identified about estimations and assumptions for costs, exposure reductions, health effects, and averted treatment costs, as well as the current inability to assess national and subnational cost-effectiveness. CBA may be more suitable for interventions in this and similar areas but will require better description of environmental, social, and economic effects and further development of valuation methods. New health studies and broadly based evaluations of interventions should help fill some of these gaps.

Determination of the macroeconomic costs to countries of current household energy use and the potential gains resulting from change to more efficient and cleaner options could substantially add to the case for action.

Monitoring progress requires the development and testing of standard indicators for use in such policy documents as the *World Development Report* and for routine application at national and subnational levels. The Millennium Development Goal Indicator on the proportion of the population using solid fuels is a key starting point, and WHO, the reporting agency, is working to broaden the monitoring of this indicator through international surveys, such as demographic and health surveys (ORC Macro 2004), the Multiple Indicator Cluster Survey (UNICEF 2004), and the World Health Survey (WHO 2004d),

as well as through work on regional and national indicators conducted under the Global Initiative on Children's Environmental Health Indicators (WHO 2004e). Future reporting will need to be further refined by taking into account differences in cooking practices (for example, type of stove and cooking location), as well as in fuel use for lighting and heating.

Advocacy for stronger action, internationally and in countries, is required. Products and guidance for a range of audiences should be prepared, with clear messages on the extent of the problem, the population groups most affected, what works, and what should be avoided. Tools such as the recently published guidelines on estimating the national burden of disease from solid fuels will help provide local evidence to argue for greater attention and action (Desai, Mehta, and Smith 2004).

CONCLUSIONS

IAP from solid fuel use is responsible for a large burden of disease among the world's poorest and most vulnerable populations. Inefficient and polluting household energy systems hold back development through resulting ill health, constraints on women's time and income generation, environmental impacts, and other factors. Although there is a trend toward cleaner and more efficient energy with increasing prosperity, little improvement is in prospect for more than 2 billion of the world's poorest people, particularly in South Asia and Sub-Saharan Africa. The number of people relying on traditional biomass is actually expected to increase until 2030.

Although the development of new energy technologies has a part to play in addressing this problem, many effective interventions are already available. The single greatest challenge is to dramatically increase the access of poor households to cleaner and more efficient household energy systems. Much valuable experience has been gained from successful—and unsuccessful—programs in household energy over the past three to four decades. Despite this experience, coherent, evidence-based policy is lacking in most of the countries concerned, where the lessons from experience now need to be implemented. Implementation will require greater awareness of the problem at international and national levels, provision of support for national collaborative action, and a focus on supporting appropriate, mainly market-based interventions.

Better information is crucial to this effort, including stronger evidence of the health effects of IAP exposure; assessment of the social, economic, and environmental benefits of interventions; and indicators to monitor progress. Economic analysis can help bring the case for action into policy, but it needs to be applied at country level and to include a wider range of benefits. Results from analysis at the regional level show that interventions can be cost-effective, particularly improved stoves, as long as these interventions can deliver substantial exposure reductions in practice. This conclusion, as

well as its qualification, is important given the expectation that biomass will remain the principal household fuel in many developing countries for more than 20 years. The balance of effort and resources put into promoting cleaner biomass interventions rather than cleaner fuels, or vice-versa, will be an important policy issue for many countries and for the international community (Smith 2002).

With a range of innovative projects and programs under way in a number of countries and regions of the world, now is an important time to focus attention and effort on achieving the health, social, and economic gains that should result from improvements in household energy systems in developing countries.

NOTE

1. Particles are typically described according to the aerodynamic diameter, and although the devices used to separate particles of a given size do not yield a very sharp cutoff, this classification is functionally useful because smaller particles are able to penetrate farther into the lungs. Total suspended particles (TSP) include suspended particles of all sizes. Commonly defined smaller particles include PM₁₀ (up to 10 microns diameter); respirable PM (includes all very small particles, about 50 percent of those 4 microns in diameter, and none above 10 microns in diameter); and PM_{2.5} (up to 2.5 microns in diameter).

Chapter 43

Air and Water Pollution: Burden and Strategies for Control

Tord Kjellstrom, Madhumita Lodh, Tony McMichael, Geetha Ranmuthugala, Rupendra Shrestha, and Sally Kingsland

Environmental pollution has many facets, and the resultant health risks include diseases in almost all organ systems. Thus, a chapter on air and water pollution control links with chapters on, for instance, diarrheal diseases (chapter 19), respiratory diseases in children and adults (chapters 25 and 35), cancers (chapter 29), neurological disorders (chapter 32), and cardiovascular disease (chapter 33), as well as with a number of chapters dealing with health care issues.

NATURE, CAUSES, AND BURDEN OF AIR AND WATER POLLUTION

Each pollutant has its own health risk profile, which makes summarizing all relevant information into a short chapter difficult. Nevertheless, public health practitioners and decision makers in developing countries need to be aware of the potential health risks caused by air and water pollution and to know where to find the more detailed information required to handle a specific situation. This chapter will not repeat the discussion about indoor air pollution caused by biomass burning (chapter 42) and water pollution caused by poor sanitation at the household level (chapter 41), but it will focus on the problems caused by air and water pollution at the community, country, and global levels.

Estimates indicate that the proportion of the global burden of disease associated with environmental pollution hazards ranges from 23 percent (WHO 1997) to 30 percent (Smith, Corvalan, and Kjellstrom 1999). These estimates include infectious diseases related to drinking water, sanitation, and

food hygiene; respiratory diseases related to severe indoor air pollution from biomass burning; and vectorborne diseases with a major environmental component, such as malaria. These three types of diseases each contribute approximately 6 percent to the updated estimate of the global burden of disease (WHO 2002).

As the World Health Organization (WHO) points out, outdoor air pollution contributes as much as 0.6 to 1.4 percent of the burden of disease in developing regions, and other pollution, such as lead in water, air, and soil, may contribute 0.9 percent (WHO 2002). These numbers may look small, but the contribution from most risk factors other than the “top 10” is within the 0.5 to 1.0 percent range (WHO 2002).

Because of space limitations, this chapter can give only selected examples of air and water pollution health concerns. Other information sources on environmental health include Yassi and others (2001) and the Web sites of or major reference works by WHO, the United Nations Environment Programme (UNEP), Division of Technology, Industry, and Economics (<http://www.unep.org/>); the International Labour Organization (ILO), the United Nations Industrial Development Organization (UNIDO; <http://www.unido.org/>), and other relevant agencies.

Table 43.1 indicates some of the industrial sectors that can pose significant environmental and occupational health risks to populations in developing countries. Clearly, disease control measures for people working in or living around a smelter may be quite different from those for people living near a tannery or a brewery. For detailed information about industry-specific

Table 43.1 Selected Industrial Sectors and Their Contribution to Air and Water Pollution and to Workplace Hazards

Industrial sector	Air	Water	Workplace ^a
Base metal and iron ore mining	PM	Toxic metal sludge	Silica
Cement manufacturing	PM	Sludge	Silica
Coalmining and production	PM, coal dust	Sludge	Coal dust, silica
Copper smelting	Arsenic	Arsenic	Arsenic, cadmium
Electricity generation	PM, SO ₂	Hot water	SO ₂
Foundries	PM	Solvents	Silica, solvents
Iron and steel smelting	PM	Sludge	Carbon monoxide, nickel
Lead and zinc smelting	PM, SO ₂ , lead, cadmium, arsenic	Lead, cadmium, arsenic	PM, SO ₂ , lead, cadmium, arsenic
Meat processing and rendering	Odor	High biological oxygen demand	Infections
Oil and gas development	SO ₂ , carcinogens	Oil	Hydrocarbons
Pesticide manufacturing	Pesticides and toxic intermediates	Pesticides and toxic intermediates	Pesticides and toxic intermediates
Petrochemicals manufacturing	SO ₂	Oil	Hydrocarbons
Petroleum refining	SO ₂	Sludge, hydrocarbons	Hydrocarbons
Phosphate fertilizer plants	PM	Nutrients	
Pulp and paper mills	Odor	High biological oxygen demand, mercury	Chlorine
Tanning and leather finishing	Odor	Chromium, acids	Chromium, acids
Textile manufacturing		Toxic dyes

a. In all the cases, the workplaces are subject to risk of injury, noise, dust, and excessively hot or cold temperatures.

pollution control methods, see the Web sites of industry sector organizations, relevant international trade union organizations, and the organizations listed above.

Air Pollution

Air pollutants are usually classified into suspended particulate matter (PM) (dusts, fumes, mists, and smokes); gaseous pollutants (gases and vapors); and odors.

Suspended PM can be categorized according to total suspended particles: the finer fraction, PM₁₀, which can reach the alveoli, and the most hazardous, PM_{2.5} (median aerodynamic diameters of less than 10.0 microns and 2.5 microns, respectively). Much of the PM_{2.5} consists of secondary pollutants created by the condensation of gaseous pollutants—for example, sulfur dioxide (SO₂) and nitrogen dioxide (NO₂). Types of suspended PM include diesel exhaust particles; coal fly ash; wood smoke; mineral dusts, such as coal, asbestos, limestone, and cement; metal dusts and fumes; acid mists (for example, sulfuric acid); and pesticide mists.

Gaseous pollutants include sulfur compounds such as SO₂ and sulfur trioxide; carbon monoxide; nitrogen compounds such as nitric oxide, NO₂, and ammonia; organic compounds such as hydrocarbons; volatile organic compounds; polycyclic aromatic hydrocarbons and halogen derivatives such as aldehydes; and odorous substances. Volatile organic compounds are released from burning fuel (gasoline, oil, coal, wood,

charcoal, natural gas, and so on); solvents; paints; glues; and other products commonly used at work or at home. Volatile organic compounds include such chemicals as benzene, toluene, methylene chloride, and methyl chloroform. Emissions of nitrogen oxides and hydrocarbons react with sunlight to eventually form another secondary pollutant, ozone, at ground level. Ozone at this level creates health concerns, unlike ozone in the upper atmosphere, which occurs naturally and protects life by filtering out ultraviolet radiation from the sun.

Sources of Outdoor Air Pollution. Outdoor air pollution is caused mainly by the combustion of petroleum products or coal by motor vehicles, industry, and power stations. In some countries, the combustion of wood or agricultural waste is another major source. Pollution can also originate from industrial processes that involve dust formation (for example, from cement factories and metal smelters) or gas releases (for instance, from chemicals production). Indoor sources also contribute to outdoor air pollution, and in heavily populated areas, the contribution from indoor sources can create extremely high levels of outdoor air pollution.

Motor vehicles emit PM, nitric oxide and NO₂ (together referred to as NO_x), carbon monoxide, organic compounds, and lead. Lead is a gasoline additive that has been phased out in industrial countries, but some developing countries still use leaded gasoline. Mandating the use of lead-free gasoline is an important intervention in relation to health. It eliminates

Box 43.1

The Bhopal Catastrophe

The Bhopal plant, owned by the Union Carbide Corporation, produced methyl isocyanate, an intermediate in the production of the insecticide carbaryl. On December 2, 1984, a 150,000-gallon storage tank containing methyl isocyanate apparently became contaminated with water, initiating a violent reaction and the release of a cloud of toxic gas to which 200,000 people living near the plant were exposed. Low wind speed and the high vapor pressure of methyl isocyanate exacerbated the severity of toxic exposure, resulting in the immediate death of at least 6,000 people.

Source: Dhara and Dhara 2002.

The dominating nonlethal effects of this emission were severe irritation of the eyes, lungs, and skin. Effects on the nervous system and reproductive organs were also reported. The reaction of methyl isocyanate with water had a corrosive effect on the respiratory tract, which resulted in extensive necrosis, bleeding, and edema. Treatment was impeded by the unknown and disputed composition of the gas cloud and a lack of knowledge about its health effects and about antidotes.

vehicle-related lead pollution and permits the use of catalytic converters, which reduce emissions of other pollutants.

Catastrophic emissions of organic chemicals, as occurred in Bhopal, India, in 1984 (box 43.1), can also have major health consequences (McGranahan and Murray 2003; WHO 1999).

Another type of air pollution that can have disastrous consequences is radioactive pollution from a malfunctioning nuclear power station, as occurred in Chernobyl in 1986 (WHO 1996). Radioactive isotopes emitted from the burning reactor spread over large areas of what are now the countries of Belarus, the Russian Federation, and Ukraine, causing thousands of cases of thyroid cancer in children and threatening to cause many cancer cases in later decades.

Exposure to Air Pollutants. The extent of the health effects of air pollution depends on actual exposure. Total daily exposure is determined by people's time and activity patterns, and it combines indoor and outdoor exposures. Young children and elderly people may travel less during the day than working adults, and their exposure may therefore be closely correlated with air pollution levels in their homes. Children are particularly vulnerable to environmental toxicants because of their possibly greater relative exposure and the effects on their growth and physiological development.

Meteorological factors, such as wind speed and direction, are usually the strongest determinants of variations in air pollution, along with topography and temperature inversions. Therefore, weather reports can be a guide to likely air pollution levels on a specific day.

Workplace air is another important source of air pollution exposure (chapter 60). Resource extraction and processing industries, which are common in developing countries, emit

dust or hazardous fumes at the worksite (table 43.1). Such industries include coalmining, mineral mining, quarrying, and cement production. Developed countries have shifted much of their hazardous production to developing countries (LaDou 1992). This shift creates jobs in the developing countries, but at the price of exposure to air pollution resulting from outdated technology. In addition, specific hazardous compounds, such as asbestos, have been banned in developed countries (Kazan-Allen 2004), but their use may still be common in developing countries.

Impacts on Health. Epidemiological analysis is needed to quantify the health impact in an exposed population. The major pollutants emitted by combustion have all been associated with increased respiratory and cardiovascular morbidity and mortality (Brunekreef and Holgate 2002). The most famous disease outbreak of this type occurred in London in 1952 (U.K. Ministry of Health 1954), when 4,000 people died prematurely in a single week because of severe air pollution, followed by another 8,000 deaths during the next few months (Bell and Davis 2001).

In the 1970s and 1980s, new statistical methods and improved computer technology allowed investigators to study mortality increases at much lower concentrations of pollutants. A key question is the extent to which life has been shortened. Early loss of life in elderly people, who would have died soon regardless of the air pollution, has been labeled *mortality displacement*, because it contributes little to the overall burden of disease (McMichael and others 1998).

Long-term studies have documented the increased cardiovascular and respiratory mortality associated with exposure to PM (Dockery and others 1993; Pope and others 1995).

A 16-year follow-up of a cohort of 500,000 Americans living in different cities found that the associations were strongest with PM_{2.5} and also established an association with lung cancer mortality (Pope and others 2002). Another approach is ecological studies of small areas based on census data, air pollution information, and health events data (Scoggins and others 2004), with adjustments for potential confounding factors, including socioeconomic status. Such studies indicate that the mortality increase for every 10 micrograms per cubic meter ($\mu\text{g per m}^3$) of PM_{2.5} ranges from 4 to 8 percent for cities in developed countries where average annual PM_{2.5} levels are 10 to 30 $\mu\text{g/m}^3$. Many urban areas of developing countries have similar or greater levels of air pollution.

The major urban air pollutants can also give rise to significant respiratory morbidity (WHO 2000). For instance, Romieu and others (1996) report an exacerbation of asthma among children in Mexico City, and Xu and Wang (1993) note an increased risk of respiratory symptoms in middle-aged non-smokers in Beijing.

In relation to the very young, Wang and others (1997) find that PM exposure, SO₂ exposure, or both increased the risk of low birthweight in Beijing, and Pereira and others (1998) find that air pollution increased intrauterine mortality in São Paulo.

Other effects of ambient air pollution are postneonatal mortality and mortality caused by acute respiratory infections, as well as effects on children's lung function, cardiovascular and respiratory hospital admissions in the elderly, and markers for functional damage of the heart muscle (WHO 2000). Asthma is another disease that researchers have linked to urban air pollution (McConnell and others 2002; Rios and others 2004). Ozone exposure as a trigger of asthma attacks is of particular concern. The mechanism behind an air pollution and asthma link is not fully known, but early childhood NO₂ exposure may be important (see, for example, Ponsonby and others 2000).

Leaded gasoline creates high lead exposure conditions in urban areas, with a risk for lead poisoning, primarily in young children. The main concern is effects on the brain from low-level exposure leading to behavioral aberrations and reduced or delayed development of intellectual or motoric ability (WHO 1995). Lead exposure has been implicated in hypertension in adults, and this effect may be the most important for the lead burden of disease at a population level (WHO 2002). Other pollutants of concern are the carcinogenic volatile organic compounds, which may be related to an increase in lung cancer, as reported by two recent epidemiological studies (Nyberg and others 2000; Pope and others 2002).

Urban air pollution and lead exposure are two of the environmental hazards that WHO (2002) assessed as part of its burden-of-disease calculations for the *World Health Report 2002*. The report estimates that pollution by urban PM causes as much as 5 percent of the global cases of lung cancer, 2 percent of deaths from cardiovascular and respiratory conditions,

and 1 percent of respiratory infections, adding up to 7.9 million disability-adjusted life years based on mortality only. This burden of disease occurs primarily in developing countries, with China and India contributing the most to the global burden. Eastern Europe also has major air pollution problems, and in some countries, air pollution accounts for 0.6 to 1.4 percent of the total disability-adjusted life years from mortality.

The global burden of disease caused by lead exposure includes subtle changes in learning ability and behavior and other signs of central nervous system damage (Fewthrell, Kaufmann, and Preuss 2003). WHO (2002) concludes that 0.4 percent of deaths and 0.9 percent (12.9 million) of all disability-adjusted life years may be due to lead exposure.

Water Pollution

Chemical pollution of surface water can create health risks, because such waterways are often used directly as drinking water sources or connected with shallow wells used for drinking water. In addition, waterways have important roles for washing and cleaning, for fishing and fish farming, and for recreation.

Another major source of drinking water is groundwater, which often has low concentrations of pathogens because the water is filtered during its transit through underground layers of sand, clay, or rocks. However, toxic chemicals such as arsenic and fluoride can be dissolved from the soil or rock layers into groundwater. Direct contamination can also occur from badly designed hazardous waste sites or from industrial sites. In the United States in the 1980s, the government set in motion the Superfund Program, a major investigation and cleanup program to deal with such sites (U.S. Environmental Protection Agency 2000).

Coastal pollution of seawater may give rise to health hazards because of local contamination of fish or shellfish—for instance, the mercury contamination of fish in the infamous Minamata disease outbreak in Japan in 1956 (WHO 1976). Seawater pollution with persistent chemicals, such as polychlorinated biphenyls (PCBs) and dioxins, can also be a significant health hazard even at extremely low concentrations (Yassi and others 2001).

Sources of Chemical Water Pollution. Chemicals can enter waterways from a point source or a nonpoint source. Point-source pollution is due to discharges from a single source, such as an industrial site. Nonpoint-source pollution involves many small sources that combine to cause significant pollution. For instance, the movement of rain or irrigation water over land picks up pollutants such as fertilizers, herbicides, and insecticides and carries them into rivers, lakes, reservoirs, coastal waters, or groundwater. Another nonpoint source is stormwater that collects on roads and eventually reaches rivers or

lakes. Table 43.1 shows examples of point-source industrial chemical pollution.

Paper and pulp mills consume large volumes of water and discharge liquid and solid waste products into the environment. The liquid waste is usually high in biological oxygen demand, suspended solids, and chlorinated organic compounds such as dioxins (World Bank 1999). The storage and transport of the resulting solid waste (wastewater treatment sludge, lime sludge, and ash) may also contaminate surface waters. Sugar mills are associated with effluent characterized by biological oxygen demand and suspended solids, and the effluent is high in ammonium content. In addition, the sugarcane rinse liquid may contain pesticide residues. Leather tanneries produce a significant amount of solid waste, including hide, hair, and sludge. The wastewater contains chromium, acids, sulfides, and chlorides. Textile and dye industries emit a liquid effluent that contains toxic residues from the cleaning of equipment. Waste from petrochemical manufacturing plants contains suspended solids, oils and grease, phenols, and benzene. Solid waste generated by petrochemical processes contains spent caustic and other hazardous chemicals implicated in cancer.

Another major source of industrial water pollution is mining. The grinding of ores and the subsequent processing with water lead to discharges of fine silt with toxic metals into waterways unless proper precautions are taken, such as the use of sedimentation ponds. Lead and zinc ores usually contain the much more toxic cadmium as a minor component. If the cadmium is not retrieved, major water pollution can occur. Mining was the source of most of the widespread cadmium poisoning (Itai-Itai disease) in Japan in 1940–50 (Kjellstrom 1986).

Other metals, such as copper, nickel, and chromium, are essential micronutrients, but in high levels these metals can be harmful to health. Wastewater from mines or stainless steel production can be a source of exposure to these metals. The presence of copper in water can also be due to corrosion of drinking water pipes. Soft water or low pH makes corrosion more likely. High levels of copper may make water appear bluish green and give it a metallic taste. Flushing the first water out of the tap can minimize exposure to copper. The use of lead pipes and plumbing fixtures may result in high levels of lead in piped water.

Mercury can enter waterways from mining and industrial premises. Incineration of medical waste containing broken medical equipment is a source of environmental contamination with mercury. Metallic mercury is also easily transported through the atmosphere because of its highly volatile nature. Sulfate-reducing bacteria and certain other micro-organisms in lake, river, or coastal underwater sediments can methylate mercury, increasing its toxicity. Methylmercury accumulates and concentrates in the food chain and can lead to serious

neurological disease or more subtle functional damage to the nervous system (Murata and others 2004).

Runoff from farmland, in addition to carrying soil and sediments that contribute to increased turbidity, also carries nutrients such as nitrogen and phosphates, which are often added in the form of animal manure or fertilizers. These chemicals cause eutrophication (excessive nutrient levels in water), which increases the growth of algae and plants in waterways, leading to an increase in cyanobacteria (blue-green algae). The toxics released during their decay are harmful to humans.

The use of nitrogen fertilizers can be a problem in areas where agriculture is becoming increasingly intensified. These fertilizers increase the concentration of nitrates in groundwater, leading to high nitrate levels in underground drinking water sources, which can cause methemoglobinemia, the life-threatening “blue baby” syndrome, in very young children, which is a significant problem in parts of rural Eastern Europe (Yassi and others 2001).

Some pesticides are applied directly on soil to kill pests in the soil or on the ground. This practice can create seepage to groundwater or runoff to surface waters. Some pesticides are applied to plants by spraying from a distance—even from airplanes. This practice can create spray drift when the wind carries the materials to nearby waterways. Efforts to reduce the use of the most toxic and long-lasting pesticides in industrial countries have largely been successful, but the rules for their use in developing countries may be more permissive, and the rules of application may not be known or enforced. Hence, health risks from pesticide water pollution are higher in such countries (WHO 1990).

Naturally occurring toxic chemicals can also contaminate groundwater, such as the high metal concentrations in underground water sources in mining areas. The most extensive problem of this type is the arsenic contamination of groundwater in Argentina, Bangladesh (box 43.2), Chile, China, India, Mexico, Nepal, Taiwan (China), and parts of Eastern Europe and the United States (WHO 2001). Fluoride is another substance that may occur naturally at high concentrations in parts of China, India, Sri Lanka, Africa, and the eastern Mediterranean. Although fluoride helps prevent dental decay, exposure to levels greater than 1.5 milligrams per liter in drinking water can cause pitting of tooth enamel and deposits in bones. Exposure to levels greater than 10 milligrams per liter can cause crippling skeletal fluorosis (Smith 2003).

Water disinfection using chemicals is another source of chemical contamination of water. Chlorination is currently the most widely practiced and most cost-effective method of disinfecting large community water supplies. This success in disinfecting water supplies has contributed significantly to public health by reducing the transmission of waterborne disease. However, chlorine reacts with naturally occurring organic matter in water to form potentially toxic chemical compounds,

Box 43.2

Arsenic in Bangladesh

The presence of arsenic in tube wells in Bangladesh because of natural contamination from underground geological layers was first confirmed in 1993. Ironically, the United Nations Children's Fund had introduced the wells in the 1960s and 1970s as a safe alternative to water contaminated with microbes, which contributed to a heavy diarrheal disease burden. Estimates indicate that 28 million to 35 million people of Bangladesh's population of 130 million are exposed to arsenic levels exceeding 50 micrograms per liter, the prescribed limit for drinking water in Bangladesh (Kinniburgh and Smedley 2001).

Source: Authors.

This number increases to 46 million to 57 million if the WHO guideline level of 10 micrograms per liter is used. The most common sign of arsenic poisoning in Bangladesh is skin lesions characterized by hyperkeratosis and melanosis. Other effects reported, but not epidemiologically confirmed, include cancer (particularly of the skin, lungs, and bladder); liver damage; diabetes; hypertension; and reproductive effects (spontaneous abortions and stillbirths). Cancer and vascular effects are the dominating effects in other arsenic-polluted areas (WHO 2001).

known collectively as disinfection by-products (International Agency for Research on Cancer 2004).

Exposure to Chemical Water Pollution. Drinking contaminated water is the most direct route of exposure to pollutants in water. The actual exposure via drinking water depends on the amount of water consumed, usually 2 to 3 liters per day for an adult, with higher amounts for people living in hot areas or people engaged in heavy physical work. Use of contaminated water in food preparation can result in contaminated food, because high cooking temperatures do not affect the toxicity of most chemical contaminants.

Inhalation exposure to volatile compounds during hot showers and skin exposure while bathing or using water for recreation are also potential routes of exposure to water pollutants. Toxic chemicals in water can affect unborn or young children by crossing the placenta or being ingested through breast milk.
